The reader now has to conceptualize that the CMB patterns change over time! Although statistically they remain the same, and although it will not be noticeable on human timescales!

The CMB we observe now comes from a thin shell with us in the center, and with a radius equal to the distance that the light has travelled from the Universe was 379,000 years old and until now. As time passes, we will receive CMB from a shell with an increasingly larger radius. As that light has travelled farther through space, it will, as you say, be more red-shifted, or "cooler". But it will also have been emitted from more distant regions in the early Universe that, although statistically equivalent, simply will be other regions and hence look different.

The patterns that change the fastest are the smallest patterns we can observe. The angular resolution of the Planck satellite is 5 to 10 arcmin. Since the CMB comes from a redshift of ~ 1100, the angular diameter distance defining the physical distance spanned by a given angle - is ~ 13 [Mpc], so 5 arcmin corresponds to a physical scale of roughly 19 [kpc] in physical coordinates, or 21 [Mpc] in comoving coordinates (that is, a structure spanning 5 arcmin today were ~ 19 [kpc] across at the time of emission, but have now expanded to a size of ~ 21 [Mpc], with $1\,[\text{Mpc}] = 1000\,[\text{kpc}] = 3,261 \cdot 10^3$ lightyears).

Assuming an isotropic Universe, if the smallest observable parcels of gas were 19 [kpc] across perpendicular to our line of sight, they are also on average 19 [kpc] across along our line of sight.

So the question of how fast the CMB changes comes down to how much time did it take light to travel 19 [kpc] when the Universe was $379,000$ years old. This is not simply 19 [kpc] divided by the speed of light, since the Universe expands as the light travels, but it's pretty close. Hence, it took light roughly $62,000$ years to traverse such a patch.

Since we see events at redshift z time dilated by a factor $1+z$, we will have to wait $62\,[\text{kyr}] \cdot 1,100$, or roughly 70 million years to see a changes in the pattern of the CMB.

12.5.6 Friedmann-Lemaître-Robertson-Walker Cosmological Models

Ok... We have seen a lot of stuff and all this without involving General Relativity! Let us see now a more robust way to derivate a more complete version of Friedmann equations using a special metric AND General Relativity. The results will be what we name the "standard cosmological model" or "ΛCDM" (Lambda Cold Dark Matter also abbreviated LCDM) or "Lambda-CDM model" that is a parametrization of the Big Bang cosmological model in which the Universe contains the cosmological constant Λ, associated with dark energy, and cold dark matter. The field is often named "relativistic cosmology" or "concordance cosmology".

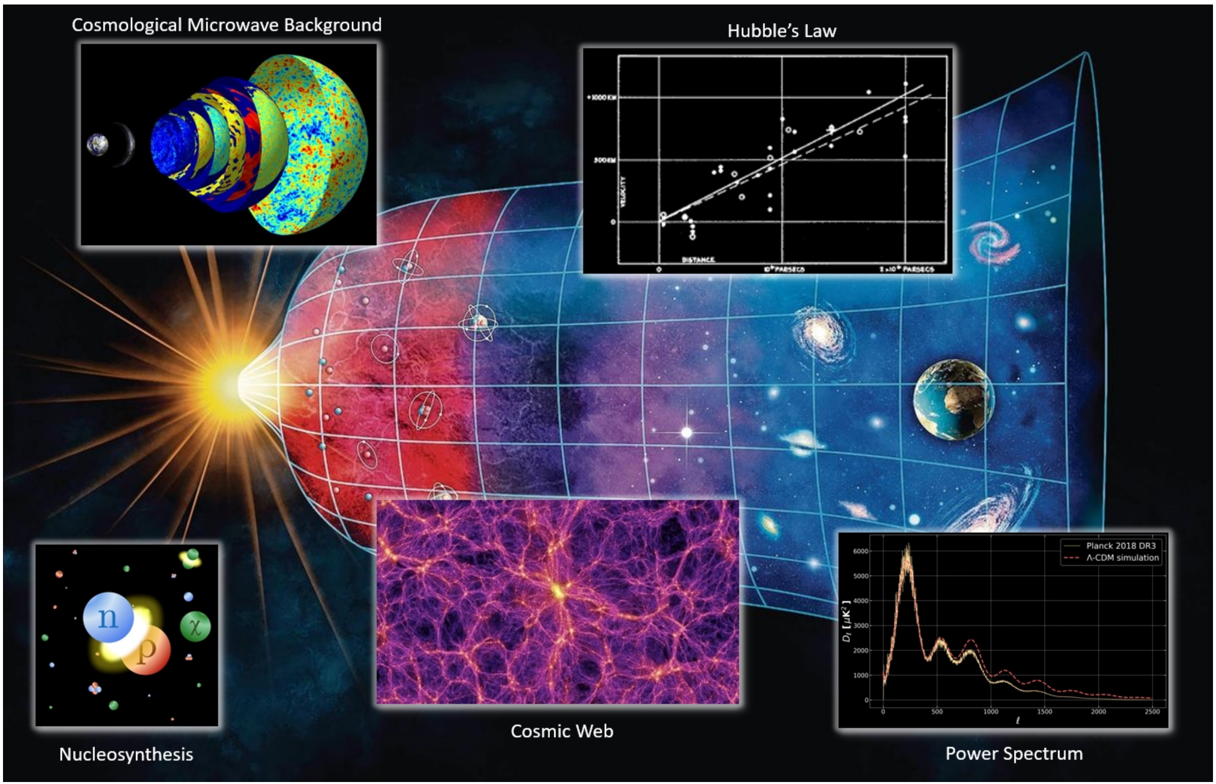

Figure 12.293: **ΛCDM theory experimental evidence as in the beginning of the 121st century**

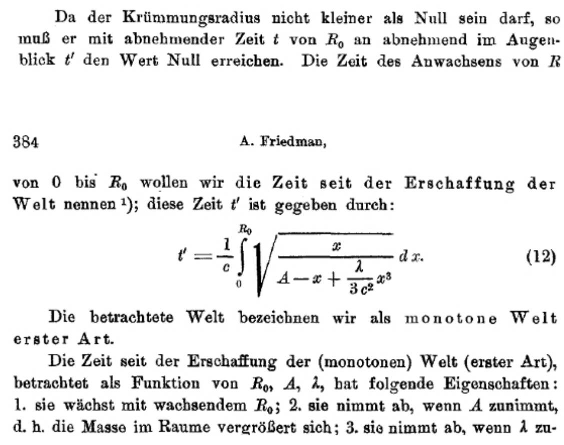
12.5.6.1 Robertson-Walker metric

We will now introduce an important metric for General Relativity and Cosmology that is the "Friedmann–Lemaître–Robertson–Walker (FLRW) metric". This metric is the basis of the Einstein cosmological model!

Remark

Contrary to a popular misconception, and as already mentioned in the Chronology section of this textbook (see page 9166), it was not Georges Lemaître who first developed a dynamic model of a Universe with a beginning in his 11927 (holocene calendar) publication [345] but Alexander Friedmann in his 11922 (holocene calendar) publication [193] (and Lemaître neither Friedman created the expression "Big Bang" but the astronomer Fred Hoyle in 11949 according to holocene calendar). Lemaître just rediscovered independently what Friedman already published before him but backed it up by a possible observational evidence trick! The fact that most people retain Georges Lemaître is mainly for three reasons: the first one is that he was a catholic priest and therefore it adds some spice to the legend (...) and the second is that Einstein knew already the paper of Friedmann but was hesitating and started really to change his mind about a static Universe when he saw that even a second scientist was able to fall back on the result of a dynamic Universe and the third and last one is that Friedmann died in 11925 so he wasn't here anymore to claim the discovery. For more, see [192] and [421].

For example in the paper of 11922 of Friedmann we can clearly check and see that Friedmann developed a model of the "World" (Welt) in expansion (i.e. Universe) as visible in the screenshot below of its original paper (for the detailed derivation see page 6050):



Da der Krümmungsradius nicht kleiner als Null sein darf, so muß er mit abnehmender Zeit t von R_0 an abnehmend im Augenblick t' den Wert Null erreichen. Die Zeit des Anwachsens von R

384 A. Friedman,

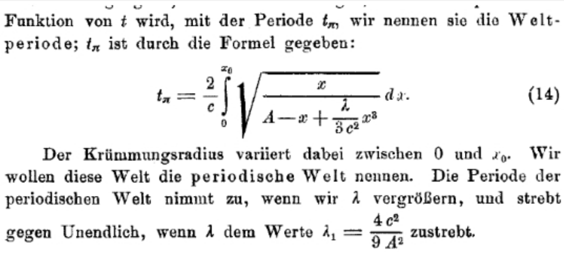
von 0 bis R_0 wollen wir die Zeit seit der Erschaffung der Welt nennen[1]); diese Zeit t' ist gegeben durch:

$$t' = \frac{1}{c}\int_0^{R_0}\sqrt{\frac{x}{A - x + \frac{\lambda}{3c^2}x^3}}\,dx. \qquad (12)$$

Die betrachtete Welt bezeichnen wir als monotone Welt erster Art.

Die Zeit seit der Erschaffung der (monotonen) Welt (erster Art), betrachtet als Funktion von R_0, A, λ, hat folgende Eigenschaften: 1. sie wächst mit wachsendem R_0; 2. sie nimmt ab, wenn A zunimmt, d. h. die Masse im Raume vergrößert sich; 3. sie nimmt ab, wenn λ zu-

He also developed the cyclic model of the "World" (i.e. Universe) as also visible in the screenshot below of its original paper:



Funktion von t wird, mit der Periode t_π, wir nennen sie die Weltperiode; t_π ist durch die Formel gegeben:

$$t_\pi = \frac{2}{c}\int_0^{x_0}\sqrt{\frac{x}{A - x + \frac{\lambda}{3c^2}x^3}}\,dx. \qquad (14)$$

Der Krümmungsradius variiert dabei zwischen 0 und x_0. Wir wollen diese Welt die periodische Welt nennen. Die Periode der periodischen Welt nimmt zu, wenn wir λ vergrößern, und strebt gegen Unendlich, wenn λ dem Werte $\lambda_1 = \frac{4c^2}{9A^2}$ zustrebt.

To see how we derive this metric with first consider the elementary distance on a 2D hypersurface:

$$\mathrm{d}s^2 = \mathrm{d}x^2 + \mathrm{d}y^2 \qquad (12.5.406)$$

on if the 2D hypersurface is a sphere, we have:

$$R^2 = x^2 + y^2 \Leftrightarrow y^2 = R^2 - x^2 \qquad (12.5.407)$$

For that latter relation if $R = c^{te}$ we have:

$$\mathrm{d}(R^2) = 0 = \mathrm{d}(x^2) + \mathrm{d}(y^2) = 2x\mathrm{d}x + 2y\mathrm{d}y \qquad (12.5.408)$$

After simplification:

$$0 = x\mathrm{d}x + y\mathrm{d}y \Leftrightarrow \mathrm{d}y = -x\frac{\mathrm{d}x}{y} \qquad (12.5.409)$$

Therefore:

$$\mathrm{d}s^2=\mathrm{d}x^2+\mathrm{d}y^2=\mathrm{d}x^2+\left(-\frac{x\mathrm{d}x}{y}\right)^2=\mathrm{d}x^2+\frac{x^2\mathrm{d}^2x}{y^2}=\mathrm{d}x^2+\frac{x^2\mathrm{d}^2x}{R^2-x^2}\tag{12.5.410}$$

We see that if $R\rightarrow+\infty$, then:

$$\mathrm{d}s^2=\mathrm{d}x^2\tag{12.5.411}$$

Now let us consider a 3D hypersurface in a 4D space such that:

$$\mathrm{d}s^2=\mathrm{d}x_1^2+\mathrm{d}x_2^2+\mathrm{d}x_3^2+\mathrm{d}x_4^2\tag{12.5.412}$$

The trick that explains why we put ourselves on the $\mathcal{S}^3$ sphere is that we anticipate in advanced that by doing a change of variable we will reduce this metric to three coordinates only!

We have also obviously:

$$R^2=x_1^2+x_2^2+x_3^2+x_4^2\Leftrightarrow x_4^2=R^2-(x_1^2+x_2^2+x_3^2)\tag{12.5.413}$$

If we assume $R=c^{te}$ we get by differentiation:

$$\mathrm{d}(R^2)=0=2x_1\mathrm{d}x_1+2x_2\mathrm{d}x_2+2x_3\mathrm{d}x_3+2x_4\mathrm{d}x_4\tag{12.5.414}$$

After simplification:

$$0=x_1\mathrm{d}x_1+x_2\mathrm{d}x_2+x_3\mathrm{d}x_3+x_4\mathrm{d}x_4\Leftrightarrow \mathrm{d}x_4=-\frac{x_1\mathrm{d}x_1+x_2\mathrm{d}x_2+x_3\mathrm{d}x_3}{x_4}\tag{12.5.415}$$

That is:

$$\begin{aligned}\mathrm{d}s^2&=\mathrm{d}x_1^2+\mathrm{d}x_2^2+\mathrm{d}x_3^2+\mathrm{d}x_4^2=\mathrm{d}x_1^2+\mathrm{d}x_2^2+\mathrm{d}x_3^2+\left(-\frac{(x_1\mathrm{d}x_1+x_2\mathrm{d}x_2+x_3\mathrm{d}x_3)}{x_4}\right)^2\\&=\mathrm{d}x_1^2+\mathrm{d}x_2^2+\mathrm{d}x_3^2+\frac{(x_1\mathrm{d}x_1+x_2\mathrm{d}x_2+x_3\mathrm{d}x_3)^2}{x_4^2}=\mathrm{d}x_1^2+\mathrm{d}x_2^2+\mathrm{d}x_3^2+\frac{(x_1\mathrm{d}x_1+x_2\mathrm{d}x_2+x_3\mathrm{d}x_3)^2}{R^2-(x_1^2+x_2^2+x_3^2)}\end{aligned}\tag{12.5.416}$$

Now we use spherical coordinates (see section Vector Calculus page 1849):

$$\vec{r}=\begin{pmatrix}x_1\\x_2\\x_3\end{pmatrix}=\begin{pmatrix}r\sin(\theta)\cos(\phi)\\r\sin(\theta)\sin(\phi)\\r\cos(\theta)\end{pmatrix}\tag{12.5.417}$$

But as we know that in the general:

$$\begin{aligned}\mathrm{d}x_1^2+\mathrm{d}x_2^2+\mathrm{d}x_3^2=g_{11}\mathrm{d}x_1^2+g_{22}\mathrm{d}x_2^2+g_{33}\mathrm{d}x_3^2=g_r\mathrm{d}r^2+g_\theta\mathrm{d}\theta^2+g_\phi\mathrm{d}\phi^2\\=\mathrm{d}r^2+r^2\mathrm{d}\theta^2+r^2\sin^2(\theta)\mathrm{d}\phi^2\end{aligned}\tag{12.5.418}$$

Therefore having all this, we can rewrite:

$$\mathrm{d}s^2=\mathrm{d}x_1^2+\mathrm{d}x_2^2+\mathrm{d}x_3^2+\frac{(x_1\mathrm{d}x_1+x_2\mathrm{d}x_2+x_3\mathrm{d}x_3)^2}{R^2-(x_1^2+x_2^2+x_3^2)}\tag{12.5.419}$$

as following:

$$\begin{aligned}\mathrm{d}s^2 &= \mathrm{d}r^2+r^2\mathrm{d}\theta^2+r^2\sin^2(\theta)\mathrm{d}\phi^2+\frac{(\vec{r}\circ\mathrm{d}\vec{r})^2}{R^2-\|\vec{r}\|^2}\\ &= \mathrm{d}r^2+r^2\mathrm{d}\theta^2+r^2\sin^2(\theta)\mathrm{d}\phi^2+\frac{(\|\vec{r}\|\cdot\|\mathrm{d}\vec{r}\|\cos(\alpha))^2}{R^2-\|\vec{r}\|^2}\end{aligned} \tag{12.5.420}$$

We will denote obviously $\|\vec{r}\|$ as r, and $\|\mathrm{d}\vec{r}\|$ as $\mathrm{d}r$, and as they are collinear, we have $\cos(\alpha)=1$, therefore:

$$\begin{aligned}\mathrm{d}s^2 &= \mathrm{d}r^2+r^2\mathrm{d}\theta^2+r^2\sin^2(\theta)\mathrm{d}\phi^2+\frac{r^2\mathrm{d}r^2}{R^2-r^2}\\ &= \mathrm{d}r^2\left(\frac{r^2}{R^2-r^2}+1\right)+r^2(\mathrm{d}\theta^2+\sin^2(\theta)\mathrm{d}\phi^2)\\ &= \mathrm{d}r^2\frac{R^2}{R^2-r^2}+r^2(\mathrm{d}\theta^2+\sin^2(\theta)\mathrm{d}\phi^2)\end{aligned} \tag{12.5.421}$$

It is traditional to put:

$$\mathrm{d}\Omega^2=\mathrm{d}\theta^2+\sin^2(\theta)\mathrm{d}\phi^2 \tag{12.5.422}$$

and name it the "unit three-sphere metric" (also sometimes denoted $\mathrm{d}\Omega_3^2$). Therefore:

$$\mathrm{d}s^2=\mathrm{d}r^2\frac{R^2}{R^2-r^2}+r^2\mathrm{d}\Omega^2 \tag{12.5.423}$$

As for the comoving time introduce earlier before, let us introduce the "comoving coordinates" as being:

$$r=Rx\Leftrightarrow\mathrm{d}r=R\mathrm{d}x \tag{12.5.424}$$

Therefore:

$$\begin{aligned}\mathrm{d}s^2 &= R^2\mathrm{d}x^2\frac{R^2}{R^2-R^2x^2}+R^2x^2\mathrm{d}\Omega^2=R^2\mathrm{d}x^2\frac{R^2}{R^2-R^2x^2}+R^2x^2\mathrm{d}\Omega^2\\ &= R^2\left(\frac{\mathrm{d}x^2}{1-x^2}+x^2\mathrm{d}\Omega^2\right)\end{aligned} \tag{12.5.425}$$

If we had made the same development but with the hyperbolic metric (see section Differential Geometry page 2855), we would have obtain:

$$\mathrm{d}s^2=R^2\left(\frac{\mathrm{d}x^2}{1+x^2}+x^2\mathrm{d}\Omega^2\right) \tag{12.5.426}$$

This is why we write more generally:

$$\mathrm{d}s^2=R^2\left(\frac{\mathrm{d}x^2}{1-kx^2}+x^2\mathrm{d}\Omega^2\right) \tag{12.5.427}$$

with:

- If $k=0$ we fall back on the flat Euclidean space (but don't forget we are on comoving coordinates!)

- If $k=+1$ we are on a spherical space
- If $k=-1$ we are in a hyperbolic space

Then the metric tensor including time coordinates with $(-,+,+,+)$ signature is given by:

$$g_{\mu\nu}=\begin{bmatrix} -1 & 0 & 0 & 0 \\ 0 & \dfrac{R^2}{1-kx^2} & 0 & 0 \\ 0 & 0 & R^2x^2 & 0 \\ 0 & 0 & 0 & R^2x^2\sin^2(\theta) \end{bmatrix} \quad (12.5.428)$$

So that we can write obviously if $x^\mu=(ct,x^i)$:

$$\mathrm{d}s^2=g_{\mu\nu}\mathrm{d}x^\mu\mathrm{d}x^\nu=-(c\mathrm{d}t)^2+R^2\left(\frac{\mathrm{d}x^2}{1-kx^2}+x^2\mathrm{d}\Omega^2\right) \quad (12.5.429)$$

But R can be an arbitrary function of time so we write traditionally:

$$\mathrm{d}s^2=g_{\mu\nu}\mathrm{d}x^\mu\mathrm{d}x^\nu=-(c\mathrm{d}t)^2+R^2(t)\left(\frac{\mathrm{d}x^2}{1-kx^2}+x^2\mathrm{d}\Omega^2\right) \quad (12.5.430)$$

and as we have seen earlier it is quite common to denote the radius by a , therefore:

$$\boxed{\mathrm{d}s^2=g_{\mu\nu}\mathrm{d}x^\mu\mathrm{d}x^\nu=-(c\mathrm{d}t)^2+a^2(t)\left(\frac{\mathrm{d}x^2}{1-kx^2}+x^2\mathrm{d}\Omega^2\right)} \quad (12.5.431)$$

and this is the final form of the Friedmann–Lemaître–Robertson–Walker (FLRW) metric..

Or also written with another signature:

$$\mathrm{d}s^2=g_{\mu\nu}\mathrm{d}x^\mu\mathrm{d}x^\nu=(c\mathrm{d}t)^2-a^2(t)\left(\frac{\mathrm{d}x^2}{1-kx^2}+x^2\mathrm{d}\Omega^2\right) \quad (12.5.432)$$

Sometimes denoted:

$$\mathrm{d}s^2=N^2(t)\mathrm{d}^2t-a^2(t)\mathrm{d}\Omega_3^2 \quad (12.5.433)$$

where $\mathrm{d}\Omega_3^2$ is sometimes named the "hyperboloid metric" and $N(t)$ is chosen sometimes as an arbitrary lapse function.

Remark

In a more general framework that $\mathrm{d}\Omega_3^2$ is defined as:

$$\mathrm{d}\Omega_3^2:=h_{ij}\mathrm{d}x^i\mathrm{d}x^j=\frac{\delta_{ij}\mathrm{d}x^i\mathrm{d}x^j}{\left(1+\dfrac{1}{4}\delta_{ij}x^ix^j\right)^2} \quad (12.5.434)$$

It is important to remember that x has no units and is often denoted in textbooks with the following letter χ and that rigorously the scale factor $a(t)$ is defined by $a(t)/a(t_0)$. Keep also in mind that one of the main idea is to determine the explicit expression of $a(t)$ (Universe models) to inject it afterwards in the FLRW metrics to make further investigation on the properties of the visible Universe.

Metric Name	**Formulation**	**Characertistics**
Minkowski	$\mathrm{d}s^2_{\text{M}}=-c^2\mathrm{d}t+\mathrm{d}x^2+\mathrm{d}y^2+\mathrm{d}z^2$	Flat space Static space Non-charged space
Schwarzschild	$\mathrm{d}s^2_{\text{S}}=\left(1-\dfrac{2GM}{c^2r}\right)c^2\mathrm{d}t-\dfrac{1}{1-\dfrac{2GM}{c^2r}}\mathrm{d}r^2-r^2\left(\mathrm{d}\theta^2+\sin^2(\theta)\mathrm{d}\phi^2\right)$	Spherical symmetric space Static space Valide only outside a mass Non-charged space
Robertson-Walker	$\mathrm{d}s^2_{\text{RW}}=-c\mathrm{d}t^2+a^2(t)\left(\dfrac{\mathrm{d}x^2}{1-kx^2}+x^2\left(\mathrm{d}\theta^2+\sin^2(\theta)\mathrm{d}\phi^2\right)\right)$	Isotropic space Homogeneous space Symmetric space Expanding/Contracting space Non-rotating space Non-charged space

Table 12.26: **Summary of different types of General Relativity metrics derived so far**

The main results of the FLRW model were first derived by the Soviet mathematician Alexander Friedmann in 11922 (holocene calendar) and 11924 (holocene calendar). Although his work was published in the prestigious physics journal *Zeitschrift für Physik*, it remained relatively unnoticed by his contemporaries. Friedmann was in direct communication with Albert Einstein, who, on behalf of *Zeitschrift für Physik*, acted as the scientific referee of Friedmann's work. Eventually Einstein acknowledged the correctness of Friedmann's calculations, but failed to appreciate the physical significance of Friedmann's predictions.

Friedmann died in 11925 (holocene calendar). In 11927 (holocene calendar), Georges Lemaître, a Belgian priest, astronomer and periodic professor of physics at the Catholic University of Leuven, arrived independently at similar results as Friedmann had and published them in *Annals of the Scientific Society of Brussels*. In the face of the observational evidence for the expansion of the universe obtained by Edwin Hubble in the late 11920s (holocene calendar), Lemaître's results were noticed in particular by Arthur Eddington, and in 11930–31 (holocene calendar) his paper was translated into English and published in the *Monthly Notices of the Royal Astronomical Society*.

Howard P. Robertson from the US and Arthur Geoffrey Walker from the UK explored the problem further during the 11930s (holocene calendar). In 11935 (holocene calendar) Robertson and Walker rigorously proved that the FLRW metric is the only one on a space-time that is spatially homogeneous and isotropic (as noted above, this is a geometric result and is not tied specifically to the equations of General Relativity, which were always assumed by Friedmann and Lemaître).

The reader can subjectively judge of the homogeneity of a part of the observable universe with the 3D reconstruction below of 15 million galaxies and quasars up to 11 billion light years in distance :

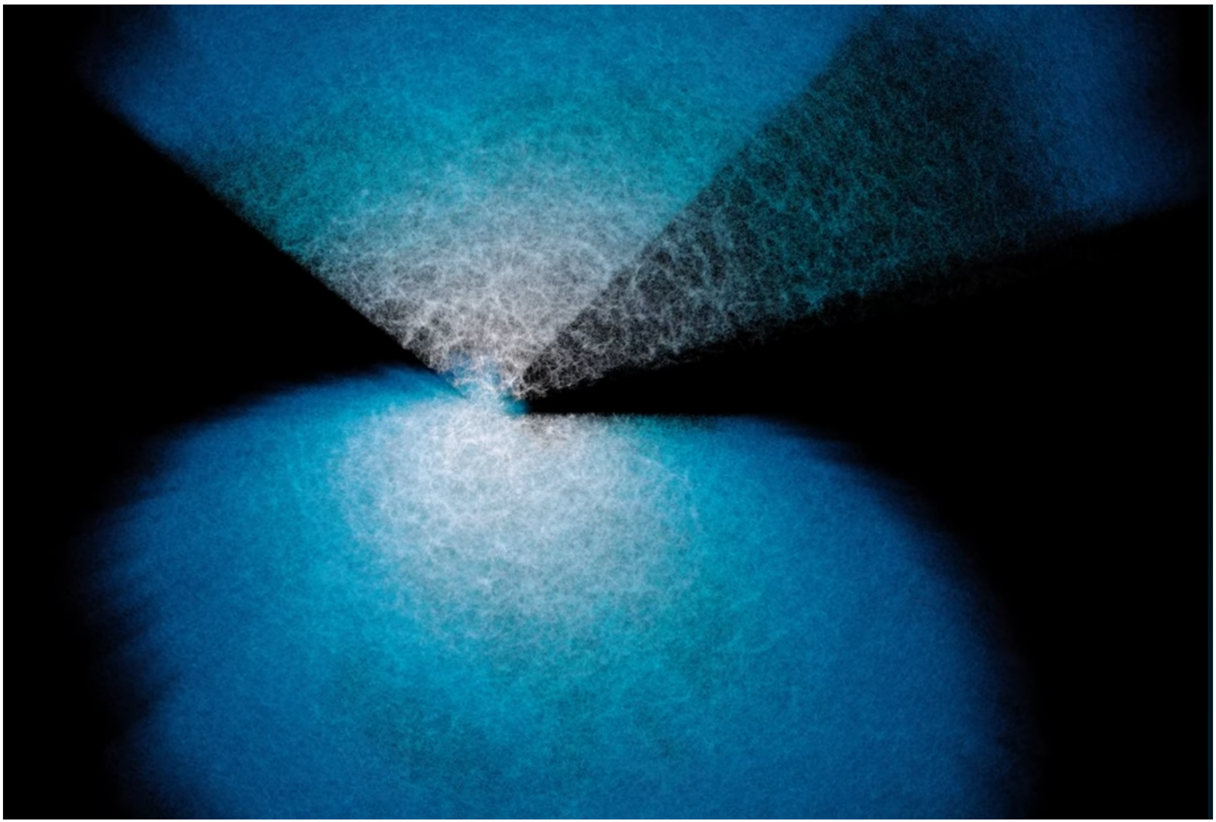


Figure 12.294: **DESI galaxies survey (credit: DESI collaboration and KPNO/NOIRLab/NSF/AURA/R. Proctor)**

Because the dynamics of the FLRW model were derived by Friedmann and Lemaître, the latter two names are often omitted by scientists outside the US. Conversely, US physicists often refer to it as simply "Robertson–Walker metric". The full four-name title seems to be the most democratic. Often the "Robertson–Walker" metric, so-named since they proved its generic properties, is distinguished from the dynamical "Friedmann-Lemaître" models, specific solutions for $a(t)$ which assume that the only contributions to stress-energy are cold matter ("dust"), radiation, and a cosmological constant.

12.5.6.2 Cosmological Redshift

Before dealing with Universe models dealing with the FLRW metric, let us consider two points in space participating in the expansion of the Universe. At one point we have a source of light and at the other an observer (us). Let us use spherical coordinates centered on the observer, so that the comoving coordinate of the observer is $c=0$ and the comoving coordinate of the source is $\chi=0$. Let us analyse the propagation of a photon emitted by the source at time t_e and received at time t_0. As the photon propagates radially towards the observer, along its trajectory in space, and hence along its worldline in space-time we have $\theta=c^{te}$ and $\phi=c^{te}$. Moreover, along the worldlines of photons (Friedmann–Lemaître–Robertson–Walker metric):

$$\begin{aligned}\mathrm{d}s^2=g_{\mu\nu}\mathrm{d}x^\mu\mathrm{d}x^\nu&=-(c\mathrm{d}t)^2+a^2(t)\left(\frac{\mathrm{d}r^2}{1-kr^2}+r^2\mathrm{d}\Omega^2\right)\\&=-(c\mathrm{d}t)^2+a^2(t)\left[\frac{\mathrm{d}r^2}{1-kr^2}+r^2\left(\mathrm{d}\theta^2+\sin^2(\theta)\mathrm{d}\phi^2\right)\right]\\&=-(c\mathrm{d}t)^2+a^2(t)\frac{\mathrm{d}r^2}{1-kr^2}=0\end{aligned}\tag{12.5.435}$$

Hence:

$$\frac{c\mathrm{d}t}{a(t)}=\pm\frac{\mathrm{d}r}{\sqrt{1-kr^2}}\tag{12.5.436}$$

Notice that we know how to calculate the three possible integrals depending on the value of k (see section Differential and Integral Calculus page 1534):

$$\int\frac{c\mathrm{d}t}{a(t)}=\pm\int\frac{\mathrm{d}r}{\sqrt{1-kr^2}}=\pm\begin{cases}\arcsin(r) & k=+1\\ r & k=0\\ \text{arcsinh}(r) & k=-1\end{cases}\tag{12.5.437}$$

Remark

Using the notation of the conformal time defined earlier above, this latter relation is sometimes written:

$$c\mathrm{d}\eta=\pm\frac{\mathrm{d}r}{\sqrt{1-kr^2}}\tag{12.5.438}$$

If we put $c=1$ we see that time and distance may be interchanged as:

$$\boxed{\Delta D=\Delta\eta=\int\frac{\mathrm{d}t}{a}=\int\frac{\mathrm{d}a}{a\dot{a}}=\int\frac{\mathrm{d}a}{a^2H(a)}}\tag{12.5.439}$$

For an observer observing the crest of a light wave at a position $r=0$ and time $t=t_{\text{now}}$, the crest of the light wave was emitted at a time $t=t_{\text{then}}$ in the past and a distant position $r=R$. Integrating over the path in both space and time that the light wave travels yields:

$$c\int_{t_{\text{then}}}^{t_{\text{now}}}\frac{\mathrm{d}t}{a}=\int_R^0\frac{\mathrm{d}r}{\sqrt{1-kr^2}}\tag{12.5.440}$$

In general, the wavelength of light is not the same for the two positions and times considered due to the changing properties of the metric. When the wave was emitted, it had a wavelength λ_{then}. The next crest of the light wave was emitted at a time:

$$t = t_{\text{then}} + \frac{\lambda_{\text{then}}}{c} \tag{12.5.441}$$

The observer sees the next crest of the observed light wave with a wavelength λ_{now} to arrive at a time:

$$t = t_{\text{now}} + \frac{\lambda_{\text{now}}}{c} \tag{12.5.442}$$

Since the subsequent crest is assumed approximately again emitted from $r = R$ and is observed at $r = 0$, the following equation can be written:

$$c \int\limits_{t_{\text{then}}+\lambda_{\text{then}}/c}^{t_{\text{now}}+\lambda_{\text{now}}/c} \frac{\mathrm{d}t}{a} \cong \int\limits_{R}^{0} \frac{\mathrm{d}r}{\sqrt{1-kr^2}} \tag{12.5.443}$$

The right-hand side of the two integral equations above are supposed as approximately equal given the small time variation, which means:

$$c \int\limits_{t_{\text{then}}+\lambda_{\text{then}}/c}^{t_{\text{now}}+\lambda_{\text{now}}/c} \frac{\mathrm{d}t}{a} \cong c \int\limits_{t_{\text{then}}}^{t_{\text{now}}} \frac{\mathrm{d}t}{a} \tag{12.5.444}$$

Remark

The approximation is considered as valid by professional astrophysicists and cosmologist because the first lights were emitted after the recombination epoch (i.e. time of the cosmological microwave background) estimated at $380,000$ years after the Big Bang when the inflation period (speculation of an exponential expansion of space in the early universe that would violated the assumption made just above) is supposed to have lasted from 10^{-36} seconds to between 10^{-33} and 10^{-32} seconds after the Big Bang. And keep in mind that the actual value of the Hubble constant is in SI units approximately equal to $2.4 \cdot 10^{-18}\;[\mathrm{s}^{-1}]$ and that's indeed (locally) a very small rate of expansion.

Using the following manipulation:

$$\begin{aligned}
0 &\cong \int\limits_{t_{\text{then}}}^{t_{\text{now}}} \frac{\mathrm{d}t}{a} - \int\limits_{t_{\text{then}}+\lambda_{\text{then}}/c}^{t_{\text{now}}+\lambda_{\text{now}}/c} \frac{\mathrm{d}t}{a} \\
&= \int\limits_{t_{\text{then}}}^{t_{\text{then}}+\lambda_{\text{then}}/c} \frac{\mathrm{d}t}{a} + \int\limits_{t_{\text{then}}+\lambda_{\text{then}}/c}^{t_{\text{now}}} \frac{\mathrm{d}t}{a} - \int\limits_{t_{\text{then}}+\lambda_{\text{then}}/c}^{t_{\text{now}}+\lambda_{\text{now}}/c} \frac{\mathrm{d}t}{a} \\
&= \int\limits_{t_{\text{then}}}^{t_{\text{then}}+\lambda_{\text{then}}/c} \frac{\mathrm{d}t}{a} - \left(\int\limits_{t_{\text{now}}}^{t_{\text{then}}+\lambda_{\text{then}}/c} \frac{\mathrm{d}t}{a} + \int\limits_{t_{\text{then}}+\lambda_{\text{then}}/c}^{t_{\text{now}}+\lambda_{\text{now}}/c} \frac{\mathrm{d}t}{a} \right) \\
&= \int\limits_{t_{\text{then}}}^{t_{\text{then}}+\lambda_{\text{then}}/c} \frac{\mathrm{d}t}{a} - \int\limits_{t_{\text{now}}}^{t_{\text{now}}+\lambda_{\text{now}}/c} \frac{\mathrm{d}t}{a}
\end{aligned} \tag{12.5.445}$$

we find that:

$$\int\limits_{t_{\text{now}}}^{t_{\text{now}}+\lambda_{\text{now}}/c}\frac{\mathrm{d}t}{a}\cong\int\limits_{t_{\text{then}}}^{t_{\text{then}}+\lambda_{\text{then}}/c}\frac{\mathrm{d}t}{a}\qquad(12.5.446)$$

For very small variations in time (over the period of one cycle of a light wave), we assume that the scale factor is essentially a constant ($a=a_{\text{now}}$ today and $a=a_{\text{then}}$ previously). This yields:

$$\frac{t_{\text{now}}+\lambda_{\text{now}}/c}{a_{\text{now}}}-\frac{t_{\text{now}}}{a_{\text{now}}}\cong\frac{t_{\text{then}}+\lambda_{\text{then}}/c}{a_{\text{then}}}-\frac{t_{\text{then}}}{a_{\text{then}}}\qquad(12.5.447)$$

which can be rewritten as:

$$\frac{\lambda_{\text{now}}}{\lambda_{\text{then}}}\cong\frac{a_{\text{now}}}{a_{\text{then}}}\qquad(12.5.448)$$

In analogy with the Doppler redshift provided earlier above, the relation:

$$\boxed{1+z\cong\frac{a_{\text{now}}}{a_{\text{then}}}\cong\frac{\lambda_{\text{now}}}{\lambda_{\text{then}}}=\frac{\nu_{\text{then}}}{\nu_{\text{now}}}}\qquad(12.5.449)$$

defines the "cosmological redshift" or"expansion redshift". Remarkably, with these approximations, the curvature of space does not appear in the final result. So redshift is related to the expansion factor of the Universe. If we measure a redshift of $z=2$, the Universe is $3\times$ bigger now than it was when that photon was emitted.

If rearranged the above relation is also famous as:

$$z\cong\frac{\lambda_{\text{now}}}{\lambda_{\text{then}}}-1=\frac{\lambda_{\text{now}}-\lambda_{\text{then}}}{\lambda_{\text{then}}}=\frac{\Delta\lambda}{\lambda_{\text{then}}}\qquad(12.5.450)$$

The most distant object observed so far at the day we write these lines is JADES-GS-z13-0 (a dark star) with a redshift of $z=13.20^{+0.04}_{-0.07}$. This correspond to a loss of energy of the emitted photon of:

$$\frac{\Delta E}{E}=\frac{h\Delta\nu}{h\nu_{\text{then}}}=\frac{(\nu_{\text{then}}-\nu_{\text{now}})}{\nu_{\text{then}}}=\frac{\left(\nu_{\text{then}}-\dfrac{\nu_{\text{then}}}{1+z}\right)}{\nu_{\text{then}}}=\left(1-\frac{1}{1+z}\right)=\frac{z}{z+1}\qquad(12.5.451)$$

Hence using the above relation for JADES-GS-z13-0 we can easily calculate that the photon has lost approximately 92.95% of its original energy.

In an expanding universe, the scale factor is monotonically increasing as time passes, thus, z is positive and distant galaxies appear red-shifted. it follows that as a photon travels across our expanding Universe its wavelength increases and its frequency decreases. Thus, the energy of the photon also decreases!

The previous relations shows that the redshift of a distant source is a measure of the total expansion of the universe that has occurred while the light was travelling between the source and the observer. It does not tell us the distance to the source or how long ago the light was emitted. These quantities depend on the precise nature of the Universe expansion between the instances of emission and observation. In different cosmological models we obtain different results for the same redshift!!! The reader must also keep in mind that the Dopplershift, Gravitational Redshift and Cosmological redshift from expansion are the same thing in the framework of General Relativity.

Obviously the redshift seems to violate the principle of conservation of energy. However remember that we have proved that this principle is valid only in a space that is translational symmetric in the time (see section Mechanics page 3132). However a quite common question that remains is: where does the energy difference go? Well if you remember our study of the wavepacket in the section of Wave Quantum Physics (see page 4786), we have proven that light is in reality infinitely spread even if the majority of its energy is especially concentrated in a small volume. We have also proven in the section of Quantum Field Theory (see page 5176) that light can be described as the excitation of an electromagnetic field that exists everywhere in the Universe. So what the reader must keep in mind, is that during the time the photon travels, a part of space-time (and hence a part of the energy of the photon that is spread infinitely through the whole space time of the Universe!) disappears beyond the Hubble horizon as our visible Universe is expanding and this is where the energy difference goes (!!!) as anything beyond this horizon is not causally related to us anymore!

Remark

The existence of the cosmological redshift explains the "Olbers' paradox" (named after the German astronomer Heinrich Wilhelm Olbers) or also known as the "dark night sky paradox". The darkness of the night sky is one of the pieces of evidence for a dynamic Universe, such as the Big Bang model (cosmic inflation theory). In the hypothetical case that the Universe is static, homogeneous at a large scale, and populated by an infinite number of stars, then any line of sight from Earth must end at the (very bright) surface of a star and hence the night sky should be completely illuminated and very bright. The Swiss mathematician Jean Philippe Loys de Cheseaux explains this paradox mathematically in 11746 (holocene calendar) by calculating that the light energy falling on Earth should be $180,000$ times more intense than that of the Sun. In 11823 (holocene calendar), Olbers refine this reasoning by observing that in a uniformly filled universe of stars, the stars are hidden from each other and deduces that the brightness of the night sky can not be infinite but at most equal to the surface brightness of a star.

This contradicts obviously the observed darkness and non-uniformity of the night as many stars are above the cosmological horizon and also a significant fraction of stars have their light that is redshifted and hence invisible to human eyes!

Notice that while dark clouds could obstruct the light, these clouds would heat up, until they were as hot as the stars, and then radiate the same amount of light.

12.5.6.3 Comobile Universe Diameter

As promised earlier, it is now time for us to determine the comobile Universe diameter using General Relativity and especially with the special case of the FLRW metric!

For this purpose we start again from the same assumption as for the cosmological redshift, i.e.:

$$\begin{aligned}\mathrm{d}s^2=g_{\mu\nu}\mathrm{d}x^\mu\mathrm{d}x^\nu&=-(c\mathrm{d}t)^2+a^2(t)\left(\frac{\mathrm{d}r^2}{1-kr^2}+r^2\mathrm{d}\Omega^2\right)\\&=-(c\mathrm{d}t)^2+a^2(t)\left[\frac{\mathrm{d}r^2}{1-kr^2}+r^2\left(\mathrm{d}\theta^2+\sin^2(\theta)\mathrm{d}\phi^2\right)\right]\\&=-(c\mathrm{d}t)^2+a^2(t)\frac{\mathrm{d}r^2}{1-kr^2}=0\end{aligned}\tag{12.5.452}$$

The horizon $d_H(t_1,t_2)$ is defined as the physical distance at time t_2 between two particles emitted at the same point but in opposite directions at time t_1, and travelling at the speed of light. If the origin of spherical comobile coordinates is chosen to coincide with the point of emission, the physical distance at time t_2 can be computed by integrating over small distance elements $\mathrm{d}l$ between the origin and the position r_2 of one particle, and multiplying by two:

$$d_H(t_1,t_2)=2\int\limits_0^{r_2}\mathrm{d}l=2\int\limits_0^{r_2}a(t_2)\frac{\mathrm{d}r}{\sqrt{1-kr^2}}\tag{12.5.453}$$

In addition, the geodesic equation for ultra-relativistic particles gives $\mathrm{d}s=0$, i.e.:

$$\mathrm{d}t=a(t)\frac{\mathrm{d}r}{\sqrt{1-kr^2}}\tag{12.5.454}$$

which can be integrated along the trajectory of the particles:

$$\int\limits_{t_1}^{t_2}\frac{\mathrm{d}t}{a(t)}=\int\limits_0^{r_2}\frac{\mathrm{d}r}{\sqrt{1-kr^2}}\tag{12.5.455}$$

We can now replace in the expression of d_H and get:

$$d_H(t_1,t_2)=2a(t_2)\int\limits_{t_1}^{t_2}\frac{\mathrm{d}t}{a(t)}\tag{12.5.456}$$

Usually, the result is presented in this form. However, for the following discussion, it is be particularly useful to eliminate the time from the integral by remembering that:

$$\mathrm{d}t=\frac{\mathrm{d}a}{aH}\tag{12.5.457}$$

Hence:

$$d_H(a_1,a_2)=2a_2\int\limits_{a_1}^{a_2}\frac{\mathrm{d}a}{a^2H(a)}\tag{12.5.458}$$

where the Hubble parameter is seen now as a function of a. Let us assume that t_1 and t_2 are two times during radiation domination. We know from the Friedmann equation that during radiation domination one has:

$$H \propto a^{-2} \tag{12.5.459}$$

so we can parametrize the Hubble rate as:

$$H(a) = H_2(a_2/a)^2 \tag{12.5.460}$$

We get:

$$d_H(a_1,a_2) = 2a_2 \int\limits_{a_1}^{a_2} \frac{\mathrm{d}a}{a_2^2 H(a)} = \frac{2}{H_2}\frac{(a_2-a_1)}{a_2} \tag{12.5.461}$$

If the time t_2 is much after t_1 so that $a_2 \gg a_1$, the expression for the horizon does not depend on a_1:

$$d_H(a_1,a_2) \cong \frac{2}{H_2} \tag{12.5.462}$$

So, the horizon equals twice the Hubble (comobile) radius at time t_2:

$$\boxed{d_H(t_1,t_2) \cong 2r_{\text{HS}}(t_2)} \tag{12.5.463}$$

This relation (that can be derived using some other ways more or less approximative but all assuming the radiation dominated era!) can lead us to a quite interesting result.

Indeed, during our basic study of the CMB (see page 5973) we have determined the original decoupling time t_{dec}. That latter relation can be injected in the previous relation that lead us to:

$$\begin{aligned} d_H(t_1,t_2) &\cong 2r_{\text{HS}}(t_2) = 2(1+z_{\text{dec}})ct_{\text{rec}} \cong 2(1+1,100)\cdot 380,000\,[\text{light years}] \\ &= 836,760,000\,[\text{light years}] \cong 255\,[\text{Mpc}] \end{aligned} \tag{12.5.464}$$

That means simply that at the time we write these lines, two points that were connected at the decoupling time, are today separated from a comobile distance (radius) of approximately 255 [Mpc] (assuming all assumptions are verified...!) on our Hubble sphere. As we have multiplied by the speed of light, this calculation assumes that today such points are causally disconnected regions of space! So this comobile distance represents like a lower-limit of two causally disconnected regions of space after the decoupling time.

12.5.6.4 Size of the Universe depending on its curvature

Many articles and videos of various social networks claim that because that our observable universe appears to be flat, then our whole universe must therefore be infinite but they never explain the underlying mathematical reasoning at all nor the calculation that leads to the approximately 40 billion light years of radius!

Remark

For reminder, the results of the Planck mission (see [446]), released in 12018 (holocene calendar) suggest that the cosmological curvature parameter, $1-\Omega=\Omega_k=-kc^2/a^2H^2$, to be 0.0007 ± 0.0019 (68%, TT,TE,EE+lowE+lensing+BAO) to a 1σ accuracy of 0.2%, consistent with a flat universe (i.e. positive curvature: $k=+1,\Omega_k<0,\Omega>1$, negative curvature: $k=-1,\Omega_k>0,\Omega<1$, zero curvature: $k=0,\Omega_k=0$, $\Omega=1$).

First, we need to be precise about the phrase «*the size of our Universe*». Specifically we are going to take it to mean the maximum possible separation between any two points. In an infinite universe two points can be separated by an arbitrarily large distance, so if the maximum distance between two points is finite this means the universe must not be infinite.

The point of all this is that the distance between any two points is calculated using a metric. For a Friedmann universe like ours (at least we assume our universe to be a Friedmann universe!) the metric is in natural units and in polar coordinates (see page 5991):

$$\mathrm{d}s^2=-\mathrm{d}t^2+a^2(t)\left[\frac{\mathrm{d}r^2}{1-kr^2}+r^2\mathrm{d}\Omega^2\right] \tag{12.5.465}$$

The value of the parameter k determines as we already know whether the universe (or just the observable universe) is closed, flat or open. Specifically $k>0$ is a closed universe, $k=0$ is a flat universe and $k<0$ is an open universe. The variable s is the proper distance.

Now, suppose we choose an origin at some starting point, choose a fixed time, and calculate the proper distance, s as we move radially away from the starting point. The question is whether s can reach infinity or not. Because only r is changing $\mathrm{d}t=\mathrm{d}\Omega=0$, so the expression for the proper distance simplifies to:

$$\mathrm{d}s^2=a^2(t)\frac{\mathrm{d}r^2}{1-kr^2} \tag{12.5.466}$$

We will choose our units of distance to make $a=1$, and we'll consider only closed or flat space, i.e. $k\geq 0$, in which case we can integrate:

$$\mathrm{d}s^2=a^2(t)\frac{\mathrm{d}r^2}{1-kr^2}\Rightarrow\mathrm{d}s=\frac{\mathrm{d}r}{\sqrt{1-kr^2}}=\frac{\mathrm{d}r}{\sqrt{1-(\sqrt{k}r)^2}} \tag{12.5.467}$$

that gives (see section Differential and Integral Calculus page 1534):

$$s(r)=\frac{\arcsin(\sqrt{k}r)}{\sqrt{k}} \tag{12.5.468}$$

So the maximum possible value for $s(r)$ is when $\sqrt{k}r=1$, in which case:

$$s_{\text{max}}=\frac{\pi}{2\sqrt{k}} \quad (12.5.469)$$

And there's the result we want. For a closed universe $k>0$ and therefore the maximum possible distance between two points is finite. However as $k\rightarrow 0_+$ the maximum possible distance $s_{\text{max}}\rightarrow +\infty$. That's why a flat universe is infinite.

However we should note that, that even a flat universe can be finite if it has a non-trivial topology (like a torus that big enough can locally appear to be flat!).

If we don't put $a(t)=1$ as we did above, the solutions are commonly denoted:

$$s(t)=a(t)\cdot\begin{cases}\frac{1}{\sqrt{k}}\sin^{-1}(r\sqrt{k}) & \text{for } k>0\\ r & \text{for } k=0\\ \frac{1}{\sqrt{|k|}}\sinh^{-1}(r\sqrt{|k|}) & \text{for } k<0\end{cases} \quad (12.5.470)$$

In a flat Universe, the proper distance to an object is just its coordinate distance, $s(t)=a(t)\cdot r$. However, because the r coordinate was introduced in the context of a flat Newtonian Universe, the coordinate distance will generally not agree with the proper distance. Because $\sin^{-1}(x)\geq x$ and $\sinh^{-1}(x)\leq x$, in a closed Universe $(k>0)$ the proper distance to an object is greater than its coordinate distance, while in an open Universe $(k<0)$ the proper distance to an object is less than its coordinate distance.

Remark

Instead of taking one measurement method, a team of scientists led by Mihran Vardanyan at the University of Oxford (see [555]) did a statistical analysis of all of the results. By using Bayesian model averaging, which focuses on how likely a model is to be correct given the data, rather than asking how well the model itself fits the data. They found that the universe, we quote: «*...The minimum size of the Universe is robustly constrained to encompass* $N_U\gtrsim 251$ *Hubble spheres...*»

Again we return to the Friedmann-Lemaître-Robertson-Walker metric:

$$\mathrm{d}s^2=c\mathrm{d}t^2-a^2(t)\left[\frac{\mathrm{d}r^2}{1-kr^2}+r^2\left(\mathrm{d}\theta^2+\sin^2(\theta)\mathrm{d}\phi^2\right)\right] \quad (12.5.471)$$

and we exploit the fact that in General Relativity the propagation of light is along a null geodesic $(\mathrm{d}s=0)$. With the observer (i.e. us, on Earth) at the origin $(r=0)$, we choose a radial null geodesic so that $\mathrm{d}\theta=\mathrm{d}\phi=0$, and the previous relation reduces to:

$$\frac{c\mathrm{d}t}{a(t)}=\pm\frac{\mathrm{d}r}{(1-kr^2)^{1/2}} \quad (12.5.472)$$

where the $+$ sign corresponds to an emitted light ray and the $-$ sign to a received one.

Placing an observer at the origin $(r=0)$ and let the particle horizon for this observer at time t be located at radial coordinate distance r_{hor}. This means that a photon emitted at $t=0$ at r_{hor} will reach our observer at the origin at time t the previous relation can be rewritten:

$$\int\limits_0^t\frac{\mathrm{d}t}{a(t)}=\frac{1}{c}\int\limits_0^{r_{\text{hor.}}}\frac{\mathrm{d}r}{(1-kr^2)^{1/2}} \quad (12.5.473)$$

from which we have immediately that:

$$r_{\text{hor.}}=\begin{cases}\sin\left(c\int\limits_0^t\frac{\mathrm{d}t}{a(t)}\right) & \text{for } k=1\\ c\int\limits_0^t\frac{\mathrm{d}t}{a(t)} & \text{for } k=0\\ \sinh\left(c\int\limits_0^t\frac{\mathrm{d}t}{a(t)}\right) & \text{for } k=-1\end{cases}\qquad(12.5.474)$$

Let us recall that the proper distance from the origin to $r_{\text{hor.}}$ is given by as we have just seen earlier above:

$$s_{\text{hor.}}(t)=a(t)\int\limits_0^{r_{\text{hor.}}}\frac{\mathrm{d}r}{(1-kr^2)^{1/2}}\qquad(12.5.475)$$

and combining it with:

$$\int\limits_0^t\frac{\mathrm{d}t}{a(t)}=\frac{1}{c}\int\limits_0^{r_{\text{hor.}}}\frac{\mathrm{d}r}{(1-kr^2)^{1/2}}\qquad(12.5.476)$$

we get the proper distance to the horizon that is found to be:

$$\boxed{s_{\text{hor.}}(t)=a(t)\int\limits_0^t\frac{c\mathrm{d}t}{a(t)}}\qquad(12.5.477)$$

and this is a nice expression as k disappears! This is the relation we will use further below when introducing the different FLRW Universe models (see page 6014) to determine their corresponding size!

Remember that at page 5914, we have proved that in the case without cosmological constant that today (this is why we have H_0 instead of H and Ω_0 instead of Ω and R_0 instead of $R(t)$):

$$H_0^2(1-\Omega_0)=-\frac{k}{R_0^2c^2}\qquad(12.5.478)$$

Hence:

$$\boxed{R_0=\frac{c\sqrt{k}}{H_0\sqrt{1-\Omega_0}}}\qquad(12.5.479)$$

In we assume a spherical universe, i.e. $k=1$ we get:

$$R_0=\frac{c}{H_0\sqrt{1-\Omega_0}}\qquad(12.5.480)$$

As by definition (for reminder Ω_k is not an actual mass/energy density and is defined as $\Omega_k=1-\Omega_0$ so that $\Omega_k=0$ for a spatially flat universe):

$$\Omega_k=1-\Omega_0\qquad(12.5.481)$$

Therefore:

$$R_0 = \frac{c}{H_0\sqrt{\Omega_k}} \qquad (12.5.482)$$

From [446], we have at 1σ:

$$\Omega_k = 0.0007 \pm 0.0019 \qquad (12.5.483)$$

If the universe is spherical, its minimum size corresponds at 1σ in absolute value to:

$$\Omega_k = 0.0012 \qquad (12.5.484)$$

If the universe is spherical with $H_0 = 67.66\,[\text{km}\cdot\text{s}\cdot\text{Mpc}^{-1}]$, its minimum radius of curvature is:

$$R = \frac{c}{H_0}\cdot\frac{1}{\sqrt{\Omega_k}} \cong \frac{299,792.458}{67.66}\cdot\frac{1}{\sqrt{0.0012}} = 127,908\,[\text{Gly}] = 417\,[\text{Gly}] \qquad (12.5.485)$$

As we prove it at page 6048, the proper size of the observable universe assumed as flat is:

$$R_{\Lambda=0,k=0} \cong 3ct \cong 41.31 \pm 0.12\,[\text{Gly}] \qquad (12.5.486)$$

Therefore if the universe is spherical, its radius is at least 10 times larger than the observable universe!

If we prefer to give the result as a function of Hubble spheres, we know that the actual Hubble radius is (see page 5888):

$$R_H \cong 14.5\,[\text{Gly}] \qquad (12.5.487)$$

Therefore if the universe is spherical, its radius is at least 29.3 times larger than the Hubble radius.

12.5.6.5 General Friedmann equations

It follows now, that using the second signature and changing x to r' we get:

$$g_{00}=1,\, g_{r'r'}=\frac{-a^2}{1-kr'^2},\, g_{\theta\theta}=-a^2r'^2,\, g_{\phi\phi}=-a^2r'^2\sin^2(\theta) \tag{12.5.488}$$

For later we need to calculate the Christoffel symbols (arrrgh!!!!). So let us do that for the non-null one only.

First let us recall that (see section Tensor Calculus page 2109) that:

$$\begin{aligned}\Gamma^{\sigma}_{\lambda\mu}&=\frac{1}{2}g^{\nu\sigma}\left[\frac{\partial g_{\mu\nu}}{\partial x^{\lambda}}+\frac{\partial g_{\lambda\nu}}{\partial x^{\mu}}-\frac{\partial g_{\lambda\mu}}{\partial x^{\nu}}\right]\\ \Gamma^{\mu}_{\mu\lambda}&=\Gamma^{\mu}_{\lambda\mu}=\frac{1}{2}g^{\mu\rho}\frac{\partial g_{\rho\mu}}{\partial x^{\lambda}}\end{aligned} \tag{12.5.489}$$

And let's go for the boring part!:

$$\begin{aligned}\Gamma^{r'}_{r'r'}&=\frac{1}{2}g^{r'\rho}\frac{\partial g_{\rho r'}}{\partial x^{r'}}=\frac{1}{2}g^{r'r'}\frac{\partial g_{r'r'}}{\partial r'}=\frac{1}{2}\left(\frac{1-kr'^2}{\cancel{-a^2}}\right)\frac{\partial\left(\frac{\cancel{-a^2}}{1-kr'^2}\right)}{\partial r'}\\ &=\frac{1}{2}\left(1-kr'^2\right)\frac{+2kr'}{\left(1-kr'^2\right)^2}=\frac{kr'}{\left(1-kr'^2\right)}\end{aligned}$$

$$\begin{aligned}\Gamma^{r'}_{0r'}=\Gamma^{r'}_{r'0}&=\frac{1}{2}g^{r'\rho}\frac{\partial g_{\rho r'}}{\partial x^{0}}=\frac{1}{2}g^{r'r'}\frac{\partial g_{r'r'}}{\partial x^{0}}=\frac{1}{2}\frac{1-kr'^2}{-a^2}\frac{\partial\left(\frac{-a^2}{1-kr'^2}\right)}{c\partial t}\\ &=\frac{1}{2c}\frac{1-kr'^2}{-a^2}\frac{-2a\dot{a}}{1-kr'^2}=\frac{\dot{a}}{ca}\\ \Gamma^{\theta}_{0\theta}=\Gamma^{\theta}_{\theta 0}&=\frac{1}{2}g^{\theta\theta}\frac{\partial g_{\theta\theta}}{\partial x^{0}}=\frac{1}{2}\frac{1}{-a^2r'^2}\frac{\partial(-a^2r'^2)}{c\partial t}=\frac{\dot{a}}{ca}\\ \Gamma^{\phi}_{0\phi}=\Gamma^{\phi}_{\phi 0}&=\frac{\dot{a}}{ca}\end{aligned}$$

$$\begin{aligned}\Gamma^{\theta}_{\theta r'}=\Gamma^{\theta}_{r'\theta}&=\frac{1}{2}g^{\theta\theta}\frac{\partial g_{\theta\theta}}{\partial r'}=\frac{1}{2}\frac{1}{-a^2r'^2}\frac{\partial(-a^2r'^2)}{\partial r'}=\frac{1}{r'}\\ \Gamma^{\phi}_{\phi r'}=\Gamma^{\phi}_{r'\phi}&=\frac{1}{2}g^{\phi\phi}\frac{\partial g_{\phi\phi}}{\partial r'}=\frac{1}{2}\frac{1}{-a^2r'^2\sin^2(\theta)}\frac{\partial(-a^2r'^2\sin^2(\theta))}{\partial r'}=\frac{1}{r'}\end{aligned}$$

$$\begin{aligned}\Gamma^{0}_{r'r'}&=\frac{1}{2}g^{\nu 0}\left[\frac{\partial g_{r'\nu}}{\partial r'}+\frac{\partial g_{r'\nu}}{\partial r'}-\frac{\partial g_{r'r'}}{\partial x^{\nu}}\right]=\frac{1}{2}g^{00}\left[\frac{\partial g_{r'0}}{\partial r'}+\frac{\partial g_{r'0}}{\partial r'}-\frac{\partial g_{r'r'}}{\partial x^{0}}\right]\\ &=-\frac{1}{2}\left[\frac{\partial\left(\frac{-a^2}{1-kr'^2}\right)}{c\partial t}\right]=\frac{a\dot{a}}{c(1-kr'^2)}\end{aligned}$$

$$\Gamma_{\theta\theta}^{0}=\frac{1}{2}g^{00}\left[\frac{\partial g_{\theta 0}}{\partial x^{\theta}}+\frac{\partial g_{\theta 0}}{\partial x^{\theta}}-\frac{\partial g_{\theta\theta}}{\partial x^{0}}\right]=-\frac{1}{2}\left[\frac{\partial(-a^2r'^2)}{c\partial t}\right]=\frac{a\dot{a}r'^2}{c}$$

$$\Gamma_{\phi\phi}^{0}=\frac{1}{2}g^{00}\left[\frac{\partial g_{\phi 0}}{\partial x^{\phi}}+\frac{\partial g_{\phi 0}}{\partial x^{\phi}}-\frac{\partial g_{\phi\phi}}{\partial x^{0}}\right]=-\frac{1}{2}\left[\frac{\partial(-a^2r'^2\sin^2(\theta))}{c\partial t}\right]=\frac{a\dot{a}r'^2\sin^2(\theta)}{c}$$

$$\begin{aligned}\Gamma_{\phi\phi}^{\theta}&=\frac{1}{2}g^{\theta\theta}\left[\frac{\partial g_{\phi\theta}}{\partial x^{\phi}}+\frac{\partial g_{\phi\theta}}{\partial x^{\phi}}-\frac{\partial g_{\phi\phi}}{\partial x^{\theta}}\right]=-\frac{1}{2}\frac{1}{-a^2r'^2}\frac{\partial(-a^2r'^2\sin^2(\theta))}{\partial\theta}\\&=-\sin(\theta)\cos(\theta)\end{aligned}$$

$$\begin{aligned}\Gamma_{\theta\phi}^{\phi}&=\frac{1}{2}g^{\phi\phi}\left[\frac{\partial g_{\phi\phi}}{\partial x^{\theta}}+\frac{\partial g_{\theta\phi}}{\partial x^{\phi}}-\frac{\partial g_{\theta\phi}}{\partial x^{\phi}}\right]=\frac{1}{2}\frac{1}{-a^2r'^2\sin^2(\theta)}\frac{\partial(-a^2r'^2\sin^2(\theta))}{\partial\theta}\\&=\frac{\cos(\theta)}{\sin(\theta)}\end{aligned}$$

$$\begin{aligned}\Gamma_{\theta\theta}^{r'}&=\frac{1}{2}g^{r'r'}\left[\frac{\partial g_{\theta r'}}{\partial x^{\theta}}+\frac{\partial g_{\theta r'}}{\partial x^{\theta}}-\frac{\partial g_{\theta\theta}}{\partial x^{r'}}\right]=-\frac{1}{2}\frac{1-kr'^2}{\cancel{-a^2}}\frac{\partial(\cancel{-a^2}r'^2)}{\partial r'}\\&=-r'(1-kr'^2)\end{aligned}$$

$$\begin{aligned}\Gamma_{\phi\phi}^{r'}&=\frac{1}{2}g^{r'r'}\left[\frac{\partial g_{\phi r'}}{\partial x^{\phi}}+\frac{\partial g_{\phi r'}}{\partial x^{\phi}}-\frac{\partial g_{\phi\phi}}{\partial x^{r'}}\right]=-\frac{1}{2}\frac{(1-kr'^2)}{\cancel{-a^2}}\frac{\partial(\cancel{-a^2}r'^2\sin^2(\theta))}{\partial r'}\\&=-r'(1-kr'^2)\sin^2(\theta)\end{aligned}$$

Let us now calculate the Ricci tensor only for the non-null terms:

$$R_{\mu k}=\frac{\partial\Gamma_{\mu k}^{\nu}}{\partial x^{\nu}}-\frac{\partial\Gamma_{\mu\nu}^{\nu}}{\partial x^{k}}+\Gamma_{\nu\sigma}^{\sigma}\Gamma_{\mu k}^{\nu}-\Gamma_{\mu\nu}^{\sigma}\Gamma_{k\sigma}^{\nu} \tag{12.5.490}$$

Then (pffff...!):

$$\begin{aligned}-R_{00}&=-\frac{\partial\overbrace{\Gamma_{00}^{\nu}}^{0}}{\partial x^{\nu}}+\frac{\partial\Gamma_{0\nu}^{\nu}}{\partial x^{0}}-\Gamma_{\nu\sigma}^{\sigma}\overbrace{\Gamma_{\mu k}^{\nu}}^{0}+\Gamma_{\nu 0}^{\sigma}\Gamma_{0\sigma}^{\nu}\\
&=\frac{\partial(\Gamma_{0r'}^{r'}+\Gamma_{0\theta}^{\theta}+\Gamma_{0\phi}^{\phi})}{c\partial t}+(\overbrace{\Gamma_{00}^{\sigma}}^{0}\Gamma_{0\sigma}^{0}+\Gamma_{r'0}^{\sigma}\Gamma_{0\sigma}^{r'}+\Gamma_{\theta 0}^{\sigma}\Gamma_{0\sigma}^{\theta}+\Gamma_{\phi 0}^{\sigma}\Gamma_{0\sigma}^{\phi})\\
&=\frac{\partial(3\cdot\frac{\dot{a}}{c\cdot a})}{c\partial t}+(\overbrace{\Gamma_{r'0}^{0}}^{0}\overbrace{\Gamma_{00}^{r'}}^{0}+\overbrace{\Gamma_{\theta 0}^{0}}^{0}\overbrace{\Gamma_{00}^{\theta}}^{0}+\overbrace{\Gamma_{\phi 0}^{0}}^{0}\overbrace{\Gamma_{00}^{\phi}}^{0})+(\overbrace{\Gamma_{r'0}^{r'}\Gamma_{0r'}^{r'}}^{(\frac{\dot{a}}{c\cdot a})^2}+\Gamma_{\theta 0}^{r'}\overbrace{\Gamma_{0r'}^{\theta}}^{0}+\overbrace{\Gamma_{\phi 0}^{r'}}^{0}\Gamma_{0r'}^{\phi})\\
&+(\Gamma_{r'0}^{\theta}\overbrace{\Gamma_{0\theta}^{r'}}^{0}+\overbrace{\Gamma_{\theta 0}^{\theta}\Gamma_{0\theta}^{\theta}}^{(\frac{\dot{a}}{c\cdot a})^2}+\overbrace{\Gamma_{\phi 0}^{\theta}}^{0}\Gamma_{0\theta}^{\phi})+(\overbrace{\Gamma_{r'0}^{\phi}}^{0}\overbrace{\Gamma_{0\phi}^{r'}}^{0}+\overbrace{\Gamma_{r'0}^{\phi}}^{0}\Gamma_{0\phi}^{\theta}+\overbrace{\Gamma_{\phi 0}^{\phi}\Gamma_{0\phi}^{\phi}}^{(\frac{\dot{a}}{c\cdot a})^2})\\
&=\frac{3}{c^2}\left(\frac{a\ddot{a}-\dot{a}^2}{a^2}\right)+3\frac{\dot{a}^2}{c^2a^2}=\frac{3\ddot{a}}{ac^2}\end{aligned} \tag{12.5.491}$$

So finally:

$$R_{00} = -\frac{3\ddot{a}}{ac^2} \tag{12.5.492}$$

And next:

$$\begin{aligned}
-R_{\phi\phi} &= -\frac{\partial\Gamma^{\nu}_{\phi\phi}}{\partial x^{\nu}} + \frac{\overbrace{\partial\Gamma^{\nu}_{\phi\nu}}^{0}}{\partial x^{\phi}} - \Gamma^{\sigma}_{\nu\sigma}\Gamma^{\nu}_{\phi\phi} + \Gamma^{\sigma}_{\phi\nu}\Gamma^{\nu}_{\phi\sigma} = \left(-\frac{\partial\Gamma^{0}_{\phi\phi}}{\partial x^{0}} - \Gamma^{\sigma}_{0\sigma}\Gamma^{0}_{\phi\phi} + \Gamma^{\sigma}_{\phi 0}\Gamma^{0}_{\phi\sigma}\right)_{0}\\
&+ \left(-\frac{\partial\Gamma^{r'}_{\phi\phi}}{\partial r'} - \Gamma^{\sigma}_{r'\sigma}\Gamma^{r'}_{\phi\phi} + \Gamma^{\sigma}_{\phi r'}\Gamma^{r'}_{\phi\sigma}\right)_{r'} + \left(-\frac{\partial\Gamma^{\theta}_{\phi\phi}}{\partial\theta} - \Gamma^{\sigma}_{\theta\sigma}\Gamma^{\theta}_{\phi\phi} + \Gamma^{\sigma}_{\phi\theta}\Gamma^{\theta}_{\phi\sigma}\right)_{\theta} + \Gamma^{\sigma}_{\phi\phi}\Gamma^{\phi}_{\phi\sigma}\\
&= \Bigg[-\frac{\left(\frac{a\dot{a}\cdot r'^2\cdot\sin^2(\theta)}{c}\right)}{c\partial t} - 3\frac{\dot{a}}{c\cdot\cancel{a}}\cdot\frac{\cancel{a}\dot{a}\cdot r'^2\cdot\sin^2(\theta)}{c} + \overbrace{\Gamma^{0}_{\phi 0}\Gamma^{0}_{\phi 0}}^{0} + \overbrace{\Gamma^{r'}_{\phi 0}\Gamma^{0}_{\phi r'}}^{0} + \overbrace{\Gamma^{\theta}_{\phi 0}\Gamma^{0}_{\phi\theta}}^{0} + \overbrace{\Gamma^{\phi}_{\phi 0}}^{\frac{\dot{a}}{c\cdot a}}\;\overbrace{\Gamma^{0}_{\phi\phi}}^{\frac{a\dot{a}\cdot r'^2\cdot\sin^2(\theta)}{c}}\Bigg]\\
&+ \Bigg[-\frac{\partial(-r'\cdot(1-k\cdot r'^2)\cdot\sin^2(\theta))}{\partial r'} - \overbrace{\Gamma^{0}_{r'0}}^{0}\Gamma^{r'}_{\phi\phi} - \overbrace{\Gamma^{r'}_{r'r'}}^{\frac{k\cdot r'}{(1-k\cdot r'^2)}}\;\overbrace{\Gamma^{r'}_{\phi\phi}}^{-r'\cdot(1-k\cdot r'^2)\cdot\sin^2(\theta)} - \cancel{\overbrace{\Gamma^{\theta}_{r'\theta}}^{\frac{1}{r'}}\;\overbrace{\Gamma^{r'}_{\phi\phi}}^{-r'\cdot(1-k\cdot r'^2)\cdot\sin^2(\theta)}}\\
&- \cancel{\overbrace{\Gamma^{\phi}_{r'\phi}}^{\frac{1}{r'}}\;\overbrace{\Gamma^{r'}_{\phi\phi}}^{-r'\cdot(1-k\cdot r'^2)\cdot\sin^2(\theta)}} + \overbrace{\Gamma^{0}_{\phi r'}}^{0}\Gamma^{r'}_{\phi 0} + \overbrace{\Gamma^{r'}_{\phi r'}}^{0}\Gamma^{r'}_{\phi r'} + \overbrace{\Gamma^{\theta}_{\phi r'}}^{0}\Gamma^{r'}_{\phi\theta} + \cancel{\overbrace{\Gamma^{\phi}_{\phi r'}}^{\frac{1}{r'}}\;\overbrace{\Gamma^{r'}_{\phi\phi}}^{-r'\cdot(1-k\cdot r'^2)\cdot\sin^2(\theta)}}\Bigg]\\
&+ \Bigg[-\frac{\partial(-\sin^2(\theta)\cdot\cos(\theta))}{\partial\theta} - \overbrace{\Gamma^{0}_{\theta 0}}^{0}\Gamma^{\theta}_{\phi\phi} - \overbrace{\Gamma^{r'}_{\theta r'}}^{0}\Gamma^{\theta}_{\phi\phi} - \overbrace{\Gamma^{\theta}_{\theta\theta}}^{0}\Gamma^{\theta}_{\phi\phi} - \cancel{\overbrace{\Gamma^{\phi}_{\theta\phi}}^{\frac{\cos(\theta)}{\sin(\theta)}}\;\overbrace{\Gamma^{\theta}_{\phi\phi}}^{-\sin(\theta)\cdot\cos(\theta)}} + \overbrace{\Gamma^{0}_{\phi\theta}}^{0}\Gamma^{\theta}_{\phi 0}\\
&+ \overbrace{\Gamma^{r'}_{\phi\theta}}^{0}\Gamma^{\theta}_{\phi r'} + \overbrace{\Gamma^{\theta}_{\phi\theta}}^{0}\Gamma^{\theta}_{\phi\theta} + \cancel{\overbrace{\Gamma^{\phi}_{\phi\theta}}^{\frac{\cos(\theta)}{\sin(\theta)}}\;\overbrace{\Gamma^{\theta}_{\phi\phi}}^{-\sin(\theta)\cdot\cos(\theta)}}\Bigg]\\
&+ \overbrace{\Gamma^{0}_{\phi\phi}}^{\frac{a\dot{a}\cdot r'^2\cdot\sin^2(\theta)}{c}}\;\overbrace{\Gamma^{\phi}_{\phi 0}}^{\frac{\dot{a}}{c\cdot a}} + \cancel{\overbrace{\Gamma^{r'}_{\phi\phi}}^{-r'\cdot(1-k\cdot r'^2)\cdot\sin^2(\theta)}\;\overbrace{\Gamma^{\phi}_{\phi r'}}^{\frac{1}{r'}}} + \overbrace{\Gamma^{\theta}_{\phi\phi}}^{-\sin(\theta)\cdot\cos(\theta)}\;\overbrace{\Gamma^{\phi}_{\phi\theta}}^{\frac{\cos(\theta)}{\sin(\theta)}} + \overbrace{\Gamma^{\phi}_{\phi\phi}}^{0}\Gamma^{\phi}_{\phi\phi}
\end{aligned} \tag{12.5.493}$$

Therefore:

$$\begin{aligned}
R_{\phi\phi} &= -\frac{r'^2\sin^2(\theta)(\dot{a}^2+a\ddot{a})}{c^2} - 2\frac{\dot{a}^2\cdot r'^2\sin^2(\theta)}{c^2} + \cancel{\sin^2(\theta)} - 3kr'^2\sin^2(\theta) + kr'^2\sin^2(\theta)\\
&+ \cancel{\cos^2(\theta)} - \cancel{\sin^2(\theta)} + \frac{\dot{a}^2\cdot r'^2\cdot\sin^2(\theta)}{c^2} - \cancel{\cos^2(\theta)}
\end{aligned} \tag{12.5.494}$$

So finally:

$$R_{\phi\phi} = \frac{r'^2\sin^2(\theta)}{c^2}\left[a\ddot{a} + 2\dot{a} + 2kc^2\right] \tag{12.5.495}$$

$$
\begin{aligned}
-R_{r'r'} &= -\frac{\partial\Gamma^{\nu}_{r'r'}}{\partial x^{\nu}} + \overbrace{\frac{\partial\Gamma^{\nu}_{r'\nu}}{\partial x^{r'}}}^{0} - \Gamma^{\sigma}_{\nu\sigma}\Gamma^{\nu}_{r'r'} + \Gamma^{\sigma}_{r'\nu}\Gamma^{\nu}_{r'\sigma}\\
&= (-\frac{\partial\Gamma^{0}_{r'r'}}{\partial x^{0}} + \frac{\partial\,\overbrace{\Gamma^{0}_{r'0}}^{0}}{\partial x^{r'}} - \Gamma^{\sigma}_{0\sigma}\Gamma^{0}_{r'r'} + \Gamma^{\sigma}_{r'0}\Gamma^{0}_{r'0})_{0} + (-\cancel{\frac{\partial\Gamma^{r}_{r'r'}}{\partial x^{r'}}} + \cancel{\frac{\partial\Gamma^{r}_{r'r'}}{\partial x^{r'}}} - \Gamma^{\sigma}_{r'\sigma}\Gamma^{r'}_{r'r'} + \Gamma^{\sigma}_{r'r'}\Gamma^{r'}_{r'\sigma})_{r'}\\
&+ (-\frac{\partial\,\overbrace{\Gamma^{\theta}_{r'r'}}^{0}}{\partial x^{\theta}} + \frac{\partial\Gamma^{\theta}_{r'\theta}}{\partial x^{r'}} - \Gamma^{\sigma}_{\theta\sigma}\,\overbrace{\Gamma^{\theta}_{r'r'}}^{0} + \Gamma^{\sigma}_{r'\theta}\Gamma^{\theta}_{r'\sigma})_{\theta} + (-\cancel{\frac{\partial\Gamma^{\phi}_{r'r'}}{\partial x^{\phi}}} + \frac{\partial\Gamma^{\phi}_{r'\phi}}{\partial x'^{r}} - \Gamma^{\sigma}_{\phi\sigma}\,\overbrace{\Gamma^{\phi}_{r'r'}}^{0} + \Gamma^{\sigma}_{r'\phi}\Gamma^{\phi}_{r'\sigma})_{\phi}\\
&= (-\frac{\partial(\frac{a\dot{a}}{c(1-kr'^2)})}{c\partial t} - (\overbrace{\Gamma^{0}_{00}}^{0} + \overbrace{\Gamma^{r'}_{0r'}}^{\frac{\dot{a}}{ca}} + \overbrace{\Gamma^{\theta}_{0\theta}}^{\frac{\dot{a}}{ca}} + \overbrace{\Gamma^{\phi}_{0\phi}}^{\frac{\dot{a}}{ca}})\,\overbrace{\Gamma^{0}_{r'r'}}^{\frac{a\dot{a}}{c(1-kr'^2)}}\\
&+ \overbrace{\Gamma^{0}_{r'0}\Gamma^{0}_{r'0}}^{0} + \overbrace{\Gamma^{r'}_{r'0}}^{\frac{\dot{a}}{ca}}\,\overbrace{\Gamma^{0}_{r'r'}}^{\frac{a\dot{a}}{c(1-kr'^2)}} + \overbrace{\Gamma^{\theta}_{r'0}\Gamma^{0}_{r'\theta}}^{0} + \overbrace{\Gamma^{\phi}_{r'0}\Gamma^{0}_{r'\phi}}^{0}\\
&+ (-(\overbrace{\Gamma^{0}_{r'0}}^{0} + \overbrace{\Gamma^{r'}_{r'r'}}^{\frac{kr'}{(1-kr'^2)}} + \overbrace{\Gamma^{\theta}_{r'\theta}}^{\frac{1}{r'}} + \overbrace{\Gamma^{\phi}_{r'\phi}}^{\frac{1}{r'}})\,\overbrace{\Gamma^{r'}_{r'r'}}^{\frac{kr'}{(1-kr'^2)}} + \overbrace{\Gamma^{0}_{r'r'}}^{\frac{a\dot{a}}{c(1-kr'^2)}}\\
&+ \overbrace{\Gamma^{r'}_{r'0}}^{\frac{\dot{a}}{ca}} + \overbrace{\Gamma^{r'}_{r'r'}}^{\frac{kr'}{(1-kr'^2)}}\,\overbrace{\Gamma^{r'}_{r'r'}}^{\frac{kr'}{(1-kr'^2)}} + \overbrace{\Gamma^{\theta}_{r'r'}}^{0}\,\Gamma^{r'}_{r'\theta} + \overbrace{\Gamma^{\phi}_{r'r'}}^{0}\,\Gamma^{r'}_{r'\phi})_{r'}\\
&+ (\frac{\partial(\frac{1}{r'})}{\partial r'} + \overbrace{\Gamma^{0}_{r'\theta}\Gamma^{\theta}_{r'0}}^{0} + \overbrace{\Gamma^{r'}_{r'\theta}}^{0}\,\Gamma^{\theta}_{r'r'} + \overbrace{\Gamma^{\theta}_{r'\theta}}^{\frac{1}{r'}}\,\overbrace{\Gamma^{\theta}_{r'\theta}}^{\frac{1}{r'}} + \overbrace{\Gamma^{\phi}_{r'\theta}\Gamma^{\theta}_{r'\phi}}^{0})_{\theta}\\
&+ (\frac{\partial(\frac{1}{r'})}{\partial r'} + \overbrace{\Gamma^{0}_{r'\phi}\Gamma^{\phi}_{r'0}}^{0} + \overbrace{\Gamma^{r'}_{r'\phi}\Gamma^{\phi}_{r'r'}}^{0} + \overbrace{\Gamma^{\theta}_{r'\phi}\Gamma^{\phi}_{r'\theta}}^{0} + \overbrace{\Gamma^{\phi}_{r'\phi}}^{\frac{1}{r'}}\,\overbrace{\Gamma^{\phi}_{r'\phi}}^{\frac{1}{r'}})_{\phi}\\
&= \left[-\frac{\dot{a}^2+a\ddot{a}}{c^2(1-kr'^2)} - 2\frac{\dot{a}}{c\cancel{a}}\frac{\cancel{a}\dot{a}}{c(1-kr'^2)}\right]\\
&+ \left[-\cancel{(\frac{kr'}{(1-kr'^2)})^2} - 2\frac{1}{\cancel{r'}}\frac{k\cancel{r'}}{(1-kr'^2)} + \frac{\cancel{a}\dot{a}}{c(1-kr'^2)}\frac{\dot{a}}{c\cancel{a}} + \cancel{(\frac{kr'}{(1-kr'^2)})^2}\right]\\
&+ \left[-\cancel{\frac{1}{r'^2}} + \cancel{\frac{1}{r'^2}}\right] + \left[-\cancel{\frac{1}{r'^2}} + \cancel{\frac{1}{r'^2}}\right]\\
&= -\frac{\dot{a}^2+a\ddot{a}}{c^2(1-kr'^2)} - \frac{\dot{a}^2}{c^2(1-kr'^2)} - \frac{2kc^2}{c^2(1-kr'^2)}
\end{aligned}
\tag{12.5.496}
$$

Therefore:

$$R_{r'r'} = \frac{a\ddot{a} + 2\dot{a}^2 + 2kc^2}{c^2(1-kr'^2)} \tag{12.5.497}$$

Also identically (sorry but we don't have the power anymore to detail the calculations...):

$$R_{\theta\theta} = \frac{r'^2}{c^2}\left[a\ddot{a} + 2\dot{a}^2 + 2kc^2\right] \tag{12.5.498}$$

Now let us calculate the scalar curvature (Ricci scalar). Let us recall (see section Tensor Calculus page 2128), that it is given by:

$$R = g^{ij}R_{ij} = R^{i}_{i} \tag{12.5.499}$$

Therefore using previous results:

$$\begin{aligned}R&=g^{00}R_{00}+g^{r'r'}R_{r'r'}+g^{\theta\theta}R_{\theta\theta}+g^{\phi\phi}R_{\phi\phi}\\&=1\cdot\frac{-3\ddot{a}}{ac^2}+\frac{\cancel{1-kr'^2}}{-a^2}\frac{(a\ddot{a}+2\dot{a}^2+2kc^2)}{c^2\cancel{(1-kr'^2)}}\\&+\frac{1}{-a^2r'^2}\frac{\cancel{r'^2}}{c^2}[a\ddot{a}+2\dot{a}+2kc^2]+\frac{1}{-a^2\cancel{r'^2\sin^2(\theta)}}\frac{\cancel{r'^2\sin^2(\theta)}}{c^2}[a\ddot{a}+2\dot{a}^2+2kc^2]\\&=\frac{-3\ddot{a}a-(a\ddot{a}+2\dot{a}^2+2kc^2)-(a\ddot{a}+2\dot{a}^2+2kc^2)-(a\ddot{a}+2\dot{a}^2+2kc^2)}{a^2c^2}\end{aligned}\tag{12.5.500}$$

So finally:

$$R=\frac{-6(a\ddot{a}+\dot{a}^2+kc^2)}{a^2c^2}\tag{12.5.501}$$

Remark

The latter equality relates spatial curvature (usually denoted k) and space-time curvature (usually denoted R). Space-time curvature R has a contribution $6k/a^2$ from spatial curvature k, but it also has two terms that come just from the spatial expansion over time, a.

Remember that space-time curvature is coordinate-independent. Spatial curvature depends on the "slicing" (into constant-time slices) imposed by coordinates; for example de Sitter is spatially flat in one slicing and spatially curved in another, but always has uniform positive space-time curvature.

Now let us recall that we have proved:

$$T^{ij}\cong\left(\rho+\frac{P}{c^2}\right)u^iu^j-Pg^{ij}\tag{12.5.502}$$

And therefore:

$$T_{ij}\cong\left(\rho+\frac{P}{c^2}\right)u_iu_j-Pg_{ij}\tag{12.5.503}$$

So don't forget that only diagonal elements are non-null and that $u_i=(c,0,0,0)$.

Therefore:

$$T_{ij}=\begin{bmatrix}\rho_0c^2&0&0&0\\0&-Pg_{r'r'}&0&0\\0&0&-Pg_{\theta\theta}&0\\0&0&0&-Pg_{\phi\phi}\end{bmatrix}=\begin{bmatrix}\rho_E&0&0&0\\0&P\dfrac{a^2}{1-kr'^2}&0&0\\0&0&Pa^2r'^2&0\\0&0&0&Pa^2r'^2\sin^2(\theta)\end{bmatrix}\tag{12.5.504}$$

Now let us recall the Einstein Field Equations (see section General Relativity page 5766):

$$R_{ij}-\frac{1}{2}g_{ij}R-\Lambda g_{ij}=\frac{8\pi G}{c^4}T_{ij}\tag{12.5.505}$$

Let us start with:

$$R_{00}-\frac{1}{2}g_{00}R-\Lambda g_{00}=\frac{8\pi G}{c^4}T_{00} \tag{12.5.506}$$

So we get after injecting the previous results:

$$-\frac{3\ddot{a}}{ac^2}-\frac{1}{2}\cdot 1\cdot\frac{-6(a\ddot{a}+\dot{a}^2+kc^2)}{a^2c^2}-\Lambda=\frac{8\pi G}{c^4}\rho_E \tag{12.5.507}$$

After elementary simplification we get immediately:

$$3\frac{\dot{a}^2}{a^2}+3\frac{kc^2}{a^2}-\Lambda c^2=\frac{8\pi G}{c^2}\rho \tag{12.5.508}$$

And now with:

$$R_{r'r'}-\frac{1}{2}g_{r'r'}R-\Lambda g_{r'r'}=\frac{8\pi G}{c^4}T_{r'r'} \tag{12.5.509}$$

So we get after injecting the previous results:

$$\frac{a\ddot{a}+2\dot{a}^2+2kc^2}{c^2\cancel{(1-kr'^2)}}-\frac{1}{2}\left(\frac{-\cancel{a^2}}{\cancel{1-kr'^2}}\right)\frac{-6(a\ddot{a}+\dot{a}^2+kc^2)}{\cancel{a^2}c^2}-\Lambda\left(\frac{-a^2}{\cancel{1-kr'^2}}\right)=\frac{8\pi G}{c^4}P\frac{a^2}{\cancel{1-kr'^2}} \tag{12.5.510}$$

After elementary simplification we get immediately:

$$-2\frac{\ddot{a}}{a}-\frac{\dot{a}^2}{a^2}-\frac{kc^2}{a^2}+\Lambda c^2=\frac{8\pi G}{c^2}P \tag{12.5.511}$$

And now with:

$$R_{\phi\phi}-\frac{1}{2}g_{\phi\phi}R-\Lambda g_{\phi\phi}=\frac{8\pi G}{c^4}T_{\phi\phi} \tag{12.5.512}$$

So we get after injecting the previous results:

$$\frac{r'^2\sin^2(\theta)}{c^2}[a\ddot{a}+2\dot{a}^2+2kc^2]-\frac{1}{2}\left(-a^2r'^2\sin^2(\theta)\right)\frac{-6(a\ddot{a}+\dot{a}^2+kc^2)}{a^2c^2}-\Lambda\left(-a^2r'^2\sin^2(\theta)\right)=\frac{8\pi G}{c^4}Pa^2r'^2\sin^2(\theta) \tag{12.5.513}$$

After elementary simplification we get immediately (same result as before! this is a consequence of space isotropy assumption):

$$-2\frac{\ddot{a}}{a}-\frac{\dot{a}^2}{a^2}-\frac{kc^2}{a^2}+\Lambda c^2=\frac{8\pi G}{c^2}P \tag{12.5.514}$$

And finally doing the same with:

$$R_{\theta\theta}-\frac{1}{2}g_{\theta\theta}R-\Lambda g_{\theta\theta}=\frac{8\pi G}{c^4}T_{\theta\theta} \tag{12.5.515}$$

we get also exactly the same result as the two previous one!

The both relations:

$$\boxed{\begin{aligned} 3\frac{\dot{a}^2}{a^2}+3\frac{kc^2}{a^2}-\Lambda c^2&=\frac{8\pi G}{c^2}\rho\\ -2\frac{\ddot{a}}{a}-\frac{\dot{a}^2}{a^2}-\frac{kc^2}{a^2}+\Lambda c^2&=\frac{8\pi G}{c^2}P \end{aligned}} \tag{12.5.516}$$

are the "general Friedmann equations".

It is very common to find them in the literature into the form of the velocity and acceleration equations (often write the cosmological constant in terms of a vacuum energy density as $\Lambda=8\pi G\rho_{\text{vac}}/c^4$):

$$\begin{aligned} H^2&=\left(\frac{\dot{a}}{a}\right)^2=\frac{8\pi G}{3c^2}\rho-\frac{kc^2}{a^2}+\frac{\Lambda c^2}{3}=\frac{8\pi G}{3c^2}(\rho+\rho_{\text{vac}})-\frac{kc^2}{a^2}\\ \frac{\ddot{a}}{a}&=\Lambda c^2-\frac{\dot{a}^2}{a^2}-\frac{kc^2}{a^2}-\frac{8\pi G}{c^2}P=\frac{8\pi G}{c^2}\rho_{\text{vac}}-\frac{\dot{a}^2}{a^2}-\frac{kc^2}{a^2}-\frac{8\pi G}{c^2}P \end{aligned} \tag{12.5.517}$$

Remark

Notice that if we assume that ρ and P depends on a (which seems quite logical if the energy in the Universe is indeed conservative), typically the decrease with the expansion (intuitive!), then is seems that the only term that does not contain the scale factor a is Λc^2. Hence the fact that some scientists assume that Λ behave like constant whatever the age of the Universe.

Now let us rewrite the first one as following:

$$\frac{\dot{a}^2}{a^2}+\frac{kc^2}{a^2}-\frac{\Lambda c^2}{3}=\frac{8\pi G}{3c^2}\rho \tag{12.5.518}$$

and let us notice that for $k=0$ and $\Lambda=0$ we get for that latter:

$$\frac{\dot{a}^2}{a^2}=\frac{8\pi G}{3c^2}\rho \tag{12.5.519}$$

and then we define the critical density that we already know:

$$\rho_c=\frac{3c^2}{8\pi G}\frac{\dot{a}^2}{a^2} \tag{12.5.520}$$

And let us recall also $\frac{\dot{a}}{a}=H$. Therefore:

$$\rho_c=\frac{3c^2H^2}{8\pi G} \tag{12.5.521}$$

Let us now define the following parameters of energy density (matter energy density, curvature energy density and radiation energy density):

$$\boxed{\Omega_m=\frac{\rho}{\rho_c}=\frac{8\pi G}{3c^2H^2}\rho \qquad \Omega_k=-\frac{kc^2}{a^2H^2} \qquad \Omega_\nu=\frac{\rho_v}{\rho_c}=\frac{\dfrac{\Lambda c^4}{8\pi G}}{\dfrac{3c^2H^2}{8\pi G}}=\frac{\Lambda c^2}{3H^2}} \tag{12.5.522}$$

Therefore our equality:

$$\frac{\dot{a}^2}{a^2}+\frac{kc^2}{a^2}-\frac{\Lambda c^2}{3}=\frac{8\pi G}{3c^2}\rho \tag{12.5.523}$$

can be rewritten:

$$H^2+\frac{kc^2}{a^2}-\frac{\Lambda c^2}{3}=\frac{8\pi G}{3c^2}\rho \tag{12.5.524}$$

Dividing both sides by H^2 we get:

$$1+\frac{kc^2}{a^2H^2}-\frac{\Lambda c^2}{3H^2}=\frac{8\pi G}{3c^2H^2}\rho \tag{12.5.525}$$

Rearranging:

$$-\frac{kc^2}{a^2H^2}+\frac{\Lambda c^2}{3H^2}+\frac{8\pi G}{3c^2H^2}\rho=1 \tag{12.5.526}$$

and injecting the density parameters we get:

$$\boxed{\Omega_m+\Omega_k+\Omega_\nu=1} \tag{12.5.527}$$

The figure below from the DESI (Dark Energy Spectroscopic Instrument) collaboration's second data release's results paper (see), shows the different values of the matter density that are preferred by six different data sets: DESI's first and second releases, the CMB, and the supernova samples of Pantheon+, Union, and DESY5 (note that BAO and supernova data sets are not really compatible with one another):

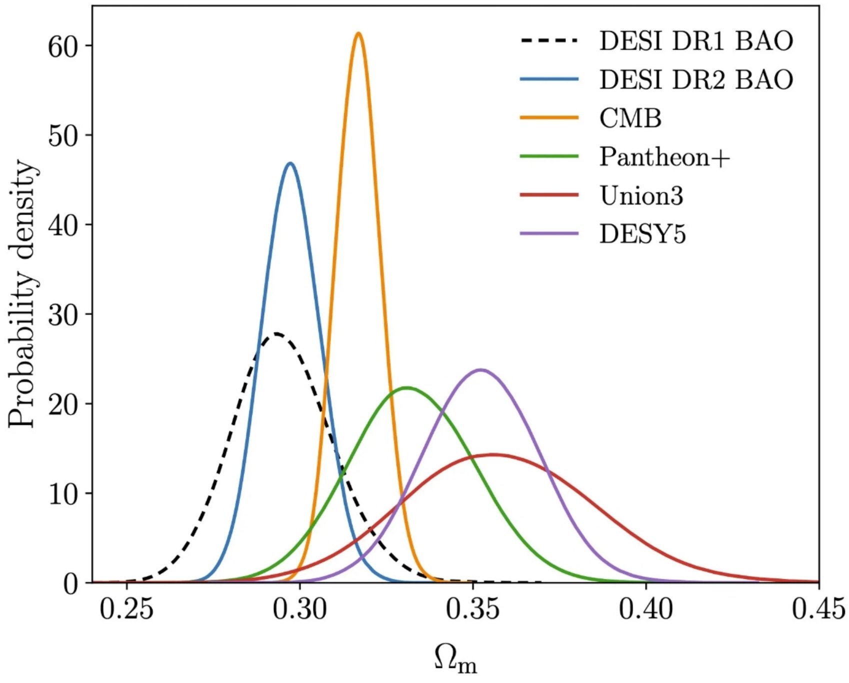

Figure 12.295: **Matter density Ω_m statistical distribution of different experiments**

Notice that is also quite common to see in textbooks:

$$\rho=\rho_m+\rho_\nu+\rho_k+\rho_\Lambda \tag{12.5.528}$$

where obviously we have the matter density, the radiation density, the curvature density and the constant energy density (there is a one to one correspondence with energy density given above but only with a c^2 factor difference as we know that $E = mc^2$).

Ok now that we have the basic tools. Let's use them by starting with the most famous wrong model:

12.5.6.6 Einstein (static) Universe model

Like most scientists of his time, Albert Einstein considered that the Universe was globally static and homogeneous (11917 according to holocene calendar). He also imagined it closed mainly for reasons related to Mach's principle, to which he believes very much. He thus built a model of a spherical Universe capable of accounting for the essential physical conditions he thinks it must respect.

However, he quickly found that his equations do not admit static solutions and so it is to satisfy what he considers as an experimental requirement (immobile universe) that he is forced to slightly modify his equations by adding as we already know an additional term: the cosmological constant.

This constant behaves like a repulsive force to exactly counterbalance the gravitational "force" due to matter, the whole being now able to be balance.

So if we take a closed universe ($k = +1$), static[68] ($a = c^{te}$) and made of a gas of dust of negligible pressure ($P \cong 0$), the general Friedmann equations, given for recall by:

$$\begin{aligned} 3\frac{\dot{a}^2}{a^2} + 3\frac{kc^2}{a^2} - \Lambda c^2 &= \frac{8\pi G}{c^2}\rho \\ -2\frac{\ddot{a}}{a} - \frac{\dot{a}^2}{a^2} - \frac{kc^2}{a^2} + \Lambda c^2 &= \frac{8\pi G}{c^2}P \end{aligned} \tag{12.5.529}$$

reduce immediately to:

$$\begin{aligned} 3\frac{c^2}{a^2} - \Lambda c^2 &= \frac{8\pi G}{c^2}\rho \\ -\frac{c^2}{a^2} + \Lambda c^2 &= 0 \end{aligned} \tag{12.5.530}$$

Therefore injecting the second relation into the first one, and rearranging the second one, we get:

$$\begin{aligned} 2\frac{c^2}{a^2} &= \frac{8\pi G}{c^2}\rho \\ \Lambda &= \frac{1}{a^2} \end{aligned} \tag{12.5.531}$$

So if $k = +1$ and $a = c^{te}$ with $P \cong 0$ we have that also $\Lambda = c^{te}$!

---

[68] For a stationary Universe the scaling factor $a(t)$ must be constant (typically equal to 1!) and hence all its time derivatives must vanish.

More explicitly:

$$a_{\text{Einstein}}=\sqrt{\frac{c^4}{4\pi G\rho}}=c^{te} \qquad \text{and} \qquad \Lambda_{\text{Einstein}}=\frac{1}{a_{\text{Einstein}}^2}=\frac{4\pi G\rho}{c^4}=c^{te} \tag{12.5.532}$$

So for the universe to be really static we should have $a=1$ and therefore $\Lambda=1$. Sadly (for Albert Einstein...), actual experimental measurements give us for $\rho_m\cong 10^{-26}\,[\text{kg}\cdot\text{m}^{-3}]$, a value of the scale factor equal to $a_{\text{Einstein}}=1.03\cdot 10^{26}\,[\text{m}]$ that is to say approximately $1\cdot 10^9$ light years, and hence $\Lambda_{\text{Einstein}}=9.31\cdot 10^{-53}\,[\text{m}^{-2}]$.

Let us see now another special case found by Edward Arthur Milne in 11932 (holocene calendar).

12.5.6.7 Milne linear Universe model

The Milne model demands that the energy density, pressure and cosmological constant all equal zero. This is of course not consistent with the fact that the universe contains stars and galaxies, but we might wonder whether it could tell us anything interesting as a simplified approximation to a very dilute universe.

Hence we get from the first Friedmann equation:

$$3\frac{\dot{a}^2}{a^2}+3\frac{kc^2}{a^2}-\Lambda c^2=\frac{8\pi G}{c^2}\rho \tag{12.5.533}$$

with $\Lambda=0$ and $\rho=0$:

$$3\frac{\dot{a}^2}{a^2}+3\frac{kc^2}{a^2}=0 \tag{12.5.534}$$

After simplification:

$$\dot{a}^2=-kc^2 \tag{12.5.535}$$

Hence:

$$\dot{a}=\sqrt{-kc^2} \tag{12.5.536}$$

To avoid a negative square root (that we will assume maybe as unphysical), we choose a negative curvature $k<0$. Therefore after integration of:

$$\mathrm{d}a=\sqrt{-kc^2}\mathrm{d}t \tag{12.5.537}$$

we get:

$$a=\sqrt{-kc^2}t \tag{12.5.538}$$

Then there exists a time at which $a=0$, but this doesn't turn out to be a real singularity (which isn't surprising, since there is no matter to generate gravitational fields). Let this universe have a scattering of test particles whose masses are too small to invalidate the approximation of $\rho=0$, and let the test particles be at rest. The linear dependence of a on t means that these particles simply move inertially and without any gravitational interactions, spreading apart from one another at a constant rate like the raisins in a rising loaf of raisin bread.

The Milne universe may be useful as an inoculation against the common misconception that the Big Bang was an explosion of matter spreading out into a pre-existing vacuum.

12.5.6.8 Friedmann Universe models

Now to continue with the Friedmann Universe models (11922-11924 according to holocene calendar) we need first an important relation. Let us recall the general Friedmann equations we get just earlier:

$$\begin{aligned} 3\frac{\dot{a}^2}{a^2}+3\frac{kc^2}{a^2}-\Lambda c^2=\frac{8\pi G}{c^2}\rho \\ -2\frac{\ddot{a}}{a}-\frac{\dot{a}^2}{a^2}-\frac{kc^2}{a^2}+\Lambda c^2=\frac{8\pi G}{c^2}P \end{aligned} \tag{12.5.539}$$

Multiplying the second one by 3 and subtracting the second one we get immediately:

$$-6\frac{\ddot{a}}{a}+2\Lambda c^2=\frac{8\pi G}{c^2}(3P+\rho) \tag{12.5.540}$$

Therefore:

$$\boxed{\frac{\ddot{a}}{a}=-\frac{4\pi G}{3c^2}(3P+\rho)+\frac{\Lambda c^2}{3}} \tag{12.5.541}$$

we fall back here on a generalization of one of the Friedmann equation[69] we used during our study of the Newtonian model of the Universe!

That latter relation is also commonly written in many textbooks as:

$$\ddot{R}=-\frac{4\pi g}{3}R\left(\rho_0+\frac{3P}{c^2}\right)+\frac{c^2\Lambda}{3}R \tag{12.5.542}$$

or:

$$\frac{\ddot{R}}{R}=-\frac{4\pi g}{3}\left(\rho_0+\frac{3P}{c^2}\right)+\frac{c^2\Lambda}{3} \tag{12.5.543}$$

To summarize a little bit, from the Einstein Field equation without cosmological constant, we have:

$$\begin{gathered} R_{\mu\nu}-\frac{1}{2}g_{\mu\nu}R=\frac{8\pi G}{c^4}T_{\mu\nu} \\ \Downarrow \\ \left(\frac{\dot{a}}{a}\right)^2=\frac{8\pi G\rho}{3c^2}-\frac{kc^2}{a^2} \\ \frac{\ddot{a}}{a}=-\frac{4\pi G}{3c^2}(\rho+3P) \end{gathered} \tag{12.5.544}$$

and obviously for the Einstein Field equation without cosmological constant, we have:

$$\begin{gathered} R_{\mu\nu}-\frac{1}{2}g_{\mu\nu}R+\Lambda g_{\mu\nu}=\frac{8\pi \mathcal{G}}{c^4}T_{\mu\nu} \\ \Downarrow \\ \left(\frac{\dot{a}}{a}\right)^2=\frac{8\pi G\rho}{3}-\frac{kc^2}{a^2}+\frac{\Lambda c^2}{3} \\ \frac{\ddot{a}}{a}=-\frac{4\pi G}{3c^2}(\rho+3P)+\frac{\Lambda c^2}{3} \end{gathered} \tag{12.5.545}$$

---

[69] The so named "Friedmann's second equation" that is also sometimes named "Raychaudhuri equation" or "acceleration equation"

Remark

The question now is how does the cosmological constant produce a repulsive force? Identifying the force from:

$$\frac{\ddot{R}}{R}=\frac{F_{\Lambda}}{mR}=\frac{c^2\Lambda}{3} \tag{12.5.546}$$

we get:

$$F_{\Lambda}=\frac{c^2\Lambda mR}{3} \tag{12.5.547}$$

This is supposed to be the cosmological force on a particle (galaxy) in a Universe with non-zero Λ.

Notice something interesting in the previous relation! If we consider (supposition!) that at the very early phases of its evolution, the universe was clearly not matter-dominated and that in the Planck epoch it was not even radiation-dominated, and the energy-momentum tensor was determined by the vacuum energy, then if we put therefore $\rho_0=0$ and $P=0$, we get:

$$\frac{\ddot{R}}{R}=\frac{c^2\Lambda}{3}\Leftrightarrow\frac{\mathrm{d}^2R(t)}{\mathrm{d}t^2}=\frac{c^2\Lambda}{3}R(t) \tag{12.5.548}$$

We see that a solution is e^{R_0t} but also e^{-R_0t} with $R_0=c\sqrt{\Lambda/3}$. So a more general solution is the sum of the solution to a given factor and therefore we can see then that:

$$R=2\frac{e^{R_0t}+e^{-R_0t}}{2}=2\cosh(R_0t) \tag{12.5.549}$$

is also a solution! When $t>0$ the second term e^{-R_0t} goes rapidly to zero and we have the inflationary expansion of the early universe. Note that nothing excludes the region $t<0$, where the first term e^{R_0t} goes rapidly to zero and the second term gives exponential inflation in the negative time direction...

Now we will use the latter relation to consider three situation: $\Lambda=0$, $\Lambda>0$, $\Lambda<0$ and for each of the latter case $k=0$, $k>0$ and $k<0$. That is a total of 9 scenarii (if we include for each scenario the case where respectively matter or radiations or vacuum dominates... we would have a total of 27 scenarii to study...!!!).

Let's start!:

- First main case we will take is $\Lambda=0$ (because it's the easiest one...) we have:

  $$\dot{R}^2=\frac{8\pi G}{3}\rho_0R^2-kc^2+\frac{c^2\Lambda}{3}R^2 \tag{12.5.550}$$

  that becomes:

  $$\dot{R}^2=\frac{8\pi G}{3}\rho_0R^2-kc^2 \tag{12.5.551}$$

  Therefore:

  $$\dot{R}^2\propto R^2-kc^2 \tag{12.5.552}$$

and:

$$\ddot{R}=-\frac{4\pi g}{3}R\left(\rho_0+\frac{3P}{c^2}\right)+\frac{c^2\Lambda}{3}R \quad (12.5.553)$$

becomes:

$$\ddot{R}=-\frac{4\pi g}{3}R\left(\rho_0+\frac{3P}{c^2}\right) \quad (12.5.554)$$

That is to say:

$$\ddot{R}<0 \quad (12.5.555)$$

So whatever happens and whatever the value of k, the Universe expansion is decelerating. Let us now see how this Universe behave according to the values of k:

- For $k=0$ (flat Universe) we get the "Einstein-De Sitter Universe model" proposed jointly by Albert Einstein and Willem De Sitter in 11932 (holocene calendar)!
  So for $k=0$ and $\Lambda=0$ we have:

  $$\dot{R}^2=\frac{8\pi G}{3c^2}\rho R^2-kc^2+\frac{c^2\Lambda}{3}R^2 \quad (12.5.556)$$

  that obviously becomes:

  $$3\frac{\dot{R}^2}{R^2}=\frac{8\pi G}{c^2}\rho \quad (12.5.557)$$

  But ρ depends on R. We have already introduced earlier (obvious) during our study of Newtonian models that (case of universe dominated by dust with the density parameter $\omega(T)=0$):

  $$\rho=\rho_0F^{-3}=\rho_0\left(\frac{R_0}{R}\right)^3 \quad (12.5.558)$$

  And it is common to take $R_0=1$ for the first time. Injecting into the Friedmann equation, we get:

  $$3\frac{\dot{R}^2}{R^2}=\frac{8\pi G}{c^2}\frac{\rho_0}{R^3} \quad (12.5.559)$$

  Therefore:

  $$\dot{R}=\sqrt{\frac{8\pi G}{3c^2}}\rho_0R^{-1/2} \quad (12.5.560)$$

  or explicitly:

  $$R^{1/2}\mathrm{d}R=\sqrt{\frac{8\pi G}{3c^2}}\rho_0\mathrm{d}t \quad (12.5.561)$$

  Integrating:

  $$\int\limits_1^R R^{1/2}\mathrm{d}R=\sqrt{\frac{8\pi G}{3c^2}}\rho_0\int\limits_0^t \mathrm{d}t \quad (12.5.562)$$

This gives:

$$\frac{2}{3}R^{3/2}-\frac{2}{3}1^{3/2}=\sqrt{\frac{8\pi G}{3c^2}\rho_0}t \tag{12.5.563}$$

We simplify a bit:

$$R^{3/2}\cong\frac{3}{2}\sqrt{\frac{8\pi G}{3c^2}\rho_0}t \tag{12.5.564}$$

Thus:

$$R_{\Lambda=0,k=0}\cong\left(\frac{6\pi G}{c^2}\rho_0\right)^{1/3}t^{2/3} \tag{12.5.565}$$

It is therefore an open Universe whose expansion will stop after an infinite time! It's exactly the same kind of expression that we have obtained during our study of Friedmann-Lemaître Euclidean cosmological models for flat spaces dominated by matter (see page **??**).

We won't redo here the case for flat space dominated by radiation that give us:

$$R_{\Lambda=0,k=0}\propto t^{1/3} \tag{12.5.566}$$

as all the details are already provided at page 5910.

But let us recall that for $k=0$ and $\Lambda=0$ we have:

$$\rho_0=\rho_c=\frac{3c^2H^2}{8\pi G} \tag{12.5.567}$$

Therefore:

$$\boxed{R_{\Lambda=0,k=0}\cong\left(\frac{9H^2}{4}\right)^{1/3}t^{2/3}} \tag{12.5.568}$$

Now we can estimate the age of the Universe according to this model. So to get the time since the beginning of our Universe we have by construction to put $R_{\Lambda=0,k=0}=1$. Therefore the above relation after rearranging becomes:

$$t_0\cong\sqrt{\frac{4}{9H^2}}=\frac{2}{3H}=\frac{2}{3}t_H\cong 8.7\cdot 10^9\text{ [years]} \tag{12.5.569}$$

This model of Universe as we already know has been abandoned because in contradiction with the ages of certain old stars whose age is estimated to be more than 10 billion years.

- Now, for the second sub-case (spherical), we have $k=+1$ (seems to have been developed first in 11922 according to holocene calendar):

$$\dot{R}^2=\frac{8\pi G}{3c^2}\rho R^2-kc^2+\frac{c^2\Lambda}{3}R^2 \tag{12.5.570}$$

that obviously becomes:

$$3\frac{\dot{R}^2}{R^2}+3\frac{c^2}{R^2}=\frac{8\pi G}{c^2}\rho \tag{12.5.571}$$

But ρ depends on R. We have already introduced earlier (obvious) during our study of Newtonian models (case of universe dominated by dust with the density parameter $\omega(T)=0$) that :

$$\rho=\rho_0 F^{-3}=\rho_0\left(\frac{R_0}{R}\right)^3 \tag{12.5.572}$$

And it is common to take $R_0=1$ for the first time. Injecting into the Friedmann equation, we get:

$$3\frac{\dot{R}^2}{R^2}+3\frac{c^2}{R^2}=\frac{8\pi G}{c^2}\frac{\rho_0}{R^3} \tag{12.5.573}$$

Therefore after rearranging and simplifying:

$$\dot{R}=\sqrt{\frac{8\pi G}{3c^2}\frac{\rho_0}{R}-c^2} \tag{12.5.574}$$

Hence:

$$\mathrm{d}R=c\sqrt{\frac{8\pi G}{3c^4}\frac{\rho_0}{R}-1}\mathrm{d}t \tag{12.5.575}$$

That we will rewrite as following for the purpose of notations simplifications and some future clever change of variables:

$$\mathrm{d}R=\frac{c}{R^{1/2}}\sqrt{\underbrace{\frac{8\pi G\rho_0}{3c^4}}_{=K}}\sqrt{1-\frac{R}{K}}\mathrm{d}t \tag{12.5.576}$$

Thus:

$$\frac{R^{1/2}}{c\sqrt{K}\sqrt{1-\dfrac{R}{K}}}\mathrm{d}R=\mathrm{d}t \tag{12.5.577}$$

Now before we continue let us recall that with $k=+1$ and $\Lambda=0$ one of the Friedmann equations becomes:

$$\frac{\dot{R}^2}{R^2}+\frac{c^2}{a^2}=\frac{8\pi G}{3c^2}\rho \tag{12.5.578}$$

Therefore:

$$\dot{R}^2=\frac{8\pi G}{3c^2}\rho R^2-c^2 \tag{12.5.579}$$

But as (still with the convention to take $R_0=1$):

$$\rho=\rho\left(\frac{R_0}{R}\right)^3 \tag{12.5.580}$$

The previous relation is then written:

$$\dot{R}^2=\frac{8\pi G\rho_0}{3Rc^2}-c^2 \tag{12.5.581}$$

As we have necessarily $\dot{R}^2 > 0$, then:

$$\dot{R}^2 = \frac{8\pi G\rho_0}{3Rc^2} - c^2 > 0 \tag{12.5.582}$$

Therefore:

$$\frac{8\pi G\rho_0}{3Rc^2} > c^2 \tag{12.5.583}$$

Thus:

$$\frac{8\pi G\rho_0}{3Rc^4} > R \Leftrightarrow K > R \Leftrightarrow \frac{R}{K} < 1 \tag{12.5.584}$$

And as $R > 0$ and $K > 0$ we have in fact:

$$0 < \frac{R}{K} < 1 \tag{12.5.585}$$

Now let us do the change of variable (since $0 < \sin^2(\theta) < 1$):

$$\frac{R}{K} = \sin^2(\theta) \Rightarrow \begin{cases} R^{1/2} = \sqrt{K}\sin(\theta) \\ \mathrm{d}R = 2K\sin(\theta)\cos(\theta)\mathrm{d}\theta \end{cases} \tag{12.5.586}$$

Therefore:

$$\frac{R^{1/2}}{c\sqrt{K}\sqrt{1-\dfrac{R}{K}}}\mathrm{d}R = \mathrm{d}t \tag{12.5.587}$$

can be rewritten:

$$\frac{R^{1/2}}{c\sqrt{K}\sqrt{1-\dfrac{R}{K}}}\mathrm{d}R = \frac{2K\cancel{\sqrt{K}}\sin^2(\theta)\cancel{\cos(\theta)}}{c\cancel{\sqrt{K}}\cancel{\cos(\theta)}}\mathrm{d}\theta = \mathrm{d}t \tag{12.5.588}$$

Therefore:

$$\int \frac{2K}{c}\sin^2(\theta)\mathrm{d}\theta = \int \mathrm{d}\theta \tag{12.5.589}$$

Using trigonometric identities:

$$\frac{2K}{c}\int_0^\theta \frac{1-\cos(2\theta)}{2}\mathrm{d}\theta = \int_0^t \mathrm{d}t \tag{12.5.590}$$

Thus:

$$\frac{K}{c}\left(\theta - \frac{1}{2}\sin(2\theta)\right) = t + c^{te} \tag{12.5.591}$$

For $t = 0$, we assume $R = 0$ and therefore $\theta = 0$. This bring us that $c^{te} = 0$.

We have then:

$$\begin{cases} t=\dfrac{K}{c}\left(\theta-\dfrac{1}{2}\sin(2\theta)\right)=\dfrac{8\pi G\rho_0}{3c^5}\left(\theta-\dfrac{1}{2}\sin(2\theta)\right) \\ R=K\sin^2(\theta)=\dfrac{8\pi G\rho_0}{3c^4}\dfrac{1}{2}(1-\cos(2\theta)) \end{cases} \tag{12.5.592}$$

Let us put $\theta'=2\theta$. Then:

$$\begin{cases} t=\dfrac{8\pi G\rho_0}{3c^5}\dfrac{1}{2}(\theta'-\sin(\theta')) \\ R=\dfrac{8\pi G\rho_0}{3c^4}\dfrac{1}{2}(1-\cos(\theta')) \end{cases} \tag{12.5.593}$$

we recognize here the parametric equations of a cycloid (see section Analytical Geometry page 2814). Therefore this is a bouncing cyclic Universe model!

We see that a will be maximum for $\theta=\pi$, then:

$$\begin{cases} t_{\text{max}}=\dfrac{8\pi^2 G\rho_0}{6c^5} \\ R_{\text{max}}=\dfrac{8\pi G\rho_0}{3c^4} \end{cases} \tag{12.5.594}$$

and the final state of the Big Crunch will occur when $\theta=2\pi$, where we then have $a=0$ and then:

$$t_{\text{Big Crunch}}=\frac{8\pi^2 G\rho_0}{3c^5} \tag{12.5.595}$$

- Now the third and last sub-case, we choose $k=-1$ (hyperbolic model that seems to have been developed in 11924 according to holocene calendar).

  The development are very similar to the previous case as just the sign change. We then also start from:

$$\dot{R}^2=\frac{8\pi G}{3c^2}\rho R^2-kc^2+\frac{c^2\Lambda}{3}R^2 \tag{12.5.596}$$

that obviously becomes:

$$3\frac{\dot{R}^2}{R^2}-3\frac{c^2}{R^2}=\frac{8\pi G}{c^2}\rho \tag{12.5.597}$$

But ρ depends on R. We have already introduced earlier (obvious) during our study of Newtonian models (case of universe dominated by dust with the density parameter $\omega(T)=0$) that:

$$\rho=\rho_0 F^{-3}=\rho_0\left(\frac{R_0}{R}\right)^3 \tag{12.5.598}$$

And it is common to take $R_0=1$ for the first time. Injecting into the Friedmann equation, we get:

$$3\frac{\dot{R}^2}{R^2}-3\frac{c^2}{R^2}=\frac{8\pi G}{c^2}\frac{\rho_0}{R^3} \tag{12.5.599}$$

Therefore after rearranging and simplifying:

$$\dot{R}=\sqrt{\frac{8\pi G}{3c^2}\frac{\rho_0}{R}+c^2} \tag{12.5.600}$$

Hence:

$$\mathrm{d}R=c\sqrt{\frac{8\pi G}{3c^4}\frac{\rho_0}{R}+1}\mathrm{d}t \tag{12.5.601}$$

That we will rewrite as following for the purpose of notations simplifications and some future clever change of variables:

$$\mathrm{d}R=\frac{c}{R^{1/2}}\sqrt{\underbrace{\frac{8\pi G\rho_0}{3c^4}}_{=K}}\sqrt{1+\frac{R}{K}}\mathrm{d}t \tag{12.5.602}$$

Thus:

$$\frac{R^{1/2}}{c\sqrt{K}\sqrt{1+\dfrac{R}{K}}}\mathrm{d}R=\mathrm{d}t \tag{12.5.603}$$

Now before we continue let us recall that with $k=-1$ and $\Lambda=0$ one of the Friedmann equations becomes:

$$\frac{\dot{R}^2}{R^2}-\frac{c^2}{a^2}=\frac{8\pi G}{3c^2}\rho \tag{12.5.604}$$

Therefore:

$$\dot{R}^2=\frac{8\pi G}{3c^2}\rho R^2+c^2 \tag{12.5.605}$$

But as (still with the convention to take $R_0=1$):

$$\rho=\rho\left(\frac{R_0}{R}\right)^3 \tag{12.5.606}$$

The previous relation is then written:

$$\dot{R}^2=\frac{8\pi G\rho_0}{3Rc^2}+c^2 \tag{12.5.607}$$

As we have necessarily $\dot{R}^2>0$ (because of the square!), then:

$$\dot{R}^2=\frac{8\pi G\rho_0}{3Rc^2}+c^2>0 \tag{12.5.608}$$

Therefore:

$$\frac{8\pi G\rho_0}{3Rc^2}>-c^2 \tag{12.5.609}$$

Thus:

$$\frac{8\pi G\rho_0}{3Rc^4}>-R\Leftrightarrow K>-R\Leftrightarrow\frac{R}{K}>-1 \tag{12.5.610}$$

But as $R>0$ and $K>0$ we have in fact:

$$\frac{R}{K}>0 \tag{12.5.611}$$

Now let us do the change of variable (since $\sinh^2(\theta)>0$):

$$\frac{R}{K}=\sinh^2(\theta)\Rightarrow\begin{cases}R^{1/2}=\sqrt{K}\sinh(\theta)\\ \mathrm{d}R=2K\sinh(\theta)\cosh(\theta)\mathrm{d}\theta\end{cases} \tag{12.5.612}$$

Therefore:

$$\frac{R^{1/2}}{c\sqrt{K}\sqrt{1+\dfrac{R}{K}}}\mathrm{d}R=\mathrm{d}t \tag{12.5.613}$$

can be rewritten:

$$\frac{R^{1/2}}{c\sqrt{K}\sqrt{1+\dfrac{R}{K}}}\mathrm{d}R=\frac{2K\cancel{\sqrt{K}}\sinh^2(\theta)\cancel{\cosh(\theta)}}{c\cancel{\sqrt{K}}\cancel{\cosh(\theta)}}\mathrm{d}\theta=\mathrm{d}t \tag{12.5.614}$$

Therefore:

$$\int\frac{2K}{c}\sinh^2(\theta)\mathrm{d}\theta=\int\mathrm{d}\theta \tag{12.5.615}$$

Using trigonometric identities:

$$\frac{2K}{c}\int\limits_0^\theta\frac{\cosh(2\theta)-1}{2}\mathrm{d}\theta=\int\limits_0^t\mathrm{d}t \tag{12.5.616}$$

Thus:

$$\frac{K}{c}\left(\frac{1}{2}\sin(2\theta)-\theta\right)=t+c^{te} \tag{12.5.617}$$

For $t=0$, we assume $R=0$ and therefore $\theta=0$. This bring us that $c^{te}=0$. We have then:

$$\begin{cases}t=\dfrac{K}{c}\left(\dfrac{1}{2}\sinh(2\theta)-\theta\right)=\dfrac{8\pi G\rho_0}{3c^5}\left(\dfrac{1}{2}\sin(2\theta)-\theta\right)\\ R=K\sinh^2(\theta)=\dfrac{8\pi G\rho_0}{3c^4}\dfrac{1}{2}(\cosh(2\theta)-1)\end{cases} \tag{12.5.618}$$

Let us put $\theta'=2\theta$. Then:

$$\begin{cases}t=\dfrac{8\pi G\rho_0}{3c^5}\dfrac{1}{2}(\sinh(\theta')-\theta')\\ R=\dfrac{8\pi G\rho_0}{3c^4}\dfrac{1}{2}(\cosh(\theta')-1)\end{cases} \tag{12.5.619}$$

So this is just an unbounded Universe!

- Now second main case with $\Lambda < 0$ (in the framework of FWLR universe all three corresponding sub-models are sometimes referred to some kind of "anti de Sitter space" abbreviated AdS).

  First let us start with a general behaviour analysis. Once again we start from the following Friedmann equations:

$$\begin{aligned}\dot{R}^2 &= \frac{8\pi G}{3c^2}\rho R^2 - kc^2 + \frac{c^2\Lambda}{3}R^2 \\ \ddot{R} &= -\frac{4\pi G}{3}\left(\rho + \frac{3P}{c^2}\right) + \frac{c^2\Lambda}{3}R\end{aligned} \tag{12.5.620}$$

  Then for $\Lambda < 0$ we can write:

$$\begin{aligned}\dot{R}^2 &= \frac{8\pi G}{3c^2}\rho R^2 - kc^2 - \frac{c^2|\Lambda|}{3}R^2 \\ \ddot{R} &= -\frac{4\pi G}{3}\left(\rho + \frac{3P}{c^2}\right) - \frac{c^2|\Lambda|}{3}R = -\frac{4\pi G}{3}R\left(\rho + \frac{3P}{c^2} + \frac{c^2|\Lambda|}{12\pi G}\right)\end{aligned} \tag{12.5.621}$$

  as the reader can see by the "$+$" in front of the Λ term we can already make the conclusion that when $\Lambda < 0$ it acts like an attractive force to the Universe.

  $R(t)$ is then monotonically increasing and therefore there exist a $\dot{R}(t)$ that will be equal to zero. So the Universe re-collapse happens even earlier due to "attractive force"!

  Now let us deal again with the three special case in the same order as before $\{k = 0, k > 0, k < 0\}$. So let's start:

  - For $k = 0$ we then have obviously:

$$\dot{R}^2 = \frac{8\pi G}{3c^2}\rho R^2 - \frac{c^2|\Lambda|}{3}R^2 \tag{12.5.622}$$

    after rearranging:

$$\left(\frac{\dot{R}}{R}\right)^2 = \frac{8\pi G}{3c^2}\rho - \frac{c^2|\Lambda|}{3} \tag{12.5.623}$$

    And now let us consider that ρ is small enough (universe without mass nor radiation but just a cosmological constant, i.e. dominated by vacuum with density parameter $\omega(T) = 1$) so that we can write:

$$\left(\frac{\dot{R}}{R}\right)^2 = -\frac{c^2|\Lambda|}{3} \tag{12.5.624}$$

    which yields the solution:

$$R = -\frac{3}{c^2|\Lambda|}e^{\sqrt{-\frac{c^2|\Lambda|}{3}}t} \tag{12.5.625}$$

    We have then a purely complex exponential as the radicand is negative! As we know that a complex exponential can be written in Euler form (trigonometric sine), that means we have an oscillating universe.

Remark

Notice that there is no constant of integration, otherwise the equality would not hold! So an interesting result (even if it's a priori not realistic to consider ρ as small...) is that when $t=0$, $R\neq 0$ (i.e. that Universe existed before the creation of time).

Obviously we have then that the Hubble parameter is a constant as by definition:

$$H=\frac{\dot{R}}{R}=\sqrt{-\frac{c^2|\Lambda|}{3}} \tag{12.5.626}$$

Against that means the Hubble parameter would be a complex value...
Now let us consider the case where ρ cannot be neglected, as we have proved earlier that in a flat universe dominated by matter we had:

$$\rho=\frac{\rho_0 R_0^3}{R^3} \tag{12.5.627}$$

then:

$$\left(\frac{\dot{R}}{R}\right)^2=\frac{8\pi G}{3c^2}\rho-\frac{c^2|\Lambda|}{3} \tag{12.5.628}$$

can be rewritten:

$$\left(\frac{\dot{R}}{R}\right)^2=\frac{8\pi G}{3c^2}\frac{\rho_0 R_0^3}{R^3}-\frac{c^2|\Lambda|}{3} \tag{12.5.629}$$

Hence:

$$\dot{R}=\sqrt{\frac{8\pi G}{3c^2}\frac{\rho_0 R_0^3}{R}-\frac{c^2|\Lambda|}{3}R^2} \tag{12.5.630}$$

Thus:

$$\mathrm{d}R=\sqrt{\frac{8\pi G}{3c^2}\frac{\rho_0 R_0^3}{R}-\frac{c^2|\Lambda|}{3}R^2}\mathrm{d}t \tag{12.5.631}$$

$$\mathrm{d}R=\sqrt{\frac{8\pi G}{3c^2}\frac{\rho_0 R_0^3}{R}+\frac{-c^2|\Lambda|}{3}R^2}\mathrm{d}t=\sqrt{\underbrace{\frac{8\pi G\rho_0 R_0^3}{3c^2}}_{:=K}\frac{1}{R}+\underbrace{\frac{-c^2|\Lambda|}{3}}_{:=B}R^2}\mathrm{d}t=\frac{\sqrt{K}}{R^{1/2}}\sqrt{1+\frac{B}{K}R^3}\mathrm{d}t \tag{12.5.632}$$

So:

$$\frac{R^{1/2}\mathrm{d}R}{\sqrt{K}\sqrt{1+\dfrac{B}{K}R^3}}=\mathrm{d}t \tag{12.5.633}$$

Let us do the following change of variable:

$$x^2=\frac{B}{K}R^3\Rightarrow\begin{cases}3R^2\mathrm{d}R=2\dfrac{K}{B}x\mathrm{d}x\\R^2=\left(\dfrac{K}{B}\right)^{2/3}x^{4/3}\\R^{1/2}=\left(\dfrac{K}{B}\right)^{1/6}x^{1/3}\end{cases}\tag{12.5.634}$$

Hence:

$$R^{1/2}\mathrm{d}R=\frac{\left(\dfrac{K}{B}\right)^{1/6}x^{1/3}\dfrac{2}{3}\dfrac{K}{B}x\mathrm{d}x}{\left(\dfrac{K}{B}\right)^{2/3}x^{4/3}}=\frac{2}{3}\left(\frac{K}{B}\right)^{1/2}\mathrm{d}x\tag{12.5.635}$$

So:

$$\frac{R^{1/2}\mathrm{d}R}{\sqrt{K}\sqrt{1+\dfrac{B}{K}R^3}}=\frac{\dfrac{2}{3}\left(\dfrac{K}{B}\right)^{1/2}\mathrm{d}x}{\sqrt{K}\sqrt{1+x^2}}=\mathrm{d}t\tag{12.5.636}$$

So we want to take the primitive of:

$$\frac{2}{3\sqrt{B}}\int\frac{\mathrm{d}x}{\sqrt{1+x^2}}=\int\mathrm{d}t\tag{12.5.637}$$

as we know from our study of usual derivatives (see section Differential and Integral Calculus page 1475) the integral is simply given by:

$$\frac{2}{3\sqrt{B}}\mathrm{arcsinh}(x)=t+c^{te}\tag{12.5.638}$$

For simplification purposes we will assume that for $t=0$, we have $R=0$ hence $c^{te}=0$ and we can write:

$$\frac{2}{3\sqrt{B}}\mathrm{arcsinh}(x)=t\Leftrightarrow\mathrm{arcsinh}\left(\sqrt{\frac{B}{K}}a^{3/2}\right)=\frac{3}{2}\sqrt{B}t\tag{12.5.639}$$

So:

$$\sqrt{\frac{B}{K}}a^{3/2}=\sinh\left(\frac{3}{2}\sqrt{B}t\right)\Leftrightarrow R=\sqrt[3]{\frac{K}{B}\sinh^2\left(\frac{3}{2}\sqrt{B}t\right)}\tag{12.5.640}$$

So finally:

$$R=R_0\sqrt[3]{-\frac{8\pi G\rho_0}{|\Lambda|c^4}\sinh^2\left(\frac{3}{2}\sqrt{\frac{-c^2|\Lambda|}{3}}t\right)}=R_0\sqrt[3]{-\frac{8\pi G\rho_0}{|\Lambda|c^4}\left[\cosh\left(\frac{3}{2}\sqrt{\frac{-c^2|\Lambda|}{3}}t\right)-1\right]}\tag{12.5.641}$$

We can plot such a function in $\mathbb{C}$ using Maple™ however its interpretation is quite non-trivial as there are no solution for $t \in \mathbb{R}^+$.

In most textbooks the final result is (we put $R_0 = 1$ by convention):

$$R = -\left(\frac{8\pi G\rho_0}{|\Lambda|c^4}\right)^{1/3} \sinh^{2/3}\left(\frac{3}{2}\sqrt{\frac{-c^2|\Lambda|}{3}}t\right) \qquad (12.5.642)$$

- Now for $k = +1$, the second sub-case (spherical).

  Let us first recall that we have already treated the case $k = +1$ with $\Lambda > 0$ and assuming $R = c^{te}$. This is the Einstein (static) Universe model already treated on page 6012. If in the same developments we put instead $\Lambda < 0$, this leads us to the same kind of conclusions.

  But let us deal with the non-static case for $k = +1$.

  For this purpose consider the general case:

$$\dot{R}^2 = \frac{8\pi G}{3c^2}\rho R^2 - kc^2 - \frac{c^2|\Lambda|}{3}R^2 \qquad (12.5.643)$$

This differential equation can be rewritten as:

$$\dot{R}^2 + \left(\frac{c^2|\Lambda|}{3} - \frac{8\pi G}{3c^2}\rho\right)R^2 + kc^2 = 0 \qquad (12.5.644)$$

To simplify let us put:

$$\alpha := \frac{c^2|\Lambda|}{3} - \frac{8\pi G}{3c^2}\rho \qquad (12.5.645)$$

Therefore:

$$\dot{R}^2 + \alpha R^2 + kc^2 = 0 \qquad (12.5.646)$$

Let us now move in natural units to get rid of the c^2:

$$\dot{R}^2 + \alpha R^2 + k = 0 \qquad (12.5.647)$$

Let us put $k = +1$ and assume that the density ρ is not dependent of time (it's a first case - equivalent to consider as we already know the universe being dominated by vacuum) and keep in mind that's equivalent also to consider ρ very small like $\rho \cong 0$ as 0 is a constant independent of time...):

$$\dot{R}^2 + \alpha R^2 + 1 = 0 \qquad (12.5.648)$$

Therefore:

$$\dot{R} = \pm\sqrt{-1 - \alpha^2 R^2} \qquad (12.5.649)$$

A simple integration leads to:

$$\int \frac{\mathrm{d}R}{\sqrt{-1-\alpha^2 R^2}} = \pm\int \mathrm{d}t \qquad (12.5.650)$$

For $\alpha \neq 0$ (we would need to treat the case $a=0$ and the case $-1-\alpha^2R^2=0 \Longrightarrow R=\pm 1/\alpha$), we substitute $u=\alpha R$:

$$\int \frac{\mathrm{d}u}{\sqrt{-1-u^2}}=\pm\alpha\int \mathrm{d}t=\pm\alpha t+c^{te} \tag{12.5.651}$$

Hence:

$$\int \frac{\mathrm{i}\mathrm{d}u}{\sqrt{1+u^2}}=\pm\alpha t+c^{te} \tag{12.5.652}$$

And we have already proven this primitive in the section of Differential and Integral Calculus (see page 1534):

$$\ln\left(u+\sqrt{u^2+\alpha^2}\right)=\pm\alpha t+c^{te} \tag{12.5.653}$$

Hence:

$$\mathrm{i}\ln\left(\alpha R+\sqrt{\alpha^2R^2+\alpha^2}\right)=\pm\alpha t+c^{te} \tag{12.5.654}$$

Hence:

$$\mathrm{i}\ln\left(\alpha R+\sqrt{\alpha^2R^2+\alpha^2}\right)=\pm\alpha t+c^{te} \tag{12.5.655}$$

Or:

$$\mathrm{i}\cdot\operatorname{arcsinh}(\alpha R)=\pm\alpha t+c^{te} \tag{12.5.656}$$

So finally:

$$R(t)=\sinh\left(\frac{\mathrm{i}(\pm\alpha t+c^{te})}{\alpha}\right) \tag{12.5.657}$$

This is a pure complex hyperbolic sine function. The interpretation is in our point of view non-trivial so will not try to extrapolate, even with a plot, this result. And remember that we assume that:

$$\alpha\neq 0\Rightarrow \frac{c^2|\Lambda|}{3}\neq\frac{8\pi G}{3c^2}\rho \tag{12.5.658}$$

Or said otherwise:

$$\rho\neq\frac{c^4|\Lambda|}{8\pi G} \tag{12.5.659}$$

Ok so that's the result for a spherical universe dominated by vacuum. Assuming that only ρ is a function of R only and that is does not explicitly depend on time, we can write:

$$\dot{R}=\frac{\mathrm{d}R}{\mathrm{d}t}=\sqrt{\frac{8\pi G}{3c^2}\rho(R)R^2-kc^2-\frac{c^2|\Lambda|}{3}R^2} \tag{12.5.660}$$

But we have proven (see page 5912) that the different most common type of density evolution are:

$$\rho(t)\propto R(t)^{-3(1+\omega(T))}\propto\begin{cases}R(t)^{-3} & \text{for } \omega(T)=0 \text{ (pressureless matter (i.e. dust))}\\ R(t)^{-4} & \text{for } \omega(T)=1/3 \text{ (radiation/relativistic matter)}\\ c^{te} & \text{for } \omega(T)=-1 \text{ (vacuum energy)}\end{cases} \tag{12.5.661}$$

Let us consider that we are interested about the first instants of the Big Bang (this is an excuse in reality because we didn't found any analytic solution for the presureless matter, i.e. $\omega(T)=0$, case.........). Then we will focus on radiation/relativistic matter, i.e. $\rho\propto R(t)^{-4}$ (and for simplicity we put $R_0=1$):

$$\dot{R}=\sqrt{\frac{8\pi G}{3c^2}\rho_0\frac{R_0^4}{R^4}R^2-kc^2-\frac{c^2|\Lambda|}{3}R^2}=\sqrt{\frac{8\pi G}{3c^2}\rho_0 R^{-2}-kc^2-\frac{c^2|\Lambda|}{3}R^2} \tag{12.5.662}$$

To simplify let us denote the latter:

$$\dot{R}=\sqrt{\alpha R^{-2}-\beta+\gamma R^2} \tag{12.5.663}$$

Hence:

$$\int\mathrm{d}t=\int\frac{1}{\sqrt{\alpha R^{-2}-\beta+\gamma R^2}}\mathrm{d}R \tag{12.5.664}$$

Let us put first the right hand side at the same denominator:

$$\int\frac{R}{\sqrt{\gamma R^4-\beta R^2+\alpha}}\mathrm{d}R \tag{12.5.665}$$

Let us substitute $u=R^2\longrightarrow\mathrm{d}u=2R\mathrm{d}R$, therefore:

$$\begin{aligned}\int\frac{R}{\sqrt{\gamma R^4-\beta R^2+\alpha}}\mathrm{d}R&=\frac{1}{2}\int\frac{1}{\sqrt{\gamma u^2-\beta u+\alpha}}\mathrm{d}u\\&=\int\frac{1}{\sqrt{\left(\sqrt{\gamma}u-\frac{\beta}{2\sqrt{\gamma}}\right)^2-\frac{\beta^2}{4\gamma}+\alpha}}\mathrm{d}u\end{aligned} \tag{12.5.666}$$

Let us substitute:

$$v=\frac{2\gamma u-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\to\mathrm{d}v=\frac{\sqrt{\gamma}}{\sqrt{\alpha-\frac{\beta^2}{4\gamma}}}\mathrm{d}u \tag{12.5.667}$$

Therefore we get:

$$\frac{1}{\sqrt{\gamma}}\int\frac{1}{\sqrt{v^2+1}}\,\mathrm{d}v \tag{12.5.668}$$

Now solving:

$$\int\frac{1}{\sqrt{v^2+1}}\,\mathrm{d}v \tag{12.5.669}$$

This is a standard integral (see section Differential and Integral Calculus page 1534):

$$\int \frac{1}{\sqrt{v^2+1}}\mathrm{d}v=\ln\left(\sqrt{v^2+1}+v\right) \tag{12.5.670}$$

Plug in solved integrals:

$$\begin{aligned}\frac{1}{\sqrt{\gamma}}\int \frac{1}{\sqrt{v^2+1}}\mathrm{d}v=\frac{\ln\left(\sqrt{v^2+1}+v\right)}{\sqrt{\gamma}}&=\frac{\ln\left(\sqrt{\frac{(2\gamma u-\beta)^2}{4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+1}+\frac{2\gamma u-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\right)}{\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{\frac{\left(2\gamma R^2-\beta\right)^2}{4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+1}+\frac{2\gamma R^2-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{\frac{\left(2\gamma R^2-\beta\right)^2+4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}{4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}}+\frac{2\gamma R^2-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\frac{1}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\left[\sqrt{\left(2\gamma R^2-\beta\right)^2+4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+2\gamma R^2-\beta\right]\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{\left(2\gamma R^2-\beta\right)^2+4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+2\gamma R^2-\beta\right)}{2\sqrt{\gamma}}-\frac{\ln\left(2\sqrt{\gamma}\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{\left(2\gamma R^2-\beta\right)^2+\alpha 4\gamma-\beta^2}+2\gamma R^2-\beta\right)}{2\sqrt{\gamma}}+c^{te}\\
&=\frac{\ln\left(2\left(\sqrt{\gamma}\sqrt{R^2\left(\gamma R^2-\beta\right)+\alpha}+\gamma R^2\right)-\beta\right)}{2\sqrt{\gamma}}+c^{te}\end{aligned} \tag{12.5.671}$$

Hence:

$$\int \frac{1}{\sqrt{\frac{\alpha}{R^2}-\beta+\gamma R^2}}\mathrm{d}R=\frac{\ln\left(2\left(\sqrt{\gamma}\sqrt{R^2\left(\gamma R^2-\beta\right)+\alpha}+\gamma R^2\right)-\beta\right)}{2\sqrt{\gamma}}+c^{te} \tag{12.5.672}$$

Reinjecting the original constants we get:

$$\int \frac{1}{\sqrt{\frac{8\pi G}{3c^2}\rho_0 R^{-2}-kc^2-\frac{c^2|\Lambda|}{3}R^2}}\mathrm{d}R=\frac{\ln\left(2\left(\sqrt{\frac{-c^2|\Lambda|}{3}}\sqrt{R^2\cdot\left(\frac{-c^2|\Lambda|}{3}R^2-kc^2\right)+\frac{8\pi G}{3c^2}\rho_0}+\frac{-c^2|\Lambda|}{3}R^2\right)-kc^2\right)}{2\sqrt{\frac{-c^2|\Lambda|}{3}}}+c^{te} \tag{12.5.673}$$

So finally for a spherical universe (replacing $k=+1$) dominated by radiation, we have:

$$t=\frac{\ln\left(2\left(\sqrt{\frac{-c^2|\Lambda|}{3}}\sqrt{R^2\cdot\left(\frac{-c^2|\Lambda|}{3}R^2-c^2\right)+\frac{8\pi G}{3c^2}\rho_0}+\frac{-c^2|\Lambda|}{3}R^2\right)-c^2\right)}{2\sqrt{\frac{-c^2|\Lambda|}{3}}}+c^{te} \tag{12.5.674}$$

Sadly we didn't found yet a way to extract the R above as a function of t nor a pertinent way to do an implicit plot with a computer software. Furthermore this situation is even worst than the case with $\Lambda>0$ as we have complex roots and therefore the function is imaginary. So we will have to stop here!

- Let us now consider the case $k=-1$ (hyperbolic).

For this, same as before, we start from:

$$\dot{R}^2=\frac{8\pi G}{3c^2}\rho R^2-kc^2-\frac{c^2|\Lambda|}{3}R^2 \tag{12.5.675}$$

This differential equation can be rewritten as:

$$\dot{R}^2+\left(\frac{c^2|\Lambda|}{3}-\frac{8\pi G}{3c^2}\rho\right)R^2+kc^2=0 \tag{12.5.676}$$

To simplify let us put:

$$\alpha:=\frac{c^2|\Lambda|}{3}-\frac{8\pi G}{3c^2}\rho \tag{12.5.677}$$

Therefore:

$$\dot{R}^2+\alpha R^2+kc^2=0 \tag{12.5.678}$$

Let us now move in natural units to get rid of the c^2:

$$\dot{R}^2+\alpha R^2+k=0 \tag{12.5.679}$$

Let us put $k=-1$ and assume that the density ρ is not dependent of time (it's a first case - equivalent to consider as we already know the universe being dominated by vacuum) and keep in mind that's equivalent also to consider ρ very small like $\rho\cong 0$ as 0 is a constant independent of time...):

$$\dot{R}^2+\alpha R^2-1=0 \tag{12.5.680}$$

Therefore:

$$\dot{R}=\pm\sqrt{1-\alpha^2R^2} \tag{12.5.681}$$

A simple integration leads to:

$$\int\frac{\mathrm{d}R}{\sqrt{1-\alpha^2R^2}}=\pm\int\mathrm{d}t \tag{12.5.682}$$

For $\alpha\neq 0$ (we would need to treat the case $\alpha=0$ and the case $1-\alpha^2R^2=0\Longrightarrow R=\pm 1/\alpha$), we substitute $u=\alpha R$:

$$\int\frac{\mathrm{d}u}{\sqrt{1-u^2}}=\pm\alpha\int\mathrm{d}t=\pm\alpha t+c^{te} \tag{12.5.683}$$

Let us substitute $u=\sin(x)$, then:

$$\int\frac{\cos(x)\mathrm{d}x}{\sqrt{1-\sin^2(x)}}=\pm\alpha t+c^{te} \tag{12.5.684}$$

After simplification using trigonometric identities:

$$\int \mathrm{d}x = \pm\alpha t + c^{te} \tag{12.5.685}$$

Therefore:

$$x(t) = \pm\alpha t + c^{te} \tag{12.5.686}$$

Hence:

$$u(t) = \sin\left(\pm\alpha t + c^{te}\right) \tag{12.5.687}$$

So finally under the assumptions taken earlier:

$$R(t) = \frac{1}{\alpha}\sin\left(\pm\alpha t + c^{te}\right) \tag{12.5.688}$$

Explicitly (in natural units $c = 1, G = 1$):

$$R(t) = \frac{3}{|\Lambda| - 8\pi\rho}\sin\left(\pm\frac{|\Lambda| - 8\pi\rho}{3}t + c^{te}\right) \tag{12.5.689}$$

Therefore we have a cyclic universe (whatever the sign of Λ) and remember that we assume that:

$$\alpha \neq 0 \Rightarrow \frac{c^2|\Lambda|}{3} \neq \frac{8\pi G}{3c^2}\rho \tag{12.5.690}$$

Or said otherwise:

$$\rho \neq \frac{c^4|\Lambda|}{8\pi G} \tag{12.5.691}$$

Ok so that's the result for a hyperbolic universe dominated by vacuum. Assuming that only ρ is a function of R only and that is does not explicitly depend on time, we can write:

$$\dot{R} = \frac{\mathrm{d}R}{\mathrm{d}t} = \sqrt{\frac{8\pi G}{3c^2}\rho(R)R^2 - kc^2 - \frac{c^2|\Lambda|}{3}R^2} \tag{12.5.692}$$

But we have proven (see page 5912) that the different most common type of density evolution are:

$$\rho(t) \propto R(t)^{-3(1+\omega(T))} \propto \begin{cases} R(t)^{-3} & \text{for } \omega(T) = 0 \text{ (pressureless matter (i.e. dust))} \\ R(t)^{-4} & \text{for } \omega(T) = 1/3 \text{ (radiation/relativistic matter)} \\ c^{te} & \text{for } \omega(T) = -1 \text{ (vacuum energy)} \end{cases} \tag{12.5.693}$$

Let us consider that we are interested about the first instants of the Big Bang (this is an excuse in reality because we didn't found any analytic solution for the presureless matter, i.e. $\omega(T) = 0$, case.........). Then we will focus on radiation/relativistic matter, i.e. $\rho \propto R(t)^{-4}$ (and for simplicity we put $R_0 = 1$):

$$\dot{R} = \sqrt{\frac{8\pi G}{3c^2}\rho_0\frac{R_0^4}{R^4}R^2 - kc^2 - \frac{c^2|\Lambda|}{3}R^2} = \sqrt{\frac{8\pi G}{3c^2}\rho_0 R^{-2} - kc^2 - \frac{c^2|\Lambda|}{3}R^2} \tag{12.5.694}$$

To simplify let us denote the latter:

$$\dot{R}=\sqrt{\alpha R^{-2}-\beta+\gamma R^{2}} \tag{12.5.695}$$

Hence:

$$\int \mathrm{d}t=\int \frac{1}{\sqrt{\alpha R^{-2}-\beta+\gamma R^{2}}}\mathrm{d}R \tag{12.5.696}$$

Let us put first the right hand side at the same denominator:

$$\int \frac{R}{\sqrt{\gamma R^{4}-\beta R^{2}+\alpha}}\mathrm{d}R \tag{12.5.697}$$

Let us substitute $u=R^{2}\longrightarrow \mathrm{d}u=2R\mathrm{d}R$, therefore:

$$\int \frac{R}{\sqrt{\gamma R^{4}-\beta R^{2}+\alpha}}\mathrm{d}R=\frac{1}{2}\int \frac{1}{\sqrt{\gamma u^{2}-\beta u+\alpha}}\mathrm{d}u=\int \frac{1}{\sqrt{\left(\sqrt{\gamma}u-\frac{\beta}{2\sqrt{\gamma}}\right)^{2}-\frac{\beta^{2}}{4\gamma}+\alpha}}\mathrm{d}u \tag{12.5.698}$$

Let us substitute:

$$v=\frac{2\gamma u-\beta}{2\sqrt{\alpha-\frac{\beta^{2}}{4\gamma}}\sqrt{\gamma}}\rightarrow \mathrm{d}v=\frac{\sqrt{\gamma}}{\sqrt{\alpha-\frac{\beta^{2}}{4\gamma}}}\mathrm{d}u \tag{12.5.699}$$

Therefore we get:

$$\frac{1}{\sqrt{\gamma}}\int \frac{1}{\sqrt{v^{2}+1}}\,\mathrm{d}v \tag{12.5.700}$$

Now solving:

$$\int \frac{1}{\sqrt{v^{2}+1}}\,\mathrm{d}v \tag{12.5.701}$$

This is a standard integral (see section Differential and Integral Calculus page 1534):

$$\int \frac{1}{\sqrt{v^{2}+1}}\mathrm{d}v=\ln\left(\sqrt{v^{2}+1}+v\right) \tag{12.5.702}$$

Plug in solved integrals:

$$\begin{aligned}\frac{1}{\sqrt{\gamma}}\int\frac{1}{\sqrt{v^2+1}}\mathrm{d}v&=\frac{\ln\left(\sqrt{v^2+1}+v\right)}{\sqrt{\gamma}}=\frac{\ln\left(\sqrt{\frac{(2\gamma u-\beta)^2}{4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+1}+\frac{2\gamma u-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\right)}{\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{\frac{\left(2\gamma R^2-\beta\right)^2}{4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+1}+\frac{2\gamma R^2-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{\frac{\left(2\gamma R^2-\beta\right)^2+4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}{4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}}+\frac{2\gamma R^2-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\frac{1}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\left[\sqrt{\left(2\gamma R^2-\beta\right)^2+4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+2\gamma R^2-\beta\right]\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{\left(2\gamma R^2-\beta\right)^2+4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+2\gamma R^2-\beta\right)}{2\sqrt{\gamma}}-\frac{\ln\left(2\sqrt{\gamma}\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{\left(2\gamma R^2-\beta\right)^2+\alpha 4\gamma-\beta^2}+2\gamma R^2-\beta\right)}{2\sqrt{\gamma}}+c^{te}\\
&=\frac{\ln\left(2\left(\sqrt{\gamma}\sqrt{R^2\left(\gamma R^2-\beta\right)+\alpha}+\gamma R^2\right)-\beta\right)}{2\sqrt{\gamma}}+c^{te}\end{aligned}\tag{12.5.703}$$

Hence:

$$\int\frac{1}{\sqrt{\frac{\alpha}{R^2}-\beta+\gamma R^2}}\mathrm{d}R=\frac{\ln\left(2\left(\sqrt{\gamma}\sqrt{R^2\left(\gamma R^2-\beta\right)+\alpha}+\gamma R^2\right)-\beta\right)}{2\sqrt{\gamma}}+c^{te}\tag{12.5.704}$$

Reinjecting the original constants we get:

$$\int\frac{1}{\sqrt{\frac{8\pi G}{3c^2}\rho_0 R^{-2}-kc^2-\frac{c^2|\Lambda|}{3}R^2}}\mathrm{d}R=\frac{\ln\left(2\left(\sqrt{\frac{-c^2|\Lambda|}{3}}\sqrt{R^2\cdot\left(\frac{-c^2|\Lambda|}{3}R^2-kc^2\right)+\frac{8\pi G}{3c^2}\rho_0}+\frac{-c^2|\Lambda|}{3}R^2\right)-kc^2\right)}{2\sqrt{\frac{-c^2|\Lambda|}{3}}}+c^{te}\tag{12.5.705}$$

So finally for a hyperbolic universe (replacing $k=-1$) dominated by radiation, we have:

$$t=\frac{\ln\left(2\left(\sqrt{\frac{-c^2|\Lambda|}{3}}\sqrt{R^2\cdot\left(\frac{-c^2|\Lambda|}{3}R^2+c^2\right)+\frac{8\pi G}{3c^2}\rho_0}+\frac{-c^2|\Lambda|}{3}R^2\right)+c^2\right)}{2\sqrt{\frac{-c^2|\Lambda|}{3}}}+c^{te}\tag{12.5.706}$$

Sadly we didn't found yet a way to extract the R above as a function of t nor a pertinent way to do an implicit plot with a computer software. Furthermore this situation is even worst than the case with $\Lambda > 0$ as we have complex roots and therefore the function is imaginary. So we will have to stop here!

- Now third and last main case with $\Lambda > 0$ (in the framework of FWLR universe all three corresponding sub-models are sometimes referred to some kind of "de Sitter space") that corresponds to the actual experimental measurements of our observable Universe in this early 121st century (according to holocene calendar)!

  First let us start also with a general behaviour analysis. Once again we start from the following Friedmann equations:

$$\begin{aligned}\dot{R}^2 &= \frac{8\pi G}{3c^2}\rho R^2 - kc^2 + \frac{c^2\Lambda}{3}R^2 \\ \ddot{R} &= -\frac{4\pi G}{3}\left(\rho + \frac{3P}{c^2}\right) + \frac{c^2\Lambda}{3}R\end{aligned} \tag{12.5.707}$$

  Then for $\Lambda > 0$ we can write:

$$\begin{aligned}\dot{R}^2 &= \frac{8\pi G}{3}\rho R^2 - kc^2 - \frac{c^2|\Lambda|}{3}R^2 = \frac{8\pi G}{3}\rho_{m-\Lambda}R^2 \\ \ddot{R} &= -\frac{4\pi G}{3}\left(\rho + \frac{3P}{c^2}\right) - \frac{c^2|\Lambda|}{3}R = -\frac{4\pi G}{3}R\left(\rho + \frac{3P}{c^2} - \frac{c^2|\Lambda|}{12\pi G}\right)\end{aligned} \tag{12.5.708}$$

  as you can see by the "$-$" in front of the Λ term we can already make the conclusion that when $\Lambda > 0$ it acts like a repulsive force to the Universe.

  $R(t)$ is then forever expanding. Notice also that ρ drops as Λ is assumed to remain constant...

  - For $k = 0$ we then have obviously:

$$\dot{R}^2 = \frac{8\pi G}{3c^2}\rho R^2 + \frac{c^2\Lambda}{3}R^2 \tag{12.5.709}$$

    after rearranging:

$$\left(\frac{\dot{R}}{R}\right)^2 = \frac{8\pi G}{3c^2}\rho + \frac{c^2\Lambda}{3} \tag{12.5.710}$$

    And now let us consider that ρ is small enough (universe without mass nor radiation but just a cosmological constant, i.e. dominated by vacuum with density parameter $\omega(T) = -1$) so that we can write:

$$\left(\frac{\dot{R}}{R}\right)^2 = \frac{c^2\Lambda}{3} \tag{12.5.711}$$

    which yields the solution:

$$R = \frac{3}{c^2\Lambda}e^{\sqrt{\frac{c^2\Lambda}{3}}t} \tag{12.5.712}$$

    Thus, the Universe expands exponentially! Some physicists (and astrophysicists/cosmologists) associate this to the "inflation" period of the Universe. There is also a solution on the negative side of the time axis that most textbooks ignore...

Remark

Notice that there is no constant of integration, otherwise the equality would not hold! So an interesting result (even if it's a priori not realistic to consider ρ as small...) is that when $t=0$, $R\neq 0$ (i.e. that Universe existed before the creation of time).

This model of universe is named the "De Sitter Universe model" (not to be confused with the Einstein-De Sitter Universe model seen earlier!).
Obviously we have then that the Hubble parameter is a constant as by definition:

$$H=\frac{\dot{R}}{R}=\sqrt{\frac{c^2\Lambda}{3}} \tag{12.5.713}$$

Before we continue on the topic, let us notice that now the reader has all the knowledge to fully understand the following table (if necessary we recommend the reader to refer again the complete table of most common w values at page 5912) that we can found in some textbook treating only of flat spaces ($k=0$):

Name	Equation	Radiation	Matter	Vacuum
Eq. of state	$p=w\rho$	$1/3$	0	-1
Energy density	$\rho\propto a^{-3(1+w)}$	a^{-4}	a^{-3}	constant
Scale Factor	$a\propto t^{2/3(1+w)}$	$t^{1/2}$	$t^{2/3}$	e^{Ht}

Table 12.27: **Friedmann-Lemaître-Robertson-Walker cosmological flat spaces summary**

Now let us consider the case where ρ cannot be neglected, as we have proved earlier that in a flat universe dominated by matter we had:

$$\rho=\frac{\rho_0 R_0^3}{R^3} \tag{12.5.714}$$

then:

$$\left(\frac{\dot{R}}{R}\right)^2=\frac{8\pi G}{3c^2}\rho+\frac{c^2\Lambda}{3} \tag{12.5.715}$$

can be rewritten:

$$\left(\frac{\dot{R}}{R}\right)^2=\frac{8\pi G}{3c^2}\frac{\rho_0 R_0^3}{R^3}+\frac{c^2\Lambda}{3} \tag{12.5.716}$$

Hence:

$$\dot{R}=\sqrt{\frac{8\pi G}{3c^2}\frac{\rho_0 R_0^3}{R}+\frac{c^2\Lambda}{3}R^2} \tag{12.5.717}$$

Thus:

$$\mathrm{d}R=\sqrt{\frac{8\pi G}{3c^2}\frac{\rho_0 R_0^3}{R}+\frac{c^2\Lambda}{3}R^2}\mathrm{d}t \tag{12.5.718}$$

$$\mathrm{d}R=\sqrt{\frac{8\pi G}{3c^2}\frac{\rho_0R_0^3}{R}+\frac{c^2\Lambda}{3}R^2}\mathrm{d}t=\sqrt{\underbrace{\frac{8\pi G\rho_0R_0^3}{3c^2}}_{:=K}\frac{1}{R}+\underbrace{\frac{c^2\Lambda}{3}}_{:=B}R^2}\mathrm{d}t=\frac{\sqrt{K}}{R^{1/2}}\sqrt{1+\frac{B}{K}R^3}\mathrm{d}t \tag{12.5.719}$$

So:

$$\frac{R^{1/2}\mathrm{d}R}{\sqrt{K}\sqrt{1+\dfrac{B}{K}R^3}}=\mathrm{d}t \tag{12.5.720}$$

Let us do the following change of variable:

$$x^2=\frac{B}{K}R^3\Rightarrow\begin{cases}3R^2\mathrm{d}R=2\dfrac{K}{B}x\mathrm{d}x\\ R^2=\left(\dfrac{K}{B}\right)^{2/3}x^{4/3}\\ R^{1/2}=\left(\dfrac{K}{B}\right)^{1/6}x^{1/3}\end{cases} \tag{12.5.721}$$

Hence:

$$R^{1/2}\mathrm{d}R=\frac{\left(\dfrac{K}{B}\right)^{1/6}x^{1/3}\dfrac{2}{3}\dfrac{K}{B}x\mathrm{d}x}{\left(\dfrac{K}{B}\right)^{2/3}x^{4/3}}=\frac{2}{3}\left(\frac{K}{B}\right)^{1/2}\mathrm{d}x \tag{12.5.722}$$

So:

$$\frac{R^{1/2}\mathrm{d}R}{\sqrt{K}\sqrt{1+\dfrac{B}{K}R^3}}=\frac{\dfrac{2}{3}\left(\dfrac{K}{B}\right)^{1/2}\mathrm{d}x}{\sqrt{K}\sqrt{1+x^2}}=\mathrm{d}t \tag{12.5.723}$$

So we want to take the primitive of:

$$\frac{2}{3\sqrt{B}}\int\frac{\mathrm{d}x}{\sqrt{1+x^2}}=\int\mathrm{d}t \tag{12.5.724}$$

as we know from our study of usual derivatives (see section Differential and Integral Calculus page 1475) the integral is simply given by:

$$\frac{2}{3\sqrt{B}}\text{arcsinh}(x)=t+c^{te} \tag{12.5.725}$$

For simplification purposes we will assume that for $t=0$, we have $R=0$ hence $c^{te}=0$ and we can write:

$$\frac{2}{3\sqrt{B}}\text{arcsinh}(x)=t\Leftrightarrow\text{arcsinh}\left(\sqrt{\frac{B}{K}}a^{3/2}\right)=\frac{3}{2}\sqrt{B}t \tag{12.5.726}$$

So:

$$\sqrt{\frac{B}{K}}a^{3/2}=\sinh\left(\frac{3}{2}\sqrt{B}t\right)\Leftrightarrow R=\sqrt[3]{\frac{K}{B}\sinh^2\left(\frac{3}{2}\sqrt{B}t\right)} \tag{12.5.727}$$

So finally:

$$R=R_0\sqrt[3]{\frac{8\pi G\rho_0}{\Lambda c^4}\sinh^2\left(\frac{3}{2}\sqrt{\frac{c^2\Lambda}{3}}t\right)}=R_0\sqrt[3]{\frac{8\pi G\rho_0}{\Lambda c^4}\left[\cosh\left(\frac{3}{2}\sqrt{\frac{c^2\Lambda}{3}}t\right)-1\right]} \tag{12.5.728}$$

Plotting such a function with Maple™ 4.00b we get:

```
>plot((cosh(x)-1)^(1/3),x=0..10);
```

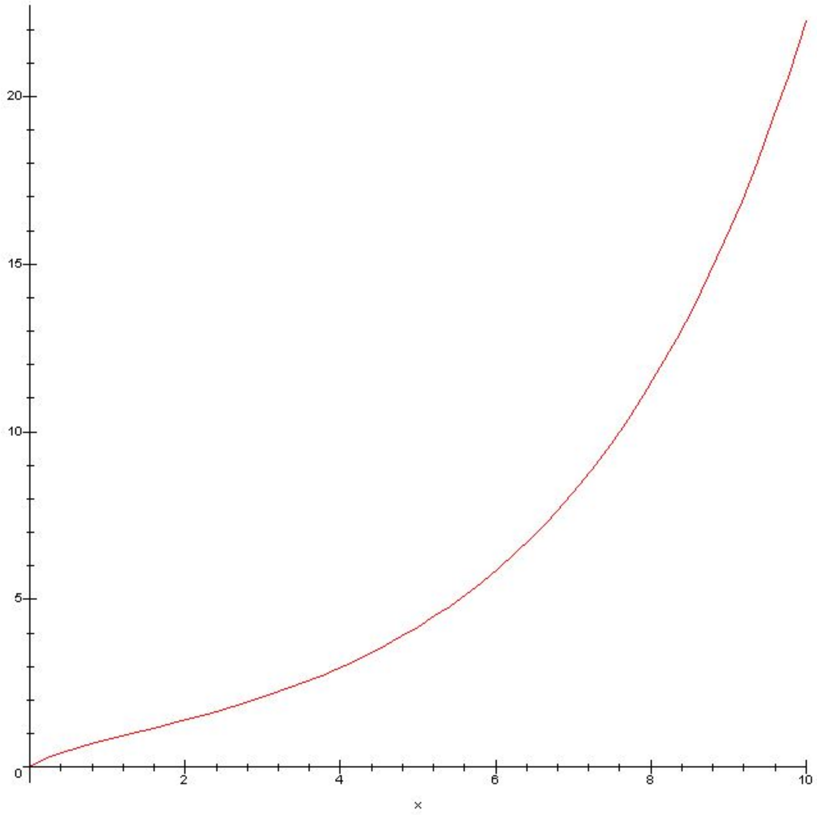

Figure 12.296: **Evolution of R for a zero curvature space with positive cosmological constant**

the quick divergent part of that curve is commonly named "big chill" or "big rip" depending on the textbooks (i.e. authors and teachers).

Looking at the plot it is quite obvious that there is somewhere and inflection point (see section Differential and Integral Calculus page 1454). Let us determine its position using again the Friedmann equation with $k=0$ (and still assuming $\Lambda>0$):

$$\dot{R}^2=\frac{8\pi G}{3c^2}\rho R^2+\frac{c^2\Lambda}{3}R^2 \tag{12.5.729}$$

That as we know, in a matter dominate Universe can be written as:

$$\dot{R}^2=\frac{8\pi G}{3c^2}\frac{\rho_0 R_0^3}{R}+\frac{c^2\Lambda}{3}R^2 \tag{12.5.730}$$

and if we differentiate with respect to time, we get:

$$2\dot{R}\ddot{R}=-\frac{8\pi G}{3c^2}\frac{\rho_0 R_0^3}{R^2}\dot{R}+2\frac{c^2\Lambda}{3}R\dot{R} \tag{12.5.731}$$

The inflection point occurs as we know when $\ddot{R}=0$, therefore we get by dividing both sides by $\dot{R}$ and after rearranging :

$$R=\sqrt[3]{\frac{3}{2}\frac{8\pi G\rho_0}{3\Lambda c^4}R_0^3}=R_0\sqrt[3]{\frac{3}{2}\frac{8\pi G\rho_0}{3\Lambda c^4}}=R_0\sqrt[3]{\frac{1}{2}\frac{8\pi G\rho_0}{\Lambda c^4}} \tag{12.5.732}$$

Equating with the previous result that was for recall:

$$R=R_0\sqrt[3]{\frac{8\pi G\rho_0}{\Lambda c^4}\sinh^2\left(\frac{3}{2}\sqrt{\frac{c^2\Lambda}{3}}t\right)} \tag{12.5.733}$$

We then have:

$$R_0\sqrt[3]{\frac{1}{2}\frac{8\pi G\rho_0}{\Lambda c^4}}=R_0\sqrt[3]{\frac{8\pi G\rho_0}{\Lambda c^4}\sinh^2\left(\frac{3}{2}\sqrt{\frac{c^2\Lambda}{3}}t\right)} \tag{12.5.734}$$

After simplification we get:

$$t_{\text{inflection}}=\frac{2}{3}\sqrt{\frac{3}{c^2\Lambda}}\text{arcsinh}\left(\sqrt{\frac{1}{2}}\right)=\frac{2}{3}\sqrt{\frac{3}{c^2\Lambda}}\text{arcsinh}\left(\frac{\sqrt{2}}{2}\right) \tag{12.5.735}$$

Now let us come back on:

$$R=R_0\sqrt[3]{\frac{8\pi G\rho_0}{\Lambda c^4}\sinh^2\left(\frac{3}{2}\sqrt{\frac{c^2\Lambda}{3}}t\right)} \tag{12.5.736}$$

It is common to rewrite it as:

$$R=R_0\left(\frac{8\pi G\rho_0}{\Lambda c^4}\right)^{1/3}\sinh^{3/2}\left(\frac{t}{t_\Gamma}\right) \tag{12.5.737}$$

It is common as we already know to choose $R_0=1$, therefore:

$$R=\left(\frac{8\pi G\rho_0}{\Lambda c^4}\right)^{1/3}\sinh^{3/2}\left(\frac{t}{t_\Gamma}\right) \tag{12.5.738}$$

That it is common to write:

$$\boxed{a(t)=\left(\frac{\Omega_m}{\Omega_\Gamma}\right)^{1/3}\sinh^{3/2}\left(\frac{t}{t_\Gamma}\right)} \tag{12.5.739}$$

that is the famous "concordance model".

- Now for $k=+1$, the second sub-case (spherical).

  Let us first recall that we have already treated the case $k=+1$ with $\Lambda>0$ and assuming $R=c^{te}$. This is the Einstein (static) Universe model already treated on page 6012.

  Let us consider now the general case:

  $$\dot{R}^2=\frac{8\pi G}{3c^2}\rho R^2-kc^2+\frac{c^2\Lambda}{3}R^2 \tag{12.5.740}$$

  This differential equation can be rewritten as:

  $$\dot{R}^2-\left(\frac{c^2\Lambda}{3}+\frac{8\pi G}{3c^2}\rho\right)R^2+kc^2=0 \tag{12.5.741}$$

  To simplify let us put:

  $$\alpha:=-\left(\frac{c^2\Lambda}{3}+\frac{8\pi G}{3c^2}\rho\right) \tag{12.5.742}$$

  Therefore:

  $$\dot{R}^2+\alpha R^2+kc^2=0 \tag{12.5.743}$$

  Let us now move in natural units to get rid of the c^2:

  $$\dot{R}^2+\alpha R^2+k=0 \tag{12.5.744}$$

  Let us put $k=+1$ and assume that the density ρ is not dependent of time (it's a first case - equivalent to consider as we already know the universe being dominated by vacuum) and keep in mind that's equivalent also to consider ρ very small like $\rho\cong 0$ as 0 is a constant independent of time...):

  $$\dot{R}^2+\alpha R^2+1=0 \tag{12.5.745}$$

  Therefore:

  $$\dot{R}=\pm\sqrt{-1-\alpha^2R^2} \tag{12.5.746}$$

  A simple integration leads to:

  $$\int\frac{\mathrm{d}R}{\sqrt{-1-\alpha^2R^2}}=\pm\int\mathrm{d}t \tag{12.5.747}$$

  For $\alpha\neq 0$ (we would need to treat the case $a=0$ and the case $-1-\alpha^2R^2=0\Longrightarrow R=\pm 1/\alpha$), we substitute $u=\alpha R$:

  $$\int\frac{\mathrm{d}u}{\sqrt{-1-u^2}}=\pm\alpha\int\mathrm{d}t=\pm\alpha t+c^{te} \tag{12.5.748}$$

  Hence:

  $$\int\frac{\mathrm{i}\mathrm{d}u}{\sqrt{1+u^2}}=\pm\alpha t+c^{te} \tag{12.5.749}$$

And we have already proven this primitive in the section of Differential and Integral Calculus (see page 1534):

$$\ln\left(u+\sqrt{u^2+\alpha^2}\right)=\pm\alpha t+c^{te} \tag{12.5.750}$$

Hence:

$$\mathrm{i}\ln\left(\alpha R+\sqrt{\alpha^2R^2+\alpha^2}\right)=\pm\alpha t+c^{te} \tag{12.5.751}$$

Hence:

$$\mathrm{i}\ln\left(\alpha R+\sqrt{\alpha^2R^2+\alpha^2}\right)=\pm\alpha t+c^{te} \tag{12.5.752}$$

Or:

$$\mathrm{i}\cdot\operatorname{arcsinh}(\alpha R)=\pm\alpha t+c^{te} \tag{12.5.753}$$

So finally:

$$R(t)=\sinh\left(\frac{\mathrm{i}(\pm\alpha t+c^{te})}{\alpha}\right) \tag{12.5.754}$$

This is a pure complex hyperbolic sine function. The interpretation is in our point of view non-trivial so will not try to extrapolate, even with a plot, this result. And remember that we assume that:

$$\alpha\neq 0\Rightarrow\frac{c^2\Lambda}{3}\neq-\frac{8\pi G}{3c^2}\rho \tag{12.5.755}$$

Or said otherwise:

$$\rho\neq-\frac{c^4\Lambda}{8\pi G} \tag{12.5.756}$$

Ok so that's the result for a spherical universe dominated by vacuum. Assuming that only ρ is a function of R only and that is does not explicitly depend on time, we can write:

$$\dot{R}=\frac{\mathrm{d}R}{\mathrm{d}t}=\sqrt{\frac{8\pi G}{3c^2}\rho(R)R^2-kc^2+\frac{c^2\Lambda}{3}R^2} \tag{12.5.757}$$

But we have proven (see page 5912) that the different most common type of density evolution are:

$$\rho(t)\propto R(t)^{-3(1+\omega(T))}\propto\begin{cases}R(t)^{-3} & \text{for } \omega(T)=0 \text{ (pressureless matter (i.e. dust))}\\ R(t)^{-4} & \text{for } \omega(T)=1/3 \text{ (radiation/relativistic matter)}\\ c^{te} & \text{for } \omega(T)=-1 \text{ (vacuum energy)}\end{cases} \tag{12.5.758}$$

Let us consider that we are interested about the first instants of the Big Bang (this is an excuse in reality because we didn't found any analytic solution for the presureless matter, i.e. $\omega(T)=0$, case.........). Then we will focus on radiation/relativistic matter, i.e. $\rho\propto R(t)^{-4}$ (and for simplicity we put $R_0=1$):

$$\dot{R}=\sqrt{\frac{8\pi G}{3c^2}\rho_0\frac{R_0^4}{R^4}R^2-kc^2+\frac{c^2\Lambda}{3}R^2}=\sqrt{\frac{8\pi G}{3c^2}\rho_0R^{-2}-kc^2+\frac{c^2\Lambda}{3}R^2} \tag{12.5.759}$$

To simplify let us denote the latter:

$$\dot{R}=\sqrt{\alpha R^{-2}-\beta+\gamma R^2} \tag{12.5.760}$$

Hence:

$$\int \mathrm{d}t=\int \frac{1}{\sqrt{\alpha R^{-2}-\beta+\gamma R^2}}\mathrm{d}R \tag{12.5.761}$$

Let us put first the right hand side at the same denominator:

$$\int \frac{R}{\sqrt{\gamma R^4-\beta R^2+\alpha}}\mathrm{d}R \tag{12.5.762}$$

Let us substitute $u=R^2 \longrightarrow \mathrm{d}u=2R\mathrm{d}R$, therefore:

$$\int \frac{R}{\sqrt{\gamma R^4-\beta R^2+\alpha}}\mathrm{d}R=\frac{1}{2}\int \frac{1}{\sqrt{\gamma u^2-\beta u+\alpha}}\mathrm{d}u=\int \frac{1}{\sqrt{\left(\sqrt{\gamma}u-\frac{\beta}{2\sqrt{\gamma}}\right)^2-\frac{\beta^2}{4\gamma}+\alpha}}\mathrm{d}u \tag{12.5.763}$$

Let us substitute:

$$v=\frac{2\gamma u-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\to \mathrm{d}v=\frac{\sqrt{\gamma}}{\sqrt{\alpha-\frac{\beta^2}{4\gamma}}}\mathrm{d}u \tag{12.5.764}$$

Therefore we get:

$$\frac{1}{\sqrt{\gamma}}\int \frac{1}{\sqrt{v^2+1}}\,\mathrm{d}v \tag{12.5.765}$$

Now solving:

$$\int \frac{1}{\sqrt{v^2+1}}\,\mathrm{d}v \tag{12.5.766}$$

This is a standard integral (see section Differential and Integral Calculus page 1534):

$$\int \frac{1}{\sqrt{v^2+1}}\mathrm{d}v=\ln\left(\sqrt{v^2+1}+v\right) \tag{12.5.767}$$

Plug in solved integrals:

$$\begin{aligned}\frac{1}{\sqrt{\gamma}}\int\frac{1}{\sqrt{v^2+1}}\mathrm{d}v=\frac{\ln\left(\sqrt{v^2+1}+v\right)}{\sqrt{\gamma}}&=\frac{\ln\left(\sqrt{\frac{(2\gamma u-\beta)^2}{4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+1}+\frac{2\gamma u-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\right)}{\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{\frac{(2\gamma R^2-\beta)^2}{4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+1}+\frac{2\gamma R^2-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{\frac{(2\gamma R^2-\beta)^2+4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}{4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}}+\frac{2\gamma R^2-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\frac{1}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\left[\sqrt{(2\gamma R^2-\beta)^2+4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+2\gamma R^2-\beta\right]\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{(2\gamma R^2-\beta)^2+4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+2\gamma R^2-\beta\right)}{2\sqrt{\gamma}}-\frac{\ln\left(2\sqrt{\gamma}\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{(2\gamma R^2-\beta)^2+\alpha 4\gamma-\beta^2}+2\gamma R^2-\beta\right)}{2\sqrt{\gamma}}+c^{te}\\
&=\frac{\ln\left(2\left(\sqrt{\gamma}\sqrt{R^2\left(\gamma R^2-\beta\right)+\alpha}+\gamma R^2\right)-\beta\right)}{2\sqrt{\gamma}}+c^{te}\end{aligned} \tag{12.5.768}$$

Hence:

$$\int\frac{1}{\sqrt{\frac{\alpha}{R^2}-\beta+\gamma R^2}}\mathrm{d}R=\frac{\ln\left(2\left(\sqrt{\gamma}\sqrt{R^2\left(\gamma R^2-\beta\right)+\alpha}+\gamma R^2\right)-\beta\right)}{2\sqrt{\gamma}}+c^{te} \tag{12.5.769}$$

Reinjecting the original constants we get:

$$\int\frac{1}{\sqrt{\frac{8\pi G}{3c^2}\rho_0R^{-2}-kc^2+\frac{c^2\Lambda}{3}R^2}}\mathrm{d}R=\frac{\ln\left(2\left(\sqrt{\frac{c^2\Lambda}{3}}\sqrt{R^2\cdot\left(\frac{c^2\Lambda}{3}R^2-kc^2\right)+\frac{8\pi G}{3c^2}\rho_0}+\frac{c^2\Lambda}{3}R^2\right)-kc^2\right)}{2\sqrt{\frac{c^2\Lambda}{3}}}+c^{te} \tag{12.5.770}$$

So finally for a spherical universe (replacing $k=+1$) dominated by radiation, we have:

$$t=\frac{\ln\left(2\left(\sqrt{\frac{c^2\Lambda}{3}}\sqrt{R^2\cdot\left(\frac{c^2\Lambda}{3}R^2-c^2\right)+\frac{8\pi G}{3c^2}\rho_0}+\frac{c^2\Lambda}{3}R^2\right)-c^2\right)}{2\sqrt{\frac{c^2\Lambda}{3}}}+c^{te} \tag{12.5.771}$$

Sadly we didn't found yet a way to extract the R above as a function of t nor a pertinent way to do an implicit plot with a computer software. So we will have to stop here!

- Let us now consider the case $k=-1$ (hyperbolic).

  For this, same as before, we start from:

  $$\dot{R}^2=\frac{8\pi G}{3c^2}\rho R^2-kc^2+\frac{c^2\Lambda}{3}R^2 \tag{12.5.772}$$

  This differential equation can be rewritten as:

  $$\dot{R}^2-\left(\frac{c^2\Lambda}{3}+\frac{8\pi G}{3c^2}\rho\right)R^2+kc^2=0 \tag{12.5.773}$$

  To simplify let us put:

  $$\alpha:=\left(\frac{c^2\Lambda}{3}+\frac{8\pi G}{3c^2}\rho\right) \tag{12.5.774}$$

  Therefore:

  $$\dot{R}^2+\alpha R^2+kc^2=0 \tag{12.5.775}$$

  Let us now move in natural units to get rid of the c^2:

  $$\dot{R}^2+\alpha R^2+k=0 \tag{12.5.776}$$

  Let us put $k=-1$ and assume that the density ρ is not dependent of time (it's a first case - equivalent to consider as we already know the universe being dominated by vacuum) and keep in mind that's equivalent also to consider ρ very small like $\rho\cong 0$ as 0 is a constant independent of time...):

  $$\dot{R}^2+\alpha R^2-1=0 \tag{12.5.777}$$

  Therefore:

  $$\dot{R}=\pm\sqrt{1-\alpha^2R^2} \tag{12.5.778}$$

  A simple integration leads to:

  $$\int\frac{\mathrm{d}R}{\sqrt{1-\alpha^2R^2}}=\pm\int\mathrm{d}t \tag{12.5.779}$$

  For $\alpha\neq 0$ (we would need to treat the case $\alpha=0$ and the case $1-\alpha^2R^2=0\Longrightarrow R=\pm 1/\alpha$), we substitute $u=\alpha R$:

  $$\int\frac{\mathrm{d}u}{\sqrt{1-u^2}}=\pm\alpha\int\mathrm{d}t=\pm\alpha t+c^{te} \tag{12.5.780}$$

  Let us substitute $u=\sin(x)$, then:

  $$\int\frac{\cos(x)\mathrm{d}x}{\sqrt{1-\sin^2(x)}}=\pm\alpha t+c^{te} \tag{12.5.781}$$

  After simplification using trigonometric identities:

  $$\int\mathrm{d}x=\pm\alpha t+c^{te} \tag{12.5.782}$$

Therefore:

$$x(t)=\pm\alpha t+c^{te} \tag{12.5.783}$$

Hence:

$$u(t)=\sin\left(\pm\alpha t+c^{te}\right) \tag{12.5.784}$$

So finally under the assumptions taken earlier:

$$R(t)=\frac{1}{\alpha}\sin\left(\pm\alpha t+c^{te}\right) \tag{12.5.785}$$

Explicitly (in natural units $c=1, G=1$):

$$R(t)=-\frac{3}{\Lambda+8\pi\rho}\sin\left(\pm\frac{\Lambda+8\pi\rho}{3}t+c^{te}\right) \tag{12.5.786}$$

Therefore we have a cyclic universe (whatever the sign of Λ) and remember that we assume that:

$$\alpha\neq 0\Rightarrow\frac{c^2\Lambda}{3}\neq-\frac{8\pi G}{3c^2}\rho \tag{12.5.787}$$

Or said otherwise:

$$\rho\neq-\frac{c^4\Lambda}{8\pi G} \tag{12.5.788}$$

Ok so that's the result for a hyperbolic universe dominated by vacuum. Assuming that only ρ is a function of R only and that is does not explicitly depend on time, we can write:

$$\dot{R}=\frac{\mathrm{d}R}{\mathrm{d}t}=\sqrt{\frac{8\pi G}{3c^2}\rho(R)R^2-kc^2+\frac{c^2\Lambda}{3}R^2} \tag{12.5.789}$$

But we have proven (see page 5912) that the different most common type of density evolution are:

$$\rho(t)\propto R(t)^{-3(1+\omega(T))}\propto\begin{cases}R(t)^{-3} & \text{for } \omega(T)=0 \text{ (pressureless matter (i.e. dust))}\\ R(t)^{-4} & \text{for } \omega(T)=1/3 \text{ (radiation/relativistic matter)}\\ c^{te} & \text{for } \omega(T)=-1 \text{ (vacuum energy)}\end{cases} \tag{12.5.790}$$

Let us consider that we are interested about the first instants of the Big Bang (this is an excuse in reality because we didn't found any analytic solution for the presureless matter, i.e. $\omega(T)=0$, case.........). Then we will focus on radiation/relativistic matter, i.e. $\rho\propto R(t)^{-4}$ (and for simplicity we put $R_0=1$):

$$\dot{R}=\sqrt{\frac{8\pi G}{3c^2}\rho_0\frac{R_0^4}{R^4}R^2-kc^2+\frac{c^2\Lambda}{3}R^2}=\sqrt{\frac{8\pi G}{3c^2}\rho_0R^{-2}-kc^2+\frac{c^2\Lambda}{3}R^2} \tag{12.5.791}$$

To simplify let us denote the latter:

$$\dot{R}=\sqrt{\alpha R^{-2}-\beta+\gamma R^2} \tag{12.5.792}$$

Hence:

$$\int \mathrm{d}t=\int \frac{1}{\sqrt{\alpha R^{-2}-\beta+\gamma R^2}}\mathrm{d}R \tag{12.5.793}$$

Let us put first the right hand side at the same denominator:

$$\int \frac{R}{\sqrt{\gamma R^4-\beta R^2+\alpha}}\mathrm{d}R \tag{12.5.794}$$

Let us substitute $u=R^2 \longrightarrow \mathrm{d}u=2R\mathrm{d}R$, therefore:

$$\int \frac{R}{\sqrt{\gamma R^4-\beta R^2+\alpha}}\mathrm{d}R=\frac{1}{2}\int \frac{1}{\sqrt{\gamma u^2-\beta u+\alpha}}\mathrm{d}u=\int \frac{1}{\sqrt{\left(\sqrt{\gamma}u-\frac{\beta}{2\sqrt{\gamma}}\right)^2-\frac{\beta^2}{4\gamma}+\alpha}}\mathrm{d}u \tag{12.5.795}$$

Let us substitute:

$$v=\frac{2\gamma u-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}} \rightarrow \mathrm{d}v=\frac{\sqrt{\gamma}}{\sqrt{\alpha-\frac{\beta^2}{4\gamma}}}\mathrm{d}u \tag{12.5.796}$$

Therefore we get:

$$\frac{1}{\sqrt{\gamma}}\int \frac{1}{\sqrt{v^2+1}}\,\mathrm{d}v \tag{12.5.797}$$

Now solving:

$$\int \frac{1}{\sqrt{v^2+1}}\,\mathrm{d}v \tag{12.5.798}$$

This is a standard integral (see section Differential and Integral Calculus page 1534):

$$\int \frac{1}{\sqrt{v^2+1}}\mathrm{d}v=\ln\left(\sqrt{v^2+1}+v\right) \tag{12.5.799}$$

Plug in solved integrals:

$$
\begin{aligned}
\frac{1}{\sqrt{\gamma}}\int\frac{1}{\sqrt{v^2+1}}\mathrm{d}v=\frac{\ln\left(\sqrt{v^2+1}+v\right)}{\sqrt{\gamma}}&=\frac{\ln\left(\sqrt{\frac{(2\gamma u-\beta)^2}{4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+1}+\frac{2\gamma u-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\right)}{\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{\frac{(2\gamma R^2-\beta)^2}{4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+1}+\frac{2\gamma R^2-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{\frac{(2\gamma R^2-\beta)^2+4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}{4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}}+\frac{2\gamma R^2-\beta}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\frac{1}{2\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\sqrt{\gamma}}\left[\sqrt{(2\gamma R^2-\beta)^2+4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+2\gamma R^2-\beta\right]\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{(2\gamma R^2-\beta)^2+4\gamma\left(\alpha-\frac{\beta^2}{4\gamma}\right)}+2\gamma R^2-\beta\right)}{2\sqrt{\gamma}}-\frac{\ln\left(2\sqrt{\gamma}\sqrt{\alpha-\frac{\beta^2}{4\gamma}}\right)}{2\sqrt{\gamma}}\\
&=\frac{\ln\left(\sqrt{(2\gamma R^2-\beta)^2+\alpha4\gamma-\beta^2}+2\gamma R^2-\beta\right)}{2\sqrt{\gamma}}+c^{te}\\
&=\frac{\ln\left(2\left(\sqrt{\gamma}\sqrt{R^2\left(\gamma R^2-\beta\right)+\alpha}+\gamma R^2\right)-\beta\right)}{2\sqrt{\gamma}}+c^{te}
\end{aligned}
\tag{12.5.800}
$$

Hence:

$$\int\frac{1}{\sqrt{\frac{\alpha}{R^2}-\beta+\gamma R^2}}\mathrm{d}R=\frac{\ln\left(2\left(\sqrt{\gamma}\sqrt{R^2\left(\gamma R^2-\beta\right)+\alpha}+\gamma R^2\right)-\beta\right)}{2\sqrt{\gamma}}+c^{te}\tag{12.5.801}$$

Reinjecting the original constants we get:

$$\int\frac{1}{\sqrt{\frac{8\pi G}{3c^2}\rho_0R^{-2}-kc^2+\frac{c^2\Lambda}{3}R^2}}\mathrm{d}R=\frac{\ln\left(2\left(\sqrt{\frac{c^2\Lambda}{3}}\sqrt{R^2\cdot\left(\frac{c^2\Lambda}{3}R^2-kc^2\right)+\frac{8\pi G}{3c^2}\rho_0}+\frac{c^2\Lambda}{3}R^2\right)-kc^2\right)}{2\sqrt{\frac{c^2\Lambda}{3}}}+c^{te}\tag{12.5.802}$$

So finally for a hyperbolic universe (replacing $k=-1$) dominated by radiation, we have:

$$t=\frac{\ln\left(2\left(\sqrt{\frac{c^2\Lambda}{3}}\sqrt{R^2\cdot\left(\frac{c^2\Lambda}{3}R^2+c^2\right)+\frac{8\pi G}{3c^2}\rho_0}+\frac{c^2\Lambda}{3}R^2\right)+c^2\right)}{2\sqrt{\frac{c^2\Lambda}{3}}}+c^{te}\tag{12.5.803}$$

Sadly we didn't found yet a way to extract the R above as a function of t nor a pertinent way to do an implicit plot with a computer software. So we will have to stop here!

To summarize for these nine common models (for reminder among 27 if for each we include the case dominated by matter, by radiation or by vacuum):

Cosmological Constant	**Curvature**	**Radius (scale factor)**
$\Lambda=0$	$k=0$ (flat)	$\left(\dfrac{9H^2}{4}\right)^{1/3} t^{2/3}$
	$k=+1$ (sphere)	$t=\dfrac{8\pi G\rho_0}{3c^5}\dfrac{1}{2}\left(\theta'-\sin\left(\theta'\right)\right)$ $R=\dfrac{8\pi G\rho_0}{3c^4}\dfrac{1}{2}\left(1-\cos\left(\theta'\right)\right)$
	$k=-1$ (hyperbolic)	$t=\dfrac{8\pi G\rho_0}{3c^5}\dfrac{1}{2}\left(\sinh\left(\theta'\right)-\theta'\right)$ $R=\dfrac{8\pi G\rho_0}{3c^4}\dfrac{1}{2}\left(\cosh\left(\theta'\right)-1\right)$
$\Lambda<0$	$k=0$ (flat)	$R=R_0\sqrt[3]{-\frac{8\pi G\rho_0}{\lvert\Lambda\rvert c^4}\sinh^2\left(\frac{3}{2}\sqrt{\frac{-c^2\lvert\Lambda\rvert}{3}}t\right)}$
	$k=+1$ (sphere)	No pretty solution known to us
	$k=-1$ (hyperbolic)	No pretty solution known to us
$\Lambda>0$	$k=0$ (flat)	$R=R_0\sqrt[3]{\frac{8\pi G\rho_0}{\Lambda c^4}\sinh^2\left(\frac{3}{2}\sqrt{\frac{c^2\Lambda}{3}}t\right)}$
	$k=+1$ (sphere)	No pretty solution known to us
	$k=-1$ (hyperbolic)	No pretty solution known to us

Table 12.28: **Friedmann-Lemaître-Robertson-Walker cosmological models equations summary**

Caution! Keep in mind that we have the knowledge now with everything that we have seen so far of the following canonical curvature values $k=\{-1,0,+1\}$, of the following typical canonical values of the density parameter $\omega(T)=\{0,1/3,-1/3,1,<-1\}$ and the following type of canonical values for the cosmological constant $\omega(T)=\{0<,=0,>0\}$. Hence in reality there are $3\times5\times3=45$ different type of dominated universes! If we take into account that a universe can contain a mixed of radiation, vacuum, matter, etc. we get in reality $3\times31\times5=465$ possible mixtures of universes....!!! Obviously we will never study all of them in this textbook!

Notice that whatever which result you pick above, if you inject into these relations the value of the Planck density or of the Planck time given for recall by:

$$\rho_\text{P}=\frac{c^5}{G^2\hbar}\cong 5.16\cdot10^{96}\,[\text{kg}\cdot\text{m}^{-3}]\qquad t_\text{P}=\sqrt{\frac{\hbar G}{c^5}}\cong 5.391\cdot10^{-44}\,[\text{s}] \tag{12.5.804}$$

there are absolutely no singularity at the opposite of a common urban legend! So when you read that «*General Relativity fails at Planck scale*» it's a supposition but not an affirmation!

Now remember that we have proven earlier above (see page 6000) that the proper distance to the horizon given by:

$$s_\text{hor.}(t)=a(t)\int\limits_0^t\frac{c\text{d}t}{a(t)} \tag{12.5.805}$$

$$R_{\Lambda=0,k=0}\cong\left(\frac{6\pi G}{c^2}\rho_0\right)^{1/3}t^{2/3}=\left(\frac{9H^2}{4}\right)^{1/3}t^{2/3}:=a_{\Lambda=0,k=0}(t) \tag{12.5.806}$$

Then we have:

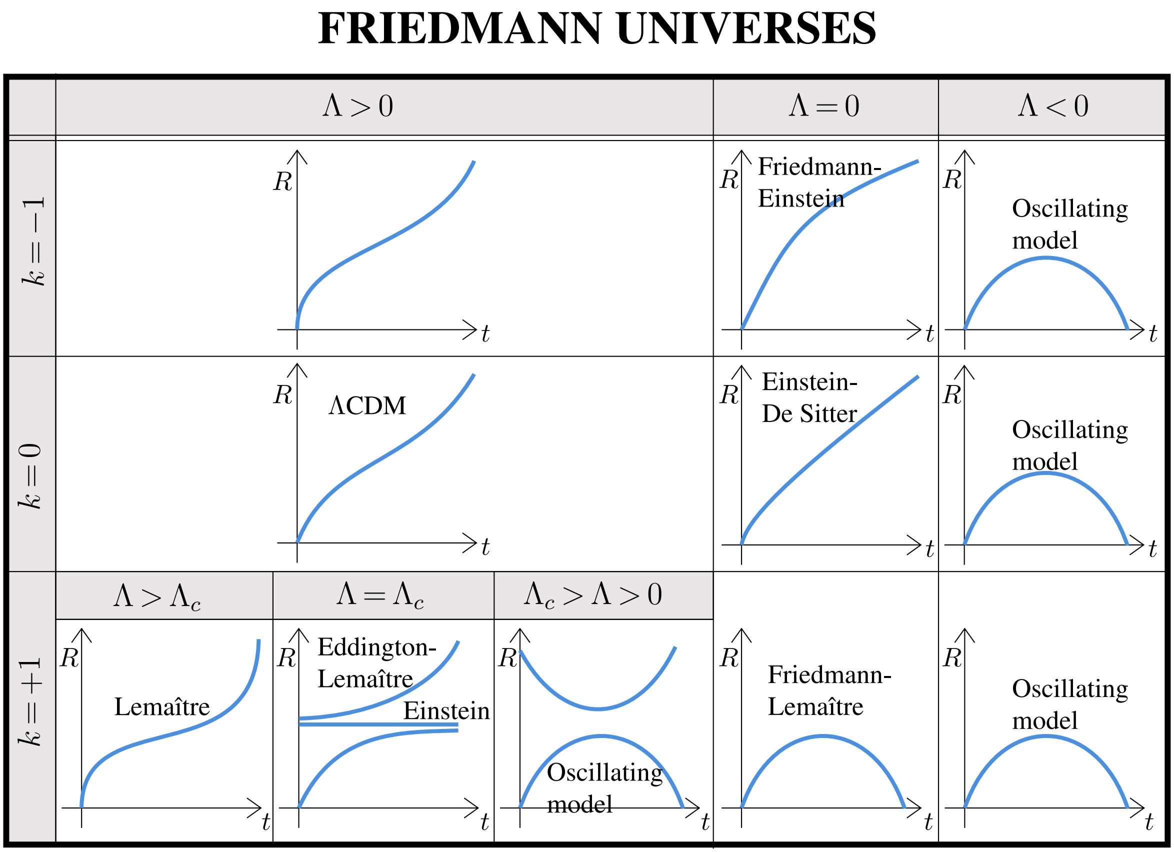
$$\begin{aligned}s_{\text{hor.},\Lambda=0,k=0}(t)&=a(t)\int\limits_0^t\frac{c\mathrm{d}t}{a(t)}\cong\left(\frac{9H^2}{4}\right)^{1/3}t^{2/3}\int\limits_0^t\frac{c\mathrm{d}t}{\left(\frac{9H^2}{4}\right)^{1/3}t^{2/3}}=t^{2/3}\int\limits_0^t\frac{c\mathrm{d}t}{t^{2/3}}\\&=t^{2/3}\cdot c3t^{1/3}=3ct\end{aligned} \tag{12.5.807}$$

Hence we have the quite famous result corresponding to our actual state of experimental evidence (last measurements from 12020 give $t\cdot c=13.77\pm 0.040$ billion years):

$$\boxed{R_{\Lambda=0,k=0}\cong 3ct\cong 41.31\pm 0.12\,[\text{billion light years}]} \tag{12.5.808}$$

So we finally found the value that we can see or listen on many Internet websites or in YouTube videos but without proof! This value can be compared to the 28.8 billion light years of the Newtonian radius approach...

Finally here is a summary of the models developed earlier above depending on the canonical values of k and Λ :



FRIEDMANN UNIVERSES
$\Lambda>0$
$\Lambda=0$
$\Lambda<0$
$k=-1$
$k=0$
$k=+1$
$\Lambda>\Lambda_c$
$\Lambda=\Lambda_c$
$\Lambda_c>\Lambda>0$
R
t
Friedmann-Einstein
Oscillating model
ΛCDM
Einstein-De Sitter
Lemaître
Eddington-Lemaître
Einstein
Friedmann-Lemaître

Figure 12.297: **Cosmological models summary (source: [147])**

The Uchuu (meaning "Outer Space" in Japanese) 12021 (holocene calendar) simulation is the largest and most detailed simulation of the universe ever made. It contains 2.1 trillion "particles" in a space 9.6 billion light-years across. The simulation models the evolution of the universe across more than 13 billion years. It doesn't focus on the formation of stars and planets but instead looks at the behaviour of dark matter within an expanding universe. The detail of Uchuu is high enough that the team can identify everything from galaxy clusters to the dark matter halos of individual galaxies. Since dark matter[70] makes up most of the matter in the universe, it is the main driver of galaxy formation and clustering. It takes a tremendous amount of computational power and storage to create such a detailed model. The team (from Japan, Spain, U.S.A., Argentina, Australia, Chile, France, and Italy) used over $40,000$ computer cores and 20 million computer hours to generate their simulation, and it produced more than 3 Petabytes of data. Using high-density compression, however, the team was able to compress their results into a mere 100 Terabytes of storage that can be downloaded and analysed with Python™.

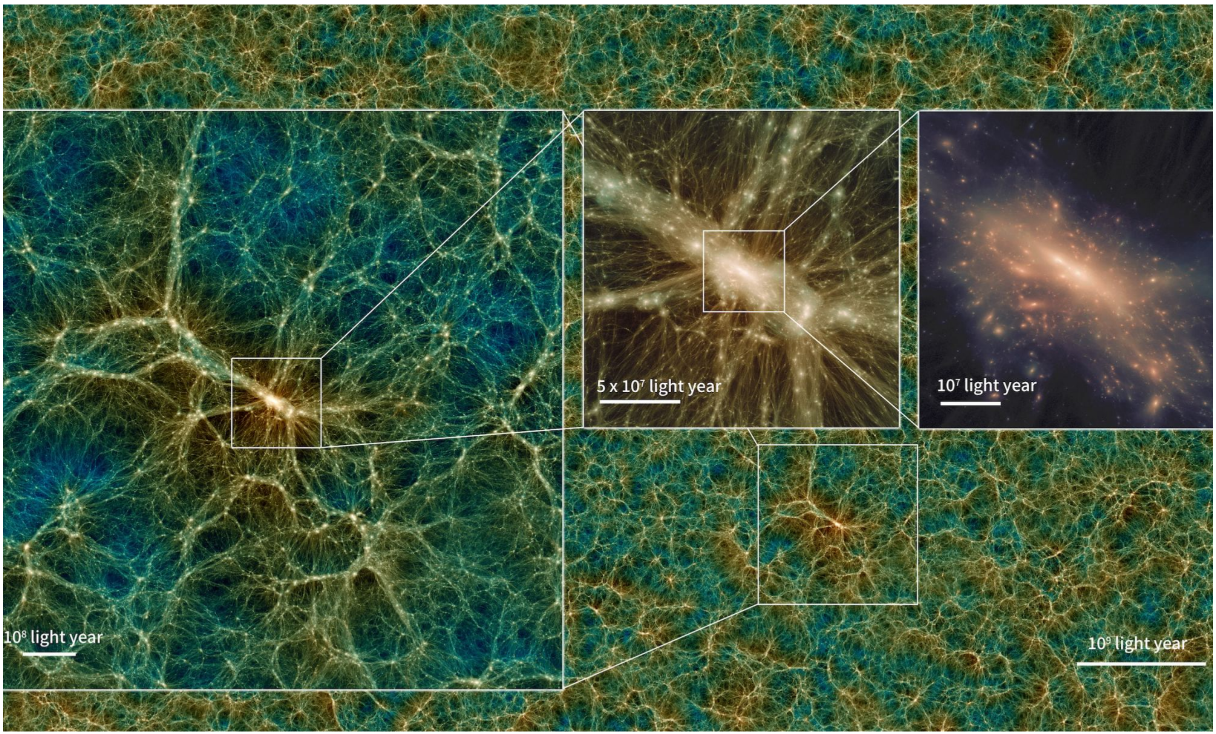


Figure 12.298: **Uchuu 21021 Universe simulation (source: [277])**

---

[70] Since June 12025 (holocene calendar) it is known thanks to FRB (Fast Radio Bursts) that approximately 76% of the Universe's baryonic matter lies in the IGM (InterGalactic Medium). About 15% resides in galaxy halos, and a small fraction is burrowed in stars or amid cold galactic galactic gas ([109]).

12.5.7 Friedmann historical derivation

OK so far we have seen how to get different types of universe using the following approaches:

- Newtonian non-relativistic approach
- Friedmann-Lemaître Euclidean models
- Friedmann-Lemaître-Robertson-Walker Cosmological Models

However some people asked us to add the original models made by Friedmann in his famous paper of 11922 [193] (holocene calendar). So let's do it but with much more details and using modern tools!

First, let us put a bit of context! The Russian mathematician and physicist Alexander Friedmann (11888-11925) is well known among relativists, but his contributions to cosmology are largely misunderstood. Even the Royal Swedish Academy of Sciences misrepresented Friedmann's work in the 12011 (holocene calendar) Nobel Prize scientific background essay. Friedmann was the first physicist who demonstrated that Albert Einstein's general relativity admits non-static solutions, and the universe can expand, oscillate, and be born in a singularity (and it's not Georges Lemaître). Friedmann's conclusion was based on his analysis of an elliptic integral as we will show it further below!

First, Friedmann considered the 3D hypersphere:

$$x_1^2+x_2^2+x_3^2+x_4^2=a(t)^2 \tag{12.5.809}$$

After he transformed that into cartesian coordinates:

$$\begin{aligned}
x_1&=a(t)\sin(\chi)\sin(\theta)\cos(\phi)\\
x_2&=a(t)\sin(\chi)\sin(\theta)\sin(\phi)\\
x_3&=a(t)\sin(\chi)\cos(\theta)\\
x_4&=a(t)\cos(\chi)
\end{aligned} \tag{12.5.810}$$

We can check that's indeed compliant:

$$\begin{aligned}
\sum_i x_i^2&=a(t)^2\left(\sin^2(\chi)\sin^2(\theta)\cos^2(\phi)+\sin^2(\chi)\sin^2(\theta)\sin^2(\phi)+\sin^2(\chi)\cos^2(\theta)+\cos^2(\chi)\right)\\
&=a(t)^2\left(\sin^2(\theta)\cos^2(\phi)+\sin^2(\theta)\sin^2(\phi)+\cos^2(\theta)\right)_{=1,S^2}\sin^2(\chi)+\cos^2(\chi)\\
&=\sin^2(\chi)+\cos^2(\chi)=1
\end{aligned} \tag{12.5.811}$$

Now to get the metric we compute:

$$\begin{aligned}
&x_1=a(t)\sin(\chi)\sin(\theta)\cos(\phi)\\
&\quad\Rightarrow \mathrm{d}x_1=a(t)\left[\cos(\chi)\mathrm{d}\chi\sin(\theta)\cos(\phi)+\sin(\chi)\cos(\theta)\mathrm{d}\theta\cos(\phi)-\sin(\chi)\sin(\theta)\sin(\phi)\mathrm{d}\phi\right]\\
&x_2=a(t)\sin(\chi)\sin(\theta)\sin(\phi)\\
&\quad\Rightarrow \mathrm{d}x_2=a(t)\left[\cos(\chi)\mathrm{d}\chi\sin(\theta)\sin(\phi)+\sin(\chi)\cos(\theta)\mathrm{d}\theta\sin(\phi)+\sin(\chi)\sin(\theta)\cos(\phi)\mathrm{d}\phi\right]\\
&x_3=a(t)\sin(\chi)\cos(\theta)\\
&\quad\Rightarrow \mathrm{d}x_3=a(t)\left[\cos(\chi)\mathrm{d}\chi\cos(\theta)-\sin(\chi)\sin(\theta)\mathrm{d}\theta\right]\\
&x_4=a(t)\cos(\chi)\\
&\quad\Rightarrow \mathrm{d}x_4=-a(t)\sin(\chi)\mathrm{d}\chi
\end{aligned}\tag{12.5.812}$$

After injecting into:

$$\mathrm{d}s^2=-c^2\mathrm{d}t^2+\mathrm{d}x_1^2+\mathrm{d}x_2^2+\mathrm{d}x_3^2+\mathrm{d}x_4^2\tag{12.5.813}$$

by remembering that:

$$\begin{aligned}
(a+b-c)^2&=a^2+b^2+c^2+2(ab-ac-bc)\\
(a+b+c)^2&=a^2+b^2+c^2+2(ab+ac+bc)\\
(a-b)^2&=a^2-2ab-b^2
\end{aligned}\tag{12.5.814}$$

and a very boring simplification work (that we will omit to do here for now...) we get the space-time geometry that is then described by the metric[71]:

$$\mathrm{d}s^2=-c\mathrm{d}t^2+a(t)^2\left(\mathrm{d}\chi^2+\sin(\chi)^2\left(\mathrm{d}\theta^2+\sin(\theta)^2\mathrm{d}\phi^2\right)\right)\tag{12.5.815}$$

After this, Friedman used the Einstein field equation (see page 5766):

$$R_{\mu\nu}-\frac{1}{2}Rg_{\mu\nu}+\Lambda g_{\mu\nu}=\frac{8\pi G}{c^4}T_{\mu\nu}\tag{12.5.816}$$

and he chose to focus only on the time component of the Einstein tensor given in general for reminder by (see section Tensor Calculus page 2107):

$$G_{\mu\nu}=R_{\mu\nu}-\frac{1}{2}g_{\mu\nu}R\tag{12.5.817}$$

With the Christoffel symbol of the first kind given by (see section Tensor Calculus page 2107):

$$\Gamma_{kji}=\frac{1}{2}\left(\partial_k g_{ij}+\partial_i g_{jk}-\partial_j g_{ki}\right)\tag{12.5.818}$$

with the Christoffel symbol of the second time given by (see section Tensor Calculus page 2107):

$$\Gamma_{ki}^{j}=g^{jl}\Gamma_{kli}\tag{12.5.819}$$

With the Ricci tensor given for recall by (see section Tensor Calculus page 2127):

$$R_{\alpha\beta}=R_{\alpha\mu\beta}^{\mu}=R_{i,jk}^{l}=\partial_j\Gamma_{ik}^{l}-\partial_k\Gamma_{ij}^{l}+\Gamma_{ik}^{r}\Gamma_{jr}^{l}-\Gamma_{ij}^{r}\Gamma_{kr}^{l}\tag{12.5.820}$$

---

[71] It can be proven that this metric is special case of the Robertson-Walker metric with $k=+1$ and when one of the term is integrally normalized.

and with the Ricci scalar given by (see section Tensor Calculus page 2128):

$$R=g^{\alpha\beta}R_{\alpha\beta}=g^{\alpha\beta}g^{\mu v}R_{\mu\alpha v\beta} \tag{12.5.821}$$

We have for the metric:

$$g^{ij}=\begin{bmatrix}-a(t)^2 & 0 & 0 & 0\\ 0 & -a(t)^2\sin^2(\chi) & 0 & 0\\ 0 & 0 & -a(t)^2\sin^2(\chi)\sin^2(\theta) & 0\\ 0 & 0 & 0 & c^2\end{bmatrix} \tag{12.5.822}$$

and for anti-metric:

$$g^{ij}=\begin{bmatrix}-\dfrac{1}{a(t)^2} & 0 & 0 & 0\\ 0 & -\dfrac{1}{a(t)^2\sin^2(\chi)} & 0 & 0\\ 0 & 0 & -\dfrac{1}{a(t)^2\sin^2(\chi)\sin^2(\theta)} & 0\\ 0 & 0 & 0 & \dfrac{1}{c^2}\end{bmatrix} \tag{12.5.823}$$

We have for the non-zero components of the Christoffel symbols of the first kind:

$$\begin{aligned}
&\Gamma_{114}=a(t)\left(\frac{\partial}{\partial t}a(t)\right)\\
&\Gamma_{122}=-a(t)^2\sin(\chi)\cos(\chi)\\
&\Gamma_{133}=-a(t)^2\sin(\chi)\sin^2(\theta)\cos(\chi)\\
&\Gamma_{141}=-a(t)\left(\frac{\partial}{\partial t}a(t)\right)\\
&\Gamma_{221}=a(t)^2\sin(x)\cos(x)\\
&\Gamma_{224}=a(t)\sin^2(\chi)\left(\frac{\partial}{\partial t}a(t)\right)\\
&\Gamma_{223}=-a(t)^2\sin^2(\chi)\sin(\theta)\cos(\theta)\\
&\Gamma_{242}=-a(t)\sin^2(\chi)\left(\frac{\partial}{\partial t}a(t)\right)\\
&\Gamma_{331}=a(t)^2\sin(\chi)\sin^2(\theta)\cos(\chi)\\
&\Gamma_{332}=a(t)^2\sin^2(\chi)\sin(\theta)\cos(\theta)\\
&\Gamma_{334}=a(t)\sin^2(\chi)\sin^2(\theta)\left(\frac{\partial}{\partial t}a(t)\right)\\
&\Gamma_{343}=-a(t)\sin^2(\chi)\sin^2(\theta)\left(\frac{\partial}{\partial t}a(t)\right)
\end{aligned} \tag{12.5.824}$$

We have for the non-zero components of the Christoffel symbols of the second kind:

$$\begin{aligned}
\Gamma^{1}_{14}&=\frac{\frac{\partial}{\partial t}a(t)}{a(t)}\\
\Gamma^{1}_{22}&=-\sin(\chi)\cos(\chi)\\
\Gamma^{1}_{33}&=-\sin(\chi)\sin^2(\theta)\cos(\chi)\\
\Gamma^{2}_{12}&=\frac{\cos(\chi)}{\sin(\chi)}\\
\Gamma^{2}_{24}&=\frac{\frac{\partial}{\partial t}a(t)}{a(t)}\\
\Gamma^{2}_{33}&=-\sin(\theta)\cos(\theta)\\
\Gamma^{3}_{13}&=\frac{\cos(\chi)}{\sin(\chi)}\\
\Gamma^{3}_{23}&=\frac{\cos(\theta)}{\sin(\theta)}\\
\Gamma^{3}_{34}&=\frac{\frac{\partial}{\partial t}a(t)}{a(t)}\\
\Gamma^{4}_{11}&=\frac{a(t)\left(\frac{\partial}{\partial t}a(t)\right)}{c^2}\\
\Gamma^{4}_{22}&=\frac{a(t)\sin^2(\chi)\left(\frac{\partial}{\partial t}a(t)\right)}{c^2}\\
\Gamma^{4}_{33}&=\frac{a(t)\sin^2(\chi)\sin^2(\theta)\left(\frac{\partial}{\partial t}a(t)\right)}{c^2}
\end{aligned}\tag{12.5.825}$$

Therefore:

$$\begin{aligned}
R_{11}&=-\frac{2c^2+2\left(\dfrac{\partial}{\partial t}a(t)\right)^2+a(t)\left(\frac{\partial^2}{\partial t^2}a(t)\right)}{c^2}\\
R_{22}&=-\frac{\sin(\chi)^2c^2+2\left(\dfrac{\partial}{\partial t}a(t)\right)^2\sin(\chi)^2+c^2-\cos(\chi)^2c^2+a(t)\sin(\chi)^2\left(\dfrac{\partial^2}{\partial t^2}a(t)\right)}{c^2}\\
R_{33}&=-\frac{\sin(\theta)^2\left(\sin(\chi)^2c^2+2\left(\dfrac{\partial}{\partial t}a(t)\right)^2\sin(\chi)^2+c^2-\cos(\chi)^2c^2+a(t)\sin(\chi)^2\left(\dfrac{\partial^2}{\partial t^2}a(t)\right)\right)}{c^2}\\
R_{44}&=3\frac{\dfrac{\partial^2}{\partial t^2}a(t)}{a(t)}
\end{aligned}\tag{12.5.826}$$

And finally:

$$R=2\frac{2\sin^2(\chi)c^2+3\left(\dfrac{\partial}{\partial t}a(t)\right)^2\sin^2(\chi)+3a(t)\sin^2(\chi)\left(\dfrac{\partial^2}{\partial t^2}a(t)\right)+c^2-\cos^2(\chi)c^2}{a(t)^2\sin(\chi)^2c^2}\tag{12.5.827}$$

Therefore the times component of the Einstein tensor:

$$G_{\mu\nu}=R_{\mu\nu}-\frac{1}{2}g_{\mu\nu}R \tag{12.5.828}$$

is equal to:

$$G_{44}=3\frac{\frac{\partial^2}{\partial t^2}a(t)}{a(t)}-3\frac{\frac{\partial^2}{\partial t^2}a(t)}{a(t)}-\frac{1}{2}\left(2\frac{2\sin^2(\chi)c^2+3\left(\frac{\partial}{\partial t}a(t)\right)^2\sin^2(\chi)+3\mathrm{a}(t)\sin^2(\chi)\left(\frac{\partial^2}{\partial t^2}a(t)\right)+c^2-\cos^2(\chi)c^2}{a(t)^2\sin(\chi)^2c^2}\right)c^2 \tag{12.5.829}$$

If we simplify, this gives:

$$G_{44}=\frac{-3c^2-3\left(\frac{\partial}{\partial t}a(t)\right)^2}{a(t)^2} \tag{12.5.830}$$

Now let us inject this into the Einstein field equation given for reminder by:

$$R_{\mu\nu}-\frac{1}{2}Rg_{\mu\nu}+\Lambda g_{\mu\nu}=\frac{8\pi G}{c^4}T_{\mu\nu} \tag{12.5.831}$$

Becomes:

$$\frac{-3c^2-3\left(\frac{\partial}{\partial t}a(t)\right)^2}{a(t)^2}+\Lambda c^2=\frac{8\pi G}{c^4}T_{44} \tag{12.5.832}$$

And we have already proof that $T_{44}=\rho c^2$ (see page 5754). Therefore:

$$\frac{-3c^2-3\left(\frac{\partial}{\partial t}a(t)\right)^2}{a(t)^2}+\Lambda c^2=\frac{8\pi G}{c^4}\rho c^2 \tag{12.5.833}$$

Let us choose now the notation used by Friedmann:

$$\frac{-3c^2-3\left(\frac{\partial}{\partial t}a(t)\right)^2}{a(t)^2}+\lambda=-\kappa\rho c^2 \tag{12.5.834}$$

If we rearrange:

$$\frac{-3\left(\frac{\mathrm{d}}{\mathrm{d}t}a(t)\right)^2-3c^2}{a(t)^2}+\lambda=-\kappa\rho c^2 \tag{12.5.835}$$

The volume of a 3D hypersphere is obtained to the integral below:

$$\begin{gathered}V=\int\limits_0^{2\pi}\int\limits_0^{\pi}\int\limits_0^{\pi}a(t)^3\sin(\chi)^2\sin(\theta)\mathrm{d}\chi\mathrm{d}\theta\mathrm{d}\phi=a(t)^3\left(-\frac{\sin(2\chi)-2\chi}{4}\right)\Big|_0^{\pi}(-\cos(\theta))\Big|_0^{\pi}(\phi)\Big|_0^{2\pi}\\=a(t)^3\frac{\pi}{2}\cdot 2\cdot 2\pi=2\pi^2a(t)^3\end{gathered} \tag{12.5.836}$$

The total mass is the product of this volume and the density such that:

$$M := 2\rho\pi^2 a(t)^3 \Leftrightarrow \rho = \frac{M}{2\pi^2 a(t)^3} \tag{12.5.837}$$

We inject it into the prior-previous relation:

$$\frac{-3\left(\dfrac{\mathrm{d}}{\mathrm{d}t}a(t)\right)^2 - 3c^2}{a(t)^2} + \lambda = -\kappa\frac{M}{2\pi^2 a(t)^3}c^2 \tag{12.5.838}$$

Let us rearrange a first time:

$$\left(\frac{\mathrm{d}}{\mathrm{d}t}a(t)\right)^2 = \frac{\kappa\dfrac{M}{2\pi^2 a(t)}c^2 + \lambda a(t)^2 - 3c^2}{3} \tag{12.5.839}$$

And rearrange a second time:

$$\frac{\left(\dfrac{\mathrm{d}}{\mathrm{d}t}a(t)\right)^2}{c^2} = \kappa\frac{M}{6\pi^2 a(t)} + \frac{\lambda}{3c^2}a(t)^2 - c^2 \tag{12.5.840}$$

Let us put as Friedmann did:

$$A = \frac{\kappa M}{6\pi^2} \tag{12.5.841}$$

Then:

$$\frac{\left(\dfrac{\mathrm{d}}{\mathrm{d}t}a(t)\right)^2}{c^2} = \frac{A}{a(t)} + \frac{\lambda}{3c^2}a(t)^2 - 1^2 \tag{12.5.842}$$

We simplify:

$$\frac{\left(\dfrac{\mathrm{d}}{\mathrm{d}t}a(t)\right)^2}{c^2} = \frac{A + \dfrac{\lambda a(t)^3}{3c^2} - a(t)}{a(t)} \tag{12.5.843}$$

And rearranging a last time to get exactly the same expression as in the paper of Friedmann:

$$\frac{\left(\dfrac{\mathrm{d}}{\mathrm{d}t}a(t)\right)^2}{c^2} = \frac{A - a(t) + \dfrac{\lambda a(t)^3}{3c^2}}{a(t)} \tag{12.5.844}$$

Let us do another change of variable a Friedmann did (we put $a(t) = x$):

$$\frac{\left(\dfrac{\mathrm{d}x}{\mathrm{d}t}\right)^2}{c^2} = \frac{A - x + \dfrac{\lambda x^3}{3c^2}}{x} \tag{12.5.845}$$

Now we take the square root on both side as did Friedmann:

$$\frac{\mathrm{d}x}{c\mathrm{d}t}=\sqrt{\frac{A-x+\dfrac{\lambda x^3}{3c^2}}{x}} \tag{12.5.846}$$

Now let us invert:

$$c\frac{\mathrm{d}t}{\mathrm{d}x}=\sqrt{\frac{x}{A-x+\dfrac{\lambda x^3}{3c^2}}} \tag{12.5.847}$$

We rearrange a bit:

$$c\mathrm{d}t=\sqrt{\frac{x}{A-x+\dfrac{\lambda x^3}{3c^2}}}\mathrm{d}x \tag{12.5.848}$$

We take the integral on both side so we get:

$$ct=\int\limits_{a_0}^{a}\sqrt{\frac{x}{A-x+\dfrac{\lambda x^3}{3c^2}}}\mathrm{d}x+b \tag{12.5.849}$$

in which a_0 and b are constants. This elliptic integral doesn't have a closed solution as far as we know. So we will use a specialized computer software like Maple™.

So let us enter this integral into Maple™ 4.00b and see what happens. First we put $\lambda/3c^2:=y$:

```
>restart:
>with(plots):
>int(sqrt(x/(A-x+y*x^3)),x):
```

Here we end the Maple™ input with colon to suppress the output, because it is lengthy and not too illuminating. The reader can change the colon to semicolon and see that the result is expressed in terms of EllipticF and EllipticPi.

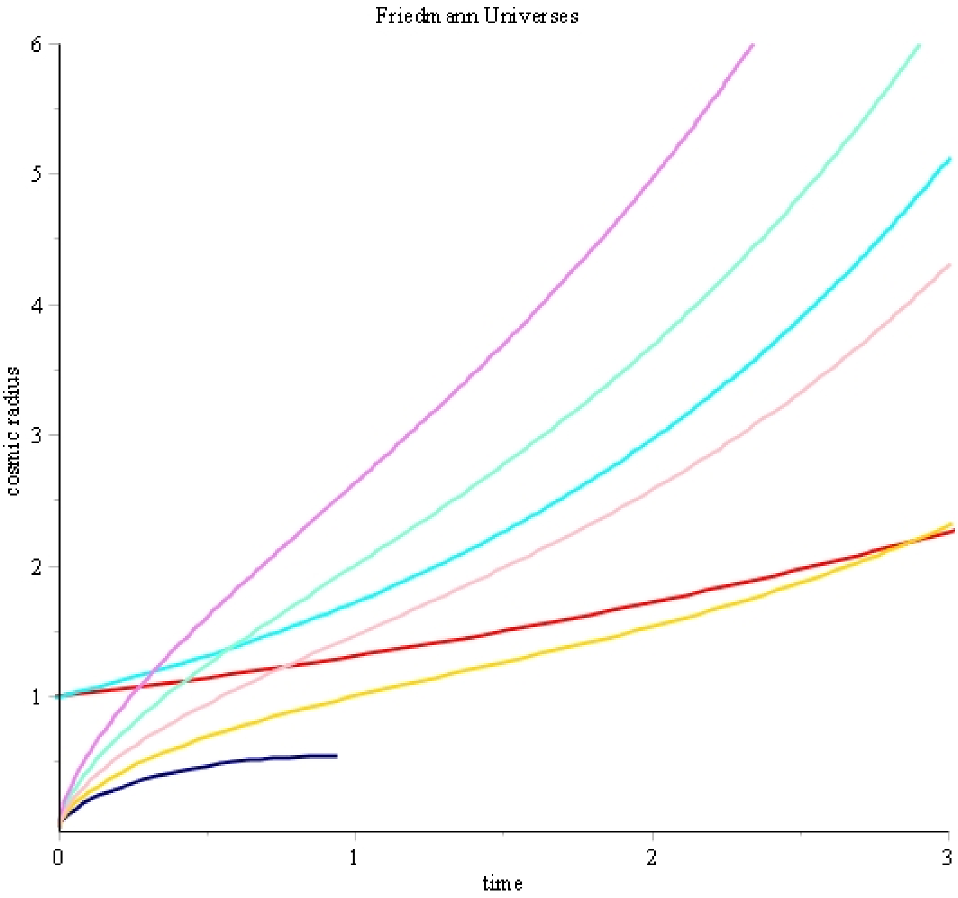
Obviously we can guess that the integral makes sense if and only if the if the sign of the cubic denominator under the square root is positive, i.e.:

$$A-x+yx^3>0 \tag{12.5.850}$$

Obviously as we have two parameters (i.e. A and y) we can play with both and there is an infinity of possibilities! So let us fixed $A:=1$, then we can have with Maple™ 17:

```
>Friedmann := int(sqrt(x/((8/27)*x^3-x+A)), x):
>plot({[int(sqrt(x/((8/27)*x^3-x+1)), x), x, x = 0
..  6], [int(sqrt(x/((8/27)*x^3-x+2)), x), x, x = 0
..  6],[int(sqrt(x/((8/27)*x^3-x+4)), x), x, x = 0
..  6], [int(sqrt(x/((8/27)*x^3-x+8)), x), x, x = 0
..  6], [int(sqrt(x/((8/27)*x^3-x+.5)), x), x, x = 0
..  6], [int(sqrt(x/((2/27)*x^3)), x), x, x = 0 ..  6],
[int(sqrt(x/((8/27)*x^3)), x), x, x = -1 ..  6]}, y = 0 ..  3,
thickness = 2, color = ["Red", "Cyan", "Navy", "Aquamarine", "Violet",
"Gold", "Pink"], labels = ["time", "cosmic radius"], labeldirections =
[horizontal, vertical], title = typeset("Friedmann Universes")):
```

This gives:



Alexander Friedmann's pioneer work is summarized in this plot. He for the first time showed that Einstein's general relativity admits non-static solutions. He named the Yellow, Pink, Aquamarine and Violet curves "monotonic worlds of the first kind." The cosmos expands at a decelerating rate from a zero-radius singularity until an inflection point, after which the expansion accelerates. This scenario provides the basis for our current view of the Big Bang and the accelerating universe. The Red and Curves curve are named as "monotonic world of the second kind" in which the universe expands from a non-zero initial radius. Half of the periodic scenario is shown in the Navy (dark blue) curve: the universe evolves from and back to zero radius.

12.5.8 The Black Hole Universe

A recent hypothesis in the history of cosmology (since the 11970 - according to the holocene calendar - as far as we know...) which is at the heart of many theoretical research (Stephen Hawking, Roger Penrose and others) is the possibility of assimilating our Universe to a Black Hole (see section General Relativity page 5835).

Remark

Keep in mind that the Black Hole Universe isn't mutually exclusive with other models like the CCC (Conformal Cyclic Cosmology) or the Universe out of Nothing (Wheeler-DeWitt Universe)! As Universe created from nothing or existing since always may have physical laws that authorize the generation of Black Holes (and their corresponding White Holes with expanding metric like the FLWR) that will themselves be compatible with the characteristics of a Big Bang.

The origin of the idea can be made from a very simple calculation:

We know that approximately the radius of the (current) Universe is given according to our previous calculations by:

$$r_0 = ct_0 = cH_0^{-1} \cong 1.2\cdot 10^{26}\,[\text{m}] \tag{12.5.851}$$

But we have proved in the section of General Relativity (and Classical Mechanics) that the Schwarzschild radius is given by:

$$R_S = \frac{2GM}{c^2} \tag{12.5.852}$$

What we can write for the Universe in the following form (under many assumptions: isotropy, homogeneity, spherical, etc.):

$$S_r = \frac{2GM}{c^2} = \frac{2G\rho_0 V}{c^2} = \frac{2G\rho_0\left(\dfrac{4}{3}\pi r_0^3\right)}{c^2} \tag{12.5.853}$$

which with the values of the critical density and the radius of the cosmological horizon calculated earlier above gives:

$$S_r = \frac{2G\rho_0\left(\dfrac{4}{3}\pi r_0^3\right)}{c^2} \cong \frac{2G\cdot 3.61\cdot 10^{52}}{c^2} \cong 0.53\cdot 10^{26} \tag{12.5.854}$$

So, roughly speaking, knowing all the uncertainties that we have accumulated in particular that on the Hubble parameter we see that the Schwarzschild radius is not very far from the radius of the present Universe.

As curious as it may seem, this question is not so far-fetched and is very seriously studied. It is therefore theoretically possible that our whole universe is encapsulated in a gigantic Black Hole (therefore of very large mass and very low density as we see it with our numerical values) of another inaccessible Universe ...

What is certain is that if this were the case, the expansion of the Universe (now observed) could not continue beyond the horizon of this super Black Hole because nothing coming from within can cross this horizon. However, recent observations seem to show that the expansion of the Universe is far from slowing and tends to accelerate with time, which is in contradiction with such a Black Hole Universe...

Figure 12.299: **Idea of Universe inside a (Schwarzschild) Black Hole**

Now a quite common question is: «*Why did the universe not collapse into a Black Hole shortly after the Big Bang?*».

First, the question is very meaningful as there is no "outside" (as far as we know) for the universe. And if we think about the Schwarzschild solution (and radius), it describes a spherical object outside of which the space is empty, and as we said there is no "outside" (as far as we know!) for the universe.

The standard cosmological model of the Big Bang (i.e. the cosmic inflation theory) fits observations to the Friedmann-Robertson-Walker solutions of General Relativity as we know, which do not form Black Holes. As far as we know, our Universe looks about the same from every point on the large scale. It is a built-in assumption of the Friedmann-Robertson-Walker family solutions, and sometimes named the "Copernican principle". In a homogeneous Friedmann-Robertson-Walker cosmology, symmetry guarantees that tidal forces vanish everywhere, and that any observer at rest relative to the average motion of matter will measure zero gravitational field. Based on these considerations the only kind of collapse that can occur in a purely homogeneous model is the recollapse of the entire universe in a "Big Crunch", and this happens only for matter densities and values of the cosmological constant that are different from what we actually observe.

Moreover, we have to remember that a high enough energy density is a necessary condition but not a sufficient condition for Black Holes to form: one needs to have a center which will ultimately become the center of the Black Holes; one needs the matter that collapses to the

Black Hole to have a low enough velocity so that gravity may squeeze it before the matter manages to fly away and dilute the density.

The latter two conditions are usually almost trivially satisfied for ordinary chunks of matter peacefully sitting at some place of the Universe; but they're almost maximally violated by the matter density right after the Big Bang. This matter has no center - it is almost uniform throughout space - and has high enough velocity (away from itself) that the density eventually gets diluted. And indeed, we know that it did get diluted.

In a survey made on 77 professional physicists (see [96]) in 12024 (holocene calendar) we get the following result for the fate of the matter that falls into a Black Hole:

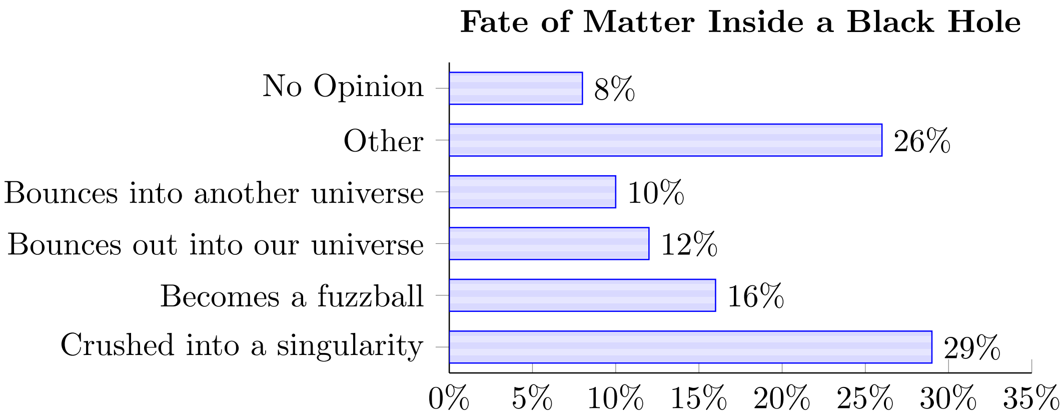


Figure 12.300: **Copenhagen survey on matter fate in a Black Hole**

In other words, a collapse of matter (e.g. a star) into a Black Hole is an idealized calculation that makes certain assumptions about the initial state of the matter. These assumptions are clearly not satisfied by matter after the Big Bang.

12.5.9 Borde-Guth-Vilenkin Theorem (BGV Theorem)

The "Borde–Guth–Vilenkin theorem", or the "BGV theorem", is a theorem in physical cosmology which deduces in the framework of General Relativity[72] that any universe that has, on average, been expanding throughout its history (expansion) cannot be infinite in the past but must have a past space-time boundary (this doesn't indicate an absolute beginning!). The theorem does not assume any specific mass content of the universe and it does not require gravity to be described by Einstein field equations.

In other words, the theorem shows that null (matter) and timelike (photons) geodesics are, in general, past-incomplete in inflationary models, whether or not energy conditions hold, provided only that the averaged expansion condition $H > 0$ holds along these past-directed geodesics.

It is named after the authors Arvind Borde, Alan Guth and Alexander Vilenkin, who developed its mathematical formulation in 12003 (holocene calendar). The BGV theorem is also popular outside physics, especially in religious and philosophical debates (where he is wrongly used by religious people... but this isn't a surprise).

Remark

Alternative models, where the average expansion of the universe throughout its history does not hold, have been proposed under the notions of emergent space-time, eternal inflation, and cyclic models (for cyclic models the expansion is obviously zero in average by construction). Vilenkin and Audrey Mithani have argued that none of these models escape the implications of the theorem. In 12017 (holocene calendar), Vilenkin stated that he does not think there are any viable cosmological models that escape the scenario (see *Alexander Vilenkin, "The Beginning of the Universe" in The Kalam Cosmological Argument: Volume 2, Bloomsbury, 2017, pp. 150-158*).

The original paper itself of Borde-Guth-Vilenking suggest possible prior cosmologies: «*What can lie beyond this boundary? Several possibilities have been discussed, one being that the boundary of the inflating region corresponds to the beginning of the Universe in a quantum nucleation event.*»

The reader must keep in mind that the BGV theorem is about classical space-time, the universe is quantum mechanical, so we don't even know yet if it breaks down for quantum space-times...

Victor Stenger asked Alexander Vilenkin the following question: «*Does your theorem prove that the universe must have had a beginning?*». Alexander Vilenkin replied: «*No. But it proves that the expansion of the universe must have had a beginning. You can evade the theorem by postulating that the universe was contracting prior to some time.*»

Alexander Vilenkin has also written about the religious significance of the BGV theorem. In October 12015 (holocene calendar), Alexander Vilenkin responded to arguments made by theist William Lane Craig and the New Atheism movement regarding the existence of God. Alexander Vilenkin stated «*What causes the universe to pop out of nothing? No cause is needed.*» (see [561]).

---

[72] Therefore in may not hold under consideration of a complete theory of quantum gravity.

Furthermore the original paper (see [64]) itself suggest possible prior cosmologies: «*What can lie beyond this boundary? Several possibilities have been discussed, one being that the boundary of the inflating region corresponds to the beginning of the Universe in a quantum nucleation event. The boundary is then a closed spacelike hypersurface which can be determined from the appropriate instanton.*»

Alan Guth has also gone on record claiming he believes the universe (i.e. the Cosmos) to be eternal.

Also, Arvind Borde has developed models of infinite universes as well as models of universe's with defined physics beyond the geodesic boundary. Literally none of the three original authors themselves believes that their theorem proves that the Universe has a beginning, because it doesn't. It shows that the expansion of the Universe has a beginning, not the entirety of the Cosmos itself.

The theorem that we will prove below is quite simple. Its proof does not go beyond undergraduate mathematics. But its implications for the beginning of the universe are very profound.... With the proof now in place, we see that the Cosmos can exist since ever but our Universe is not past-eternal (expected in a cyclic model).

Theorem 12.1. The geodesic incompleteness theorem of Borde, Guth, and Vilenkin as already stated is a general and powerful constraint on the structure of cosmological space-times in the framework of General Relativity for FLRW spaces types. A "geodesically complete space-time" is one for which all possible inertial paths in the space-time extend infinitely in proper time toward both the past and the future. By contrast, a "geodesically past-incomplete space-time" contains geodesics which encounter a boundary at finite past proper time, and a "geodesically future-incomplete space-time" contains geodesics which encounter a boundary at finite future proper time. The Borde-Guth-Vilenkin (BGV) Theorem states that any space-time for which the net expansion is positive:

$$\int H\mathrm{d}t > 0 \tag{12.5.855}$$

is necessarily geodesically past-incomplete. This has profound implications for cosmological model building, since it applies not only to trivially past-incomplete space-times such as matter- or radiation-dominated Friedmann-Lemaître-Robertson-Walker (FLRW) cosmologies, but to inflationary models as well. Furthermore, the proof is purely kinematic, and does not depend any assumption about energy conditions.

Proof 12.1.1. Before constructing a more general proof, we begin by reviewing the BGV theorem for geodesic incompleteness in an FLRW space-time. Let us remind that the latter is explicitly written (see page 5991):

$$\mathrm{d}s^2 = g_{\mu\nu}\mathrm{d}x^{\mu}\mathrm{d}x^{\nu} = -(c\,\mathrm{d}t)^2 + a^2(t)\left(\frac{\mathrm{d}x^2}{1-kx^2} + x^2\,\mathrm{d}\Omega^2\right) \tag{12.5.856}$$

We will take here a simplified notation of that metric of the following form and adopting natural units:

$$\mathrm{d}s^2=-\mathrm{d}t^2+a^2(t)\mathrm{d}\vec{x}^2 \tag{12.5.857}$$

where we assume a flat spatial geometry, $\mathrm{d}\vec{x}^2=\delta_{ij}\mathrm{d}x^i\mathrm{d}x^j$, for convenience. We wish to address the question of whether such space-times are geodesically complete, which is the statement that all inertial (or geodesic) observers see the space-time as both past- and future-infinite, as measured by the proper time along a geodesic world line in the space-time:

$$\int\limits_{-\infty}^{t}\mathrm{d}s\rightarrow+\infty,\qquad\int\limits_{t}^{+\infty}\mathrm{d}s\rightarrow+\infty \tag{12.5.858}$$

As we already know, the Friedman equations derived from the FLRW metric are singular for $a(t)=0$.

We have proven that for flat spaces that are matter- or radiation-dominated we had $a(t)\propto t^{\alpha}$ (see page 5905), and are therefore trivially geodesically incomplete, since $a(t)\rightarrow 0_+$ at finite past time. The case of the Einstein-De Sitter Universe model (see page 6016):

$$a(t)\propto e^{Ht}\qquad H=c^{te} \tag{12.5.859}$$

is more ambiguous, since singularity is reached only at $t\rightarrow-\infty$ for a comoving observer. It is, however, straightforward to show that non-comoving geodesics are past-finite.

For a timelike geodesic, normalization $u^{\mu}u_{\mu}=-1$ given for recall by:

$$g_{\mu\nu}u^{\mu}u^{\nu}=g_{\mu\nu}\frac{\mathrm{d}x^{\mu}}{\mathrm{d}\tau}\frac{\mathrm{d}x^{\nu}}{\mathrm{d}\tau}=\frac{g_{\mu\nu}\mathrm{d}x^{\mu}\mathrm{d}x^{\nu}}{\mathrm{d}\tau^2}=\frac{\mathrm{d}s^2}{\mathrm{d}\tau^2}=\frac{-\mathrm{d}\tau^2}{\mathrm{d}\tau^2}=-1 \tag{12.5.860}$$

gives (we take a photon therefore remember - in natural units - that $\mathrm{d}s=\mathrm{d}\tau$ as seen at page 5707):

$$u^{\mu}u_{\mu}=g_{\mu\nu}\frac{\mathrm{d}x^{\mu}}{\mathrm{d}\tau}\frac{\mathrm{d}x^{\tau}}{\mathrm{d}s}=-\left(\frac{\mathrm{d}t}{\mathrm{d}s}\right)^2+a^2(t)\left|\frac{\mathrm{d}\vec{x}}{\mathrm{d}s}\right|^2=-1 \tag{12.5.861}$$

The last equality is often denoted:

$$-\dot{x}_0^2+a^2(t)|\dot{\vec{x}}|^2=-1 \tag{12.5.862}$$

Hence (useful result for later):

$$\dot{x}_0^2-a^2(t)|\dot{\vec{x}}|^2=1 \tag{12.5.863}$$

Now let us remind the variational principle (see page 5747):

$$\delta\int\sqrt{g_{\mu\nu}\mathrm{d}x^{\mu}\mathrm{d}x^{\nu}}=0 \tag{12.5.864}$$

Hence in our case (still in natural units):

$$\delta\int\sqrt{-\mathrm{d}t^2+a^2(t)\mathrm{d}\vec{x}^2}=0 \tag{12.5.865}$$

But we also have the action integral (see section Analytical Mechanics page 3161):

$$\delta S=\int L\mathrm{d}t \tag{12.5.866}$$

We can identify $L=\sqrt{\dot{x}_0^2-a^2(t)|\dot{\vec{x}}|^2}=L\left(\dot{x}_0,\dot{\vec{x}}\right)$. Then, from the Euler-Lagrange equations (see section Classical Mechanics page 3162):

$$\frac{\mathrm{d}}{\mathrm{d}s}\frac{\partial L}{\partial \dot{x}_\mu}=\frac{\partial L}{\partial x_\mu} \tag{12.5.867}$$

We have in our case:

$$\frac{\partial L}{\partial x_\mu}=0 \tag{12.5.868}$$

and:

$$\frac{\partial L}{\partial \dot{x}_\mu}=\frac{-2a^2(t)\dot{\vec{x}}}{\sqrt{\dot{x}_0^2-a^2(t)|\dot{\vec{x}}|^2}} \tag{12.5.869}$$

Therefore we have:

$$\frac{\mathrm{d}}{\mathrm{d}s}\frac{-2a^2(t)\dot{\vec{x}}}{\sqrt{\dot{x}_0^2-a^2(t)|\dot{\vec{x}}|^2}}=0 \tag{12.5.870}$$

And simplifying a bit:

$$\frac{\mathrm{d}}{\mathrm{d}s}\frac{a^2(t)\dot{\vec{x}}}{\sqrt{\dot{x}_0^2-a^2(t)|\dot{\vec{x}}|^2}}=0 \tag{12.5.871}$$

But we have proved earlier above that $-\dot{x}_0^2+a^2(t)|\dot{\vec{x}}|^2=-1$, therefore:

$$\frac{\mathrm{d}}{\mathrm{d}s}a^2(t)\dot{\vec{x}}=0 \tag{12.5.872}$$

Or explicitly:

$$\frac{\mathrm{d}}{\mathrm{d}s}\left[a^2(t)\frac{\mathrm{d}\vec{x}}{\mathrm{d}s}\right]=0 \tag{12.5.873}$$

so that we can define an integration constant v_0 such that:

$$a^2(t)\left|\frac{\mathrm{d}\vec{x}}{\mathrm{d}s}\right|\equiv v_0=c^{te} \tag{12.5.874}$$

From (see earlier above):

$$u^\mu u_\mu=g_{\mu\nu}\frac{\mathrm{d}x^\mu}{\mathrm{d}\tau}\frac{\mathrm{d}x^\tau}{\mathrm{d}s}=-\left(\frac{\mathrm{d}t}{\mathrm{d}s}\right)^2+a^2(t)\left|\frac{\mathrm{d}\vec{x}}{\mathrm{d}s}\right|^2=-1 \tag{12.5.875}$$

We have:

$$\left(\frac{\mathrm{d}t}{\mathrm{d}s}\right)^2=1-a^2(t)\left|\frac{\mathrm{d}\vec{x}}{\mathrm{d}s}\right|^2 \tag{12.5.876}$$

Injecting the previous result, we have:

$$\left(\frac{\mathrm{d}t}{\mathrm{d}s}\right)^2=\gamma^2=1+v_0^2a^{-2}(t) \tag{12.5.877}$$

where:

$$\gamma^2=\frac{1}{1-v^2} \tag{12.5.878}$$

is the Lorentz boost (see section Special Relativity page 5638) as a function of the velocity v of the observer, so that the integration constant v_0 is:

$$v_0^2=\frac{a^2v^2}{1-v^2}=c^{te} \tag{12.5.879}$$

The differential proper time $\mathrm{d}s$ along the geodesic of the freely falling observer can then be written in terms of the coordinate time $\mathrm{d}t$ as:

$$\mathrm{d}s=\frac{\mathrm{d}t}{\sqrt{1+v_0^2a^{-2}(t)}} \tag{12.5.880}$$

For $a(t)=e^{Ht}$ (for reminder: a Einstein-De Sitter Universe model, i.e. flat space dominated by matter), the integral:

$$\Delta s=\int\limits_{-\infty}^{0}\frac{\mathrm{d}t}{\sqrt{1+v_0^2e^{-2Ht}}} \tag{12.5.881}$$

So let us calculate the primitive:

$$\int\frac{1}{\sqrt{v_0^2\mathrm{e}^{-2Ht}+1}}\mathrm{d}t \tag{12.5.882}$$

We substitute $u=-2Ht\longrightarrow\mathrm{d}u=-2H\mathrm{d}t$, therefore:

$$\int\frac{1}{\sqrt{v_0^2\mathrm{e}^{-2Ht}+1}}\mathrm{d}t=-\frac{1}{2H}\int\frac{1}{\sqrt{v_0^2\mathrm{e}^{u}+1}}\mathrm{d}u \tag{12.5.883}$$

Now we solve:

$$\int\frac{1}{\sqrt{v_0^2e^u+1}}\,\mathrm{d}u \tag{12.5.884}$$

For this we substitute $v=v_0^2e^u+1\longrightarrow\mathrm{d}v=v_0^2e^u\mathrm{d}u$, hence:

$$\int\frac{1}{\sqrt{v_0^2e^u+1}}\mathrm{d}u=\int\frac{1}{(v-1)\sqrt{v}}\,\mathrm{d}v \tag{12.5.885}$$

We substitute $w=\sqrt{v}\longrightarrow \mathrm{d}w=\frac{1}{2\sqrt{v}}\mathrm{d}v$ (and using $v=w^2$):

$$\begin{aligned}\int\frac{1}{(v-1)\sqrt{v}}\mathrm{d}v&=2\int\frac{1}{w^2-1}\mathrm{d}w=2\int\frac{1}{w^2-1}\mathrm{d}w=\int\frac{1}{(w-1)(w+1)}\mathrm{d}w\\&=\int\left(\frac{1}{2(w-1)}-\frac{1}{2(w+1)}\right)\mathrm{d}w\\&=\frac{1}{2}\int\frac{1}{w-1}\mathrm{d}w-\frac{1}{2}\int\frac{1}{w+1}\mathrm{d}w=\frac{\ln(w-1)}{2}-\frac{\ln(w+1)}{2}\\&=\frac{1}{2}\frac{\ln(w-1)}{\ln(w+1)}\end{aligned}\tag{12.5.886}$$

And if we undo all substitutions we get:

$$\begin{aligned}\Delta s&=\int\limits_{-\infty}^{0}\frac{\mathrm{d}t}{\sqrt{1+v_0^2e^{-2Ht}}}=\frac{1}{2H}\ln\left(\frac{\sqrt{1+v_0^2}+1}{\sqrt{1+v_0^2}-1}\right)\\&=\frac{1}{2H}\ln\left(\frac{\gamma_0+1}{\gamma_0-1}\right)\end{aligned}\tag{12.5.887}$$

This integral is finite for any $v_0\neq 0$, so the observer on a non-comoving world line sees the space as past-finite, and the space is geodesically past-incomplete.

The BGV theorem states that any space-time for which the average expansion rate $\mathcal{H}_{\text{av}}$ is positive is geodesically incomplete, where:

$$\mathcal{H}_{\text{av}}\equiv\frac{1}{\Delta s}\int H\mathrm{d}s\tag{12.5.888}$$

and $\mathrm{d}s$ is the proper time along a geodesic world line. First, let us consider the integral of the expansion rate H along a comoving world line, for which the proper time $\mathrm{d}s=\mathrm{d}t$ (see page 5887):

$$\mathcal{H}_{\text{av}}=\int\limits_{t_i}^{t_f}H\mathrm{d}t=\int\limits_{t_i}^{t_f}\frac{1}{a}\frac{\mathrm{d}a}{\mathrm{d}t}\mathrm{d}t=\int\limits_{a_i}^{a_f}\mathrm{d}\ln(a)=\ln(a_f)-\ln(a_i)\tag{12.5.889}$$

Since the integrand is a total derivative, the integral is determined by the the values of the scale factor on the boundary, and measures the total expansion from t_i to t_f. Note in particular that this integral is logarithmically divergent as $a_i\to 0$, consistent with the fact that comoving world lines are past-infinite in proper time. We can integrate the expansion rate H along a non-comoving geodesic with proper time ds as follows (using usual primitives derived in the section of Differential and Integral Calculus at page 1534):

$$\begin{aligned}\mathcal{H}_{\text{av}}&=\int\limits_{s_i}^{s_f}H\mathrm{d}s=\int\limits_{t_i}^{t_f}H\frac{\mathrm{d}s}{\mathrm{d}t}\mathrm{d}t=\int\limits_{t_i}^{t_f}\frac{1}{a}\left(\frac{\mathrm{d}a}{\mathrm{d}t}\right)\frac{1}{\sqrt{1+v_0^2/a^2}}\mathrm{d}t\\&=\int\limits_{a_i}^{a_f}\frac{\mathrm{d}a}{\sqrt{a^2+v_0^2}}=\frac{1}{2}\ln\left[\frac{\sqrt{v_0^2+a^2}+a}{\sqrt{v_0^2+a^2}-a}\right]\Bigg|_{a_i}^{a_f}\end{aligned}\tag{12.5.890}$$

Integrating from $a_i = 0$ (this assumes implicitly a beginning, i.e. bounding, of space... hence we have here a circular reasoning) to $a_f = 1$ (the scale factor of today), this integral is finite:

$$\mathcal{H}_{\text{av}} = \int\limits_{s_i}^{s_f} H \mathrm{d}s = \frac{1}{2}\ln\left(\frac{\sqrt{1+v_0^2}+1}{\sqrt{1+v_0^2}-1}\right) = \frac{1}{2}\ln\left(\frac{\gamma_0+1}{\gamma_0-1}\right) \qquad (12.5.891)$$

Note that we have not taken $H = c^{te}$. The only assumption is that the overall change in scale factor is positive, $a_f > a_i$.

The BGV theorem is then the statement that as long as $\mathcal{H}_{\text{av}}$ is finite and positive (under all the assumptions mentioned above!), the proper time Δs along a time-like world-line is finite:

$$\Delta s = \int \mathrm{d}s = \frac{1}{\mathcal{H}_{\text{av}}} \int H \mathrm{d}s \qquad (12.5.892)$$

The BGV Theorem as stated above is, however, something of a circular argument, since $\mathcal{H}_{\text{av}}$ is only well-defined if Δs is finite in the first place.

■ Q.E.D.

There is another

In summary, the BGV theorem states that an inflating universe cannot be extended infinitely into the past and must have had a beginning at some finite time in the past. This supports the idea that the universe is of a finite age, but also suggests that it may have passed through a singularity phase.

This applies not only to spaces where the scale factor a grows monotonically, but also the Ijjas-Steinhardt model of cyclic cosmology (see [311]). The IS model avoids the problem of) for which the scale factor $a(t)$ is oscillatory, but grows from one cycle to the next.

We have above only demonstrated a result for an FRW metric but in the original paper there is also another proof for non-FRW metrics.

Remark

Work done by the Landau group in the years 11960 (holocene calendar) led to the conclusion that the general solution of General Relativity does not contain a physical singularity but a chaotic singularity named de "Belinski–Khalatnikov–Lifshitz (BKL) singularity". The search for a broader class of solutions with a singularity has been done, essentially, by a trial-and-error method, since a systematic approach to the study of the Einstein equations was lacking. A negative result, obtained in this way, is not convincing by itself; a solution with the necessary degree of generality would invalidate it, and at the same time would confirm any positive results related to the specific solution.

12.5.10 Empirical evidence of the Cosmic Inflation theory (i.e. Big Bang)

Most Astronomers, Astrophysicists, Cosmologists and Physicist think actually that the Big Bang is the best way to explain how the Universe started and how it changed over time (however don't forget that in Science, scientists opinion and majority isn't important: only the Data are important!). All science is based on evidence as we know. So what are the evidence in this early 121st century (holocene calendar) for the Big Bang (obviously most of them have existing meta-analysis level 15 evidence[73]!)?

Here is a list of most common factors considered as good evidence for the Big Bang (especially the ΛCDM model):

- **Redshift of Galaxies (i.e. Hubble's law):** The light we observe from galaxies has been stretched by the time it reaches us. It looks redder than it should. This redshift is the result of galaxies moving away from us (see [264]). Observations show that pretty much everything in the Universe is moving apart. The redshift of distant galaxies tells us the Universe is expanding. Some tension still exist in this early 121st century about the measurement accuracy of the Hubble constant using different methods that doesn't converge (maybe the ΛCDM model must be adjusted)

- **Microwave Background:** A long, long time ago, the whole Universe was very hot. As it grew in the size, the heat left a "glow" which fills the entire Universe. The Big Bang theory (cosmic inflation theory) predicts this glow should still exist. It also predicts that we should be able to detect this glow as microwave light and as a perfect black body radiation distribution curve. Scientist have found this Cosmic Microwave Background (see [434]). They have accurately measured it using orbiting detectors and it follows very accurately a black body radiation distribution curve. The CMB power spectrum multipole moment is also in very good agreement with the theoretical assumption of the spherical harmonics baryon acoustic oscillations. We have evidence also for the E-modes polarization of the Big Bang (see [321]), but also the B-Modes polarization (see [227]), and Primordial gravitational waves (see [7]).

- **Mixture of Elements:** Some chemical elements were generated soon after the Big Bang. Elements like hydrogen and helium. Some models based on a Big Bang assumption predicts quite well how much of each element was made in the early universe (however sometimes they fail completely for some other elements). When astronomers look at very old galaxies and stars, the amount of each chemical they see agrees quite good with these models based on a Big Bang assumption (see [61]). A point where actually there is also a lack of comprehension is where has gone the antimatter even if we know that CPT is violated, it doesn't explained good enough what we see around us (however don't forget we can see only the observable universe and not the universe in it's entirety).

- **Galactic evolution and distribution:** Detailed observations of the morphology and distribution of galaxies and quasars are in quite good agreement with the current Big Bang models (see [125]). A combination of observations and theory suggest that the first quasars and galaxies formed within a billion years after the Big Bang, and since then, larger structures have been forming, such as galaxy clusters and superclusters. Supercomputer simulations agree well with our observations for our observable universe.

---

[73] Don't forget that its means it's factual beyond all reasonable evidence but it's not the truth as "truth" doesn't exist in experimental science!

- **Baryon acoustic oscillations:** Multiple independent surveys like the Sloan Digital Sky Survey (SDSS), the 2dF Galaxy Redshift Survey (2dFGRS) and the 6dF Galaxy Survey (6dFGS), the WiggleZ and the Baryon Oscillation Spectroscopic Survey (BOSS) mapped the spatial distribution of luminous red galaxies (LRGs) and quasars to determine their spatial distribution and detected the characteristic scale imprinted by baryon acoustic oscillations (sound waves that propagate in the early universe) in the early universe (see [125]).

- **Age of the universe:** The age of the universe that was estimated from the Hubble law and cosmic microwave background is in good agreement with the ages of the oldest stars, both as measured by applying the theory of stellar evolution to globular clusters (see [292]).

- **Olber's paradox:** The Big Bang (i.e. the cosmic inflation theory) solves this paradox, expressed by Heinrich Olbers in 11826 (holocene calendar), that asks why is the sky dark at night? In an infinitely large and unchanging universe, uniformly populated with stars and galaxies, the sky should be dazzlingly bright. Olbers suggested a solution for this paradox: he thought that the enormous amount of dust in the universe must be absorbing the greater portion of the light emitted by the stars, causing the sky to darken. It was calculated afterwards that even this dust would get hot because of the radiation it had absorbed and would radiate with the same intensity. The paradox came to be solved following the Big Bang's postulation that the universe must have had a beginning and that it was expanding. So, the fact that the night sky is dark indicates that the universe cannot have a static infinite number of evenly distributed stars over an infinite period of time (see [234]).

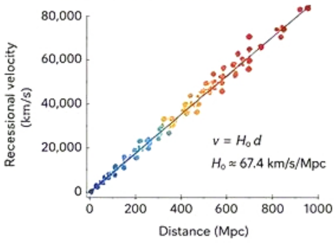
- **Gravitational potential paradox:** Johann Friendrich Zöllner's (11871 according to holocene calendar) paradox about gravitation was also invalidated by the expanding universe model. Zöllner maintained that if we imagined the stars in an infinite and static universe evenly scattered in space, as Newton had assumed, there should have been infinite gravitational potential at every point of the universe. Such a postulate was hardly compatible with common sense and observations; in this way the Big Bang model (i.e. the cosmic inflation theory) that postulated an expanding, dynamic and finite universe also resolved this paradox.

THE BIG BANG (λCDM)

ALL MAJOR LINES OF EVIDENCE

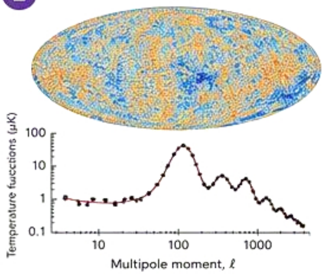
The Big Bang model, within the framework of ΛCDM (Lambda Cold Dark Matter), provides a consistent explanation for a wide range of observations across the Universe.

1 UNIVERSE EXPANSION (HUBBLE'S LAW)



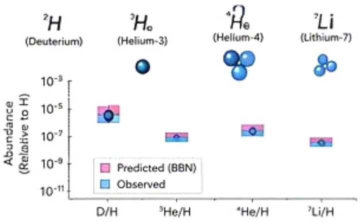
- Galaxies recede from us with a velocity proportional to their distance.
- Measuring this redshift-distance relation gives the Hubble constant.
- Consistent with an expanding Universe from a hot, dense past.

2 COSMIC MICROWAVE BACKGROUND (CMB)



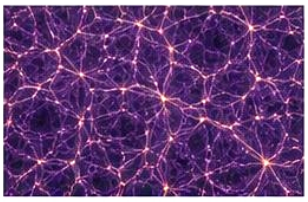
- The CMB is relic radiation from ~380,000 years after the Big Bang.
- Its near-perfect blackbody spectrum at 2.725 K matches predictions.
- Tiny anisotropies show the acoustic peaks predicted by ΛCDM.
- Measured in exquisite detail by Planck.

3 PRIMORDIAL ABUNDANCES (BIG BANG NUCLEOSYNTHESIS)



- In the first few minutes, the Universe produced light nuclei.
- Observed abundances of D, ^{3}He, ^{4}He and ^{7}Li match Big Bang predictions using a single parameter: the baryon density.

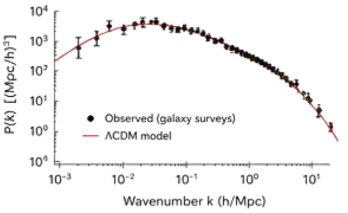
4 LARGE-SCALE STRUCTURE OF THE UNIVERSE



Cosmic Web (simulation)

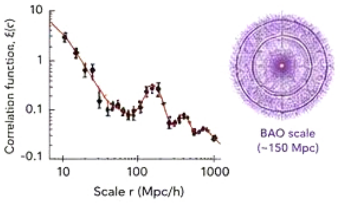
- Galaxies are not randomly distributed: they form a cosmic web of filaments, clusters and voids.
- ΛCDM, with gravity amplifying tiny primordial fluctuations, naturally produces this pattern.
- Observed by galaxy surveys (SDSS, DESI, etc.).

5 THE MATTER POWER SPECTRUM



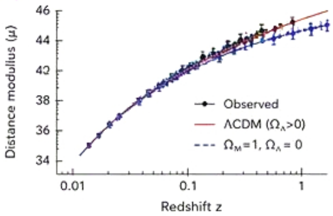
- The distribution of matter fluctuations versus scale matches ΛCDM predictions over many orders of magnitude.
- Confirms the physics of inflation (primordial fluctuations) and gravity.

6 BARYON ACOUSTIC OSCILLATIONS (BAO)



- Sound waves in the early Universe left an imprint in the matter distribution.
- Detected as a preferred scale (~150 Mpc) in galaxy clustering.
- Acts as a "standard ruler" confirming the expansion history.

7 SUPERNOVAE TYPE Ia



- Distant supernovae are dimmer than expected in a decelerating Universe.
- Indicates cosmic acceleration due to dark energy (Λ).
- Precisely measured by many surveys.

8 THE AGE OF THE UNIVERSE

ΛCDM prediction
13.80 ± 0.02 billion years

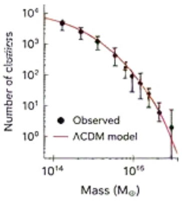
Oldest stars
13.4 ± 0.8 billion years

Globular clusters
12.8 ± 0.7 billion years

Meteorites (Solar System)
4.56 ± 0.02 billion years

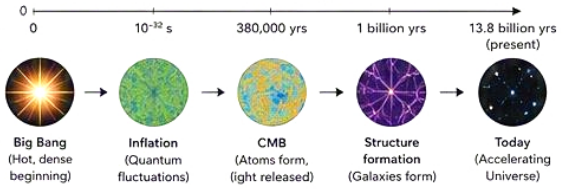
- Independent dating methods agree with the ΛCDM age.
- The Universe is old enough for galaxies, stars and planets to have formed.

9 GRAVITATIONAL LENSING & CLUSTER COUNTS



- The amount of lensing and the number of galaxy clusters as a function of mass match ΛCDM predictions.
- Requires both dark matter and dark energy with measured densities.

THE ΛCDM MODEL: A CONSISTENT PICTURE

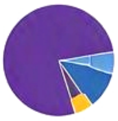


Big Bang (Hot, dense beginning) → **Inflation** (Quantum fluctuations) → **CMB** (Atoms form, (ight released) → **Structure formation** (Galaxies form) → **Today** (Accelerating Universe)

FROM THE VERY SMALL TO THE VERY LARGE, FROM THE VERY EARLY TO TODAY:
All lines of evidence converge on the same story.

ΛCDM WORKS
One model. Many tests. Remarkable agreement.

COMPOSITION OF THE UNIVERSE (TODAY)



68.5%	Dark Energy (Λ)
26.5%	Dark Matter (Cold)
5.0%	Ordinary Matter (Atoms)

The ΛCDM models has however in the early 121st century (holocene calendar) some exciting tensions/challenges like:

- Significative statistical disrepencies between the different methods of measurement of the Hubble constant value.
- There are super-amas structures observed whose size is too big to respect the homogeneity assumption of the FLWR metric.
- Stars and galaxies observed with high redshift by the JWST are observed at a percentage that isn't right statistically with theoretical models.
- The abundance of the observed Lithium is incompatible with the nucleosynthesis theoretical models.
- ...and many other (approximately 40) well summarized in the following paper [437].

Again, let us remind that alternative models challenge the assumptions of the ΛCDM model. Examples of these are modified Newtonian dynamics (MOND), entropic gravity, $f(R)$ modified gravity, theories of large-scale variations in the matter density of the universe, bimetric gravity, scale invariance of empty space, decaying dark matter (DDM), Kaluza-Klein theory (and variations like the DGP model), Timescapes that doesn't required dark energy (see), GRSI (Gravitationally Rescaled Strong Interaction) model, SIDM (Strong Interactive Dark Matter) model, Shockwave cosmology, etc.

That's why some cosmologists think that the ΛCDM model may be an approximation of a more fundamental model.

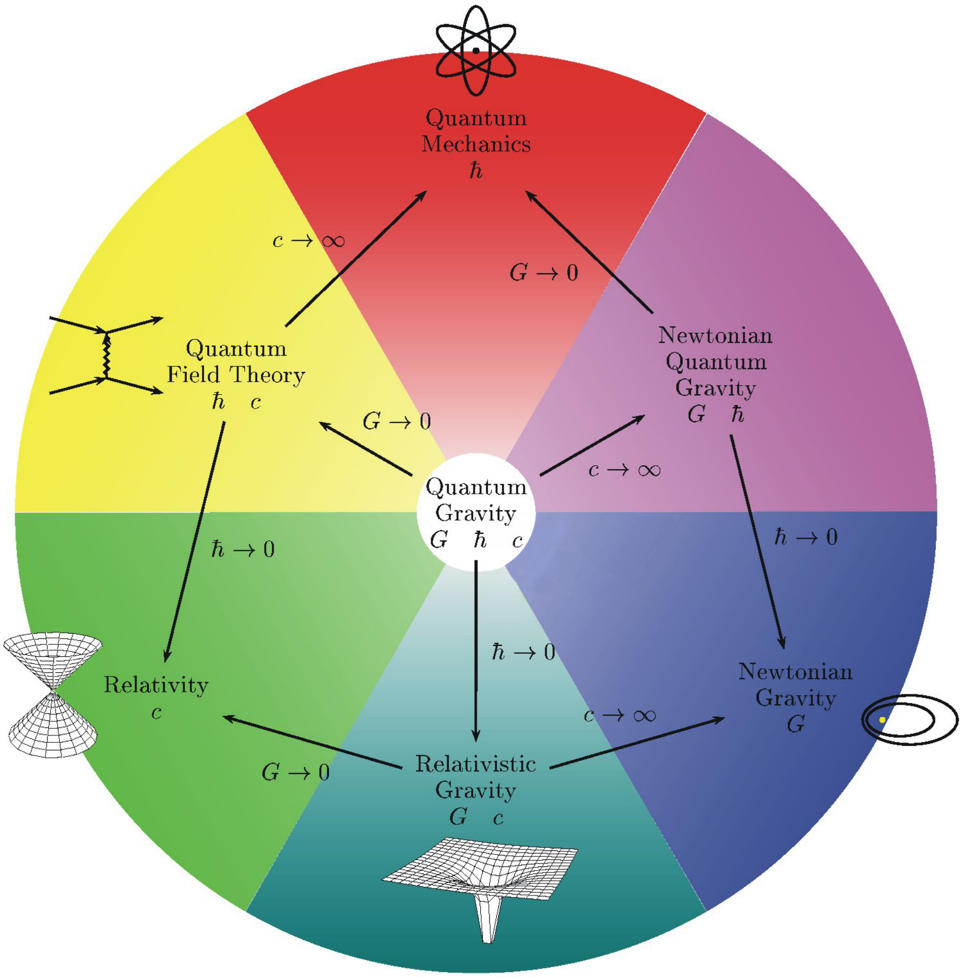
12.6. Quantum Gravity/Cosmology

Quantum gravity (QG) and Cosmology are two fields of theoretical physics that seeks to describe respectively gravity and the universe according to the principles of quantum mechanics, and where quantum effects cannot be ignored, such as near compact astrophysical objects where the effects of gravity are strong or the beginning of the universe.

To start this section we think it is maybe good to remind the reader to refer first to the Okun cube (see section Principia page 3125). Once this done, here is another restricted version of the Okun cube below (but not really accurate) that highlights an interesting field that does not appear in the Okun cube and that is the Newtonian quantum gravity that we will see first. But this figure is interesting as it highlights well the different models we will deal with in this section:



Quantum Mechanics $\hbar$
$c \to \infty$
$G \to 0$
Quantum Field Theory $\hbar$ c
$G \to 0$
Newtonian Quantum Gravity G $\hbar$
$c \to \infty$
Quantum Gravity G $\hbar$ c
$\hbar \to 0$
$\hbar \to 0$
$\hbar \to 0$
Relativity c
$c \to \infty$
Newtonian Gravity G
$G \to 0$
Relativistic Gravity G c

Figure 12.301: **Okun wheel (source: ?)**

Remark

The above figure is especially not accurate (same problem for the Okun cube) for the arrow that links together Quantum Field Theory and Quantum Mechanics as there are no obvious and unique way that really links them together.

12.6.1 Newton Quantum Gravity

A Newtonian approach to quantum gravity is studied. At least for weak gravitational fields it should be a valid approximation. Such an approach could be used to point out problems and prospects inherent in a more exact theory of quantum gravity, yet to be discovered. Newtonian quantum gravity, e.g., shows promise for prohibiting Black Holes altogether (which would eliminate singularities and also solve the Black Hole information paradox), breaks the equivalence principle of General Relativity, and supports non-local interactions (quantum entanglement). Its predictions should also be testable at length scales well above the "Planck scale", by high-precision experiments feasible even with existing technology. It turns out that, e.g., the Solar System, superficially, can be described as a quantum gravitational system, provided that the l quantum number has its maximum value, $n-1$. This results exactly in Kepler's third law. If also the m quantum number has its maximum value ($\pm l$) the probability density has a very narrow torus-like form, centered around the classical planetary orbits. However, as the probability density is independent of the azimuthal angle ϕ there is, from quantum gravity arguments, no reason for planets to be located in any unique place along the orbit (or even *in* an orbit for $m \neq \pm l$). This is, in essence, a reflection of the "measurement problem" inherent in all quantum descriptions.

The greatest fundamental challenge facing theoretical physics has for many years been to reconcile gravity with quantum physics. There have been numerous attempts to do so, but so far there is no established and experimentally/observationally tested theory of "quantum gravity", the two main contenders presently being String Theory and loop quantum gravity, with "outsiders" like twistor theory, non-commutative geometry, etc.

The motivations for studying Newtonian quantum gravity are:

- Quantum theory is supposed to be universal, i.e., it should be valid on all length scales and for all objects, as there in principle exists no size/charge/mass-limit to its applicability. In atomic physics the practical restriction comes about due to the fact that there is a limit to arbitrarily large atomic nuclei as:

  1. The Coulomb force between protons is repulsive, eventually overpowering the strong nuclear force trying to hold the nucleus together
  2. The additional weak force makes neutron-rich nuclei decay before they grow too large

  Also, the electric charge comes in both positive and negative, and as a result a big lump of matter is almost always electrically neutral[74]. Neither of these effects are present in

---

[74] The same also applies for e.g. the strong force, as the three different color charges ("red", "green", "blue") always combine to produce color-neutral hadrons and bulk matter.

"pure" quantum gravity.

- For weak gravitational fields the Newtonian theory should be sufficient. The weak-field Newtonian limit is even used for determining the constant κ in Einstein's field equations of General Relativity $G_{\mu\nu} = \kappa T_{\mu\nu}$. The Newtonian limit is also almost always sufficient for practical purposes in non-quantum gravity, except for a handful of extreme cases (notably Black Holes and the very early universe), although high-precision experiments in e.g. the Solar System can and do show deviations from the Newtonian theory, always in favour of General Relativity.

- Even for strong gravitational fields the Newtonian picture gives the same prediction as general relativity for the Schwarzschild radius of a spherically symmetric, non-rotating Black Hole, and correct order of magnitude results for neutron stars and cosmology. This could make it possible to deduce at least qualitative results about strongly coupled quantum gravity, as the Newtonian viewpoint should give reliable first order quantum gravitational results.

On the other hand would any "absurd" results obtained from Newtonian quantum gravity, deviating from observations, implicate either that:

- General relativity cannot be quantized[75]. An unsuccessful special case (the weak field limit) would disprove the general case, whereas the opposite is not true (a vindicated weak field limit will not prove that the general theory is also correct).

- Quantum mechanics fails at "macroscopic" distances and for macroscopic objects. This would mean that we in gravity have a unique opportunity to understand the "measurement problem" in quantum mechanics, as proposed by e.g. Károlyházy and Penrose. In that case we can use gravity to probe the transition between quantum $\rightarrow$ classical behaviour in detail, i.e. get experimental facts on where, how and when the inherently undecided, subjective quantum world of superpositions turns into the familiar objective classical everyday world around us. One could, at least in principle, envisage a test carried out in a free-falling (e.g. satellite) environment where one alters m (the gravitational "test-charge") and M (the gravitational "source-charge") until the expected quantum gravity results are observed, to obtain a limit of where the quantum mechanical treatment breaks down, hence making an experimental determination of the border between "quantum" and "classical", i.e. solving the quantum mechanical measurement problem. Fundamental quantum gravity and the quantum mechanical measurement problem may well be intertwined and might need to be resolved simultaneously in a successful approach.

In Newtonian quantum gravity, at least as long as the system can be approximately treated as a 2-body problem, it is possible to use the mathematical identity between the electrostatic Coulomb force in the hydrogen atom, and Newton's static gravitational force under the substitution $e^2/4\pi\varepsilon_0 \rightarrow GmM$. Therefore all analytical results from elementary quantum physics directly lifts over to the quantum gravity case. For weak electromagnetic fields, as in the hydrogen atom, the electrodynamic corrections to the static Coulomb field are very small, making the approximation excellent. The same applies to quantum gravity, dynamical effects from general relativity are negligible to a very high degree for weak gravitational fields. A gravitationally bound 2-body system should then exhibit exactly the same type of "spectrum" as a hydrogen atom, but emitted in (unobservable) hypothesized graviton form instead of photons (easily detectable as atomic spectra already in the 119th century according to holocene calendar).

---

[75] This is an automatic consequence of "emergent" gravity, e.g. Sakharov's theory, where gravity is a non-fundamental interaction and rather a macroscopic consequence of other forces and fields.

For a free-falling 2-body system, e.g. in a satellite experiment enclosed in a spherical vessel, it should in principle be possible to measure the excitation energies for a suitable system. An analogous result has seemingly already been accomplished for neutrons in the gravitational field of the Earth, although there are some quantum gravity ambiguities as noted below.

For hydrogen-like (one electron) atoms, in the dominant Coulomb central-field approximation, the energy levels depend only on the principal quantum number, $n = 1, 2, 3, \ldots$:

$$E_n = -\frac{me^4}{8\varepsilon_0^2 h^2}\frac{Z^2}{n^2} = -E_H \frac{Z^2}{n^2} \tag{12.6.1}$$

where $E_H \simeq 13.6$ [eV] is the ionization energy, i.e. the energy required to free the electron from the proton, and Z the number of protons in the nucleus.

The Bohr-radius, a_0, the innermost radius of circular orbits in the old semi-classical Bohr-model, and also the distance r for which the probability density of the Schrödinger equation for the Hydrogen ground-state peaks, is:

$$a_0 = \frac{h^2\varepsilon_0}{\pi m e^2} \tag{12.6.2}$$

whereas the expectation value for the electron-nucleus separation is:

$$\langle r\rangle_{\text{hydrogen}} \simeq \frac{n^2}{Z}a_0 = \frac{n^2 h^2 \varepsilon_0}{Z\pi m e^2} \tag{12.6.3}$$

A comparison between the Coulomb potential in Hydrogen-like atoms:

$$V_{\text{hydrogen}} = -\frac{Ze^2}{4\pi\varepsilon_0 r} \tag{12.6.4}$$

and the Newtonian gravitational potential between two masses m and M:

$$V_{\text{grav}} = -\frac{GmM}{r} \tag{12.6.5}$$

allows us to obtain all results of the gravitational case by the simple substitution:

$$\frac{Ze^2}{4\pi\varepsilon_0} \rightarrow GmM \tag{12.6.6}$$

in the well-known formulas for the Hydrogen atom.

For instance, the gravitational "Bohr-radius", b_0, becomes:

$$b_0 = \frac{h^2}{4\pi^2 G m^2 M} = \frac{\hbar^2}{G m^2 M} \tag{12.6.7}$$

and the quantum-gravitational energy levels are:

$$E_n(\text{grav}) = -\frac{2\pi^2 G^2 m^3 M^2}{h^2}\frac{1}{n^2} = -\frac{G^2 m^3 M^2}{2\hbar^2}\frac{1}{n^2} = -E_g\frac{1}{n^2} \tag{12.6.8}$$

here again $E_g = G^2 m^3 M^2/2\hbar^2$ is the energy required to totally free the mass m from M in analogy to the Hydrogen case, whereas the expectation value for the separation is:

$$\langle r\rangle_{\text{grav}} \simeq n^2 b_0 = \frac{n^2\hbar^2}{Gm^2M} \tag{12.6.9}$$

Also all the analytical solutions to the Schrödinger equation, the hydrogen wave-functions, carry over to the gravitational case with the simple substitution $a_0 \rightarrow b_0$:

$$\psi_{nlm} = R(r)\Theta(\theta)\Phi(\phi) = N_{nlm}R_{nl}Y_{lm} \tag{12.6.10}$$

where N_{nlm} is the normalization constant, R_{nl} the radial wavefunction, and Y_{lm}, the spherical harmonics, contain the angular part of the wavefunction.

Let us examine some concrete cases to obtain a feeling for these relations: For a two-body problem composed of proton and electron $b_0 \simeq 10^{29}$ [m], several orders of magnitude larger than the size of the observable universe ($\simeq 10^{26}$ [m]), whereas $E_g \simeq 10^{-78}$ [eV]. For two neutrons $b_0 \simeq 10^{22}$ [m], $E_g \simeq 10^{-68}$ [eV]. For the Earth and Sun (approximated as a two-body problem for illustrative reasons) one gets $b_0 \simeq 10^{-138}$ [m], an absurdly small ground state separation, and $E_g \simeq 10^{182}$ [J], which is unphysical as the binding energy $E_g \gg mc^2 \simeq 10^{42}$ [J]. We will see below how to deal with these "unphysical" cases and how the physical picture somewhat surprisingly is connected to the Schwarzschild radius. For a better 2-body application, let us consider a binary neutron star system (one solar mass each), $b_0 \simeq 10^{-148}$ [m], $E_g \simeq 10^{198}$ [J] $\gg mc^2 \simeq 10^{47}$ [J], again unphysical. One could also ask how much m would have to be in a gravitational binary system (taking $m = M$) in order for b_0 to be, for example, one meter: $m \simeq 10^{-19}$ [kg], or the mass of a small virus. For a pair of "Planck-objects" $m = M \simeq 10^{-8}$ [kg], we get, maybe not surprisingly, $b_0 \simeq 10^{-35}$ [m] (the "Planck length") and $E_g \simeq 10^9$ [J] (the "Planck energy") which also happens to be equal to mc^2. We could also ask for the binary system mass (again taking $m = M$) giving exactly the same numerical energy spectrum as for the Hydrogen atom, i.e. taking $E_g = E_H = 13.6$ [eV], resulting in $m \simeq 10^{-13}$ [kg], the mass of one human cell, and $b_0 \simeq 10^{-19}$ [m].

One could ask for the mass, m, required to produce exactly the quantum gravitational energy spectrum of hydrogen in a gravitational field like that of Earth, $M = M_\oplus \simeq 6\cdot 10^{24}$ [kg]. This turns out to be $m \simeq 10^{-38}$ [kg], or an equivalent mass-energy of $\sim 10^{-3}$ [eV], comparable to the conjectured mass of neutrinos. As $b_0 \sim 1\,[\mu\text{m}]$ in this case, only very highly excited states would be possible above the Earth surface. The matter would of course be quite different around cosmic compact objects, for example the conjectured "preon stars" with masses comparable to the Earth's and radii $\sim b_0$.

We notice (e.g. through b_0) that the planets in the Solar System must be in very highly excited quantum gravitational states. In that sense they are analogous to electrons in "Rydberg atoms" in atomic physics. To obtain a good two-body approximation, let us study the Sun-Jupiter system in a little more detail.

For excited states with $l \neq 0$, and very large n and l, the expectation value of the distance is:

$$\langle r\rangle \simeq \frac{1}{2}(3n^2 - l^2)b_0 \tag{12.6.11}$$

however as that is for an ensemble (average over many measurements), for a single state it is in principle more appropriate to use the most probable radial distance ("radius" of orbital):

$$\tilde{r} = n^2 b_0 \tag{12.6.12}$$

as a measure for the expected separation. However, for n large and $l = l_{\text{max}} = n-1$ the two coincide so that $\langle r \rangle = \tilde{r}$.

The angular momentum for Jupiter around the Sun (actually a G2V-type star, aka yellow dwarf) is $L \simeq 2 \cdot 10^{43}$ [J · s], giving an l-quantum number of $l = L/\hbar \simeq 2 \cdot 10^{77}$. The most probable Sun-Jupiter distance is given by $\tilde{r} = n^2 b_0 \geq l^2 b_0 \simeq 7.6 \cdot 10^{11}$ [m], which is the same as the actual separation. $E_n = -E_g/n^2 \simeq -1.6 \cdot 10^{35}$ [J], so the magnitude of the binding energy is much less than $mc^2 \simeq 1.8 \cdot 10^{44}$ [J], making it physically allowed, and also of the same order of magnitude as its classical counterpart $-GmM/r \simeq -3.4 \cdot 10^{35}$ [J]. The Sun-Jupiter system can thus seemingly be treated as a quantum gravitational 2-body system, provided that it is taken to have its maximally allowed value for its angular momentum ($l \simeq n$).

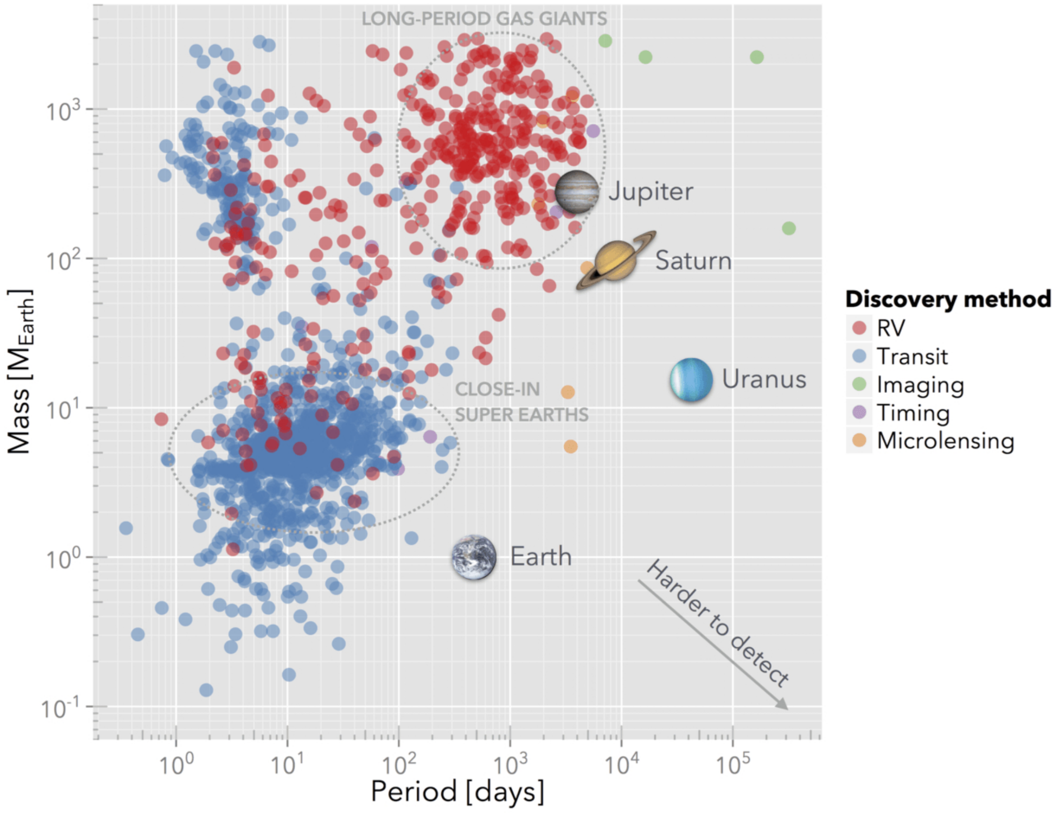


Figure 12.302: A mass-period diagram. Each dot marks the mass and orbital period of a confirmed exoplanet in 12015 (author: Stefano Meschiari)

In fact, it is easy to show that for Kepler's law to apply, l must be very close to n.

The period of revolution can be written:

$$T = \frac{2\pi m\tilde{r}^2}{L} = \frac{2\pi m\tilde{r}^2}{l\hbar} \tag{12.6.13}$$

and assuming maximality for the angular momentum, $l \simeq n$, gives:

$$T \simeq \frac{2\pi m\tilde{r}^2}{n\hbar} \tag{12.6.14}$$

Solving for n gives:

$$n = \frac{m\sqrt{GM\tilde{r}}}{\hbar} \tag{12.6.15}$$

so that:

$$T \simeq \frac{2\pi\tilde{r}^{3/2}}{\sqrt{GM}} \tag{12.6.16}$$

which exactly is Kepler's law. So, the conclusion is that all the planets in the Solar System are in maximally allowed angular momentum states quantum mechanically. The $l \simeq n$ quantum numbers are as follows: $l_{\text{Sun}} \simeq 2 \cdot 10^{75}$, $l_{\text{mercury}} \simeq 8 \cdot 10^{72}$, $l_{\text{venus}} \simeq 2 \cdot 10^{74}$, $l_{\text{Earth}} \simeq 3 \cdot 10^{74}$, $l_{\text{Mars}} \simeq 4 \cdot 10^{73}$, $l_{\text{jupiter}} \simeq 2 \cdot 10^{77}$, $l_{\text{saturn}} \simeq 8 \cdot 10^{76}$, $l_{\text{uranus}} \simeq 2 \cdot 10^{76}$, $l_{\text{neptune}} \simeq 2 \cdot 10^{76}$, $l_{\text{pluto}} \simeq 3 \cdot 10^{72}$. Even though the maximality of L and L_z are automatic from the classical description, it is far from obvious why the same should result from the more fundamental quantum treatment, as noted below.

For states with $l = l_{\max} = n - 1$ and $m = \pm l$:

1. There is only one peak, at $r = \tilde{r}$, for the radial probability density, and the "spread" (variance) in the r-direction is given by[76] $\Delta r = \sqrt{\langle r^2 \rangle - \langle r \rangle^2} \simeq n^{3/2} b_0/2$. For the Earth-Sun system it means $\Delta r \simeq 10^{-26}$ [m]

2. The angular θ-part of the wavefunction for maximal m-quantum number $|m| = l$, is $\propto \sin^l(\theta)$.

The probability density thus goes as $\sin^{2l}(\theta)$ in the θ-direction, meaning that only $\theta = \pi/2$ is non-vanishing for large l. The azimuthal (ϕ) part of the angular wavefunction Y_{lm} is purely imaginary, making it drop out of the probability density, so that *all* values of ϕ are equally likely (this ϕ-symmetry is a consequence of conservation of angular momentum in a central potential). The total planetary probability density is thus "doughnut" (torus-like) shaped, narrowly peaking around the classical trajectory.

So, at first sight, it seems like the Solar System is perfectly described as a quantum gravitational system. It even seems reasonable. Gravity totally dominates as all other forces, especially the only other known force with infinite reach, the electromagnetic, cancel due to charge neutrality. The Solar System could thus be seen as a test-vehicle for quantum gravity. In the Solar System the Sun totally dominates the gravitational field, making the central field approximation an excellent one, even though it in principle is a n-body problem. Contrast this to the case of multi-electron atoms in atomic physics where all electrons carry the same charge ($1/N$ of the charge of the nucleus), making the central field approximation a very bad one.

---

[76] The hydrogen wavefunctions for the gravitational case give $\langle r^2 \rangle = [5n^2 + 1 - 3l(l+1)]n^2 b_0^2/2$ and $\langle r \rangle = [3n^2 - l(l+1)]b_0/2$.

However, from a quantum gravity standpoint, the system could be in any and all of the degenerate states, and usually at the same time, so typical for quantum mechanical superposition. Even for given energy and angular momentum there is no reason for the planets to be in any particular eigenstate at all of the $2l+1$ allowed, and certainly not exclusively $m = \pm l$. The radial probability distribution in general has $n-l$ maxima. Thus, only for $l = l_{\text{max}} = n-1$ has it got a unique, highly peaked maximum. The degeneracy for a given n is n^2. Whenever $l < l_{\text{max}}$, the radial wave function is highly oscillatory in r as it has $n-l$ nodes. The same goes for the angular distribution as there in general are $l-m$ nodes in the θ-direction. For a general $R_{nl}Y_{lm}$ the planets could be "all over the place", and if this weren't bad enough, according to quantum mechanics the Solar System more probable than not should be in simultaneous, co-existing superposed states with different quantum numbers as is generic in atomic physics. Consequently, Newtonian quantum gravity cannot solve the quantum mechanical measurement problem, perhaps because it lacks the non-linear terms conjectured to be needed.

To get the innermost allowed physical orbit for any "test-particle", m, we must impose the physical restriction that the binding energy cannot exceed the test particle energy, thus:

$$E_g(\max) = mc^2 \tag{12.6.17}$$

As E_g can be written:

$$E_g = \frac{GmM}{2b_0} \tag{12.6.18}$$

we get:

$$b_0(\min) = \frac{GM}{2c^2} = \frac{R_S}{4} \tag{12.6.19}$$

where $R_S = 2GM/c^2$ is the Schwarzschild radius. The expression $b_0(\min)$ gives a limit for b_0 of the system to be physically attainable. It is amusing to see how close $b_0(\min)$ is to R_S and one cannot help speculate that a more complete theory of quantum gravity could ensure that $r > R_S$ always, and thus forbid Black Holes altogether[77]. The object M must be put together somehow, but if $r_{\text{min}} > R_S$ it can never accrete enough matter to become a Black Hole, as the in-falling mass (energy) instead will be radiated away in its totality (in gravitons if they exist...), making a Black Hole state impossible[78]. This would, in an unexpected way, resolve the Black Hole information loss paradox. Even though $r = R_S$ represents no real singularity, as it can be removed by a coordinate transformation, anything moving inside $r < R_S$ will, according to classical general relativity, in a (short) finite proper time reach the true singularity at $r = 0$. If quantum gravity could ensure that $r > R_S$ always, gravity would of course be singularity free.

Let us also briefly look at radiative transitions. From the dipole approximation in atomic physics an elementary quantum (photon) transition requires $\Delta l = \pm 1$. A quadrupole (graviton) approximation in quantum gravity instead requires $\Delta l = \pm 2$. So, a typical elementary energy transfer in a highly excited, gravitationally bound 2-body quantum gravitational system is:

$$\Delta E = -E_g(n^{-2} - (n-2)^{-2}) \simeq \frac{4E_g}{n^3} \tag{12.6.20}$$

---

[77] For the hydrogen atom the corresponding value is $a_0(\min) \simeq 1.4 \cdot 10^{-15}$ [m], or one-half the "classical electron radius", whereas $R_S \simeq 10^{-53}$ [m], so that $a_0(\min) \gg R_S$. But we implicitly already knew that. The Coulomb force does not turn atoms into Black Holes.

[78] For the classical case, the relation is even closer, $GmM/r_{\text{min}} = mc^2$, giving $r_{\text{min}} = R_S/2$, but then one cannot really speak of energy being carried away by gravitons.

For the Earth-Sun system this means $\Delta E \simeq 2 \cdot 10^{-20}$ [eV], carried by a graviton with frequency $\nu \simeq 5 \cdot 10^{-6}$ [Hz], and wavelength $\lambda \simeq 6 \cdot 10^{13}$ [m] $\simeq 400$ [AU] (1 AU being for recall the mean distance between the Earth and Sun).

The average time required for each elementary quantum gravity transition to take place can be estimated roughly by $\Delta t \sim \hbar/\Delta E \simeq 3 \cdot 10^4$ [s] $\simeq$ 8h20 min. Thus the power radiated by a spontaneously emitted individual graviton is very roughly $\sim 10^{-43}$ [W], compared to the prediction from the usual quadrupole formula (first non-vanishing contribution) in classical general relativity of $\simeq 300$ [W] for the total power. We also see that the gravitational force is not really conservative, even in the static Newtonian approximation, but the difference is exceedingly small in the Sun-Earth system. The changes in kinetic and potential energies do not exactly balance, $\Delta K \neq \Delta U$, the difference being carried away by gravitons in steps of $\Delta l = 2$. Also, in quantum gravity there is gravitational radiation even in the spherically symmetric case, which is forbidden according to the classical general relativistic description.

Let us now return to the experiment with neutrons in the gravitational field of the Earth, claiming to have seen, for the first time, quantum gravitational states in the potential well formed by the approximately linear gravitational potential near the Earth surface and a horizontal neutron mirror. An adjustable vertical gap between the mirror and a parallel neutron absorber above was found to be non-transparent for traversing neutrons for separations less than $\sim 15\,[\mu\text{m}]$ (essentially due to the fact that the neutron ground state wavefunction then overlaps the absorber). As the neutron in such a well, from solving the Schrödinger equation, has a ground state wavefunction peaking at $\sim 10\,[\mu\text{m}]$, with a corresponding energy of $\simeq 1.4 \cdot 10^{-12}$ [eV], the experimental result is interpreted to implicitly having verified, for the first time, a gravitational quantum state.

If we instead analyse the experiment in the framework of the present article, the same experimental setup gives $b_0 \simeq 9.5 \cdot 10^{-30}$ [m], $E_g \simeq 2.2 \cdot 10^{35}$ [eV]. Close to the Earth's surface, $\tilde{r} \simeq R_\oplus \simeq 6.4 \cdot 10^6$ [m], the radius of the Earth, giving $n \simeq 8.2 \cdot 10^{17}$, resulting in a typical energy for an elementary quantum gravity transition $\Delta E \simeq 4E_g/n^3 \simeq 1.6 \cdot 10^{-18}$ [eV]. For a cavity of $\Delta\tilde{r} = 15\,[\mu\text{m}]$, and $n \gg \Delta n \gg 1$, one gets $\Delta E = E_g b_0 \Delta\tilde{r}/\tilde{r}^2 \simeq 0.7 \cdot 10^{-12}$ [eV] $= 0.7$ [peV], to be compared to the value 1.4 [peV]. Even though the present treatment gives a similar value for the required energy, it need *not* be the result of a *single* quantum gravity state, but rather $\leq 10^6$ gravitons can be emitted/absorbed. From the treatment in this article it is thus not self-evident to see why the experimental apparatus should be non-transparent to neutrons for vertical separations $\Delta h < 15\,[\mu\text{m}]$.

To appreciate the potential importance of this, let us digress briefly on the equivalence principle, the main conceptual pillar of general relativity. A classic example for illustrating it involves two rockets: One rocket stands firmly on the surface of the Earth, while the other accelerates constantly in empty space with $a = g$. According to the equivalence principle there is no way to, locally, distinguish one from the other if one is not allowed/able to make outside observations, meaning that acceleration and gravity are equivalent. However, in the quantum gravity case, for example considering a neutron inside each rocket, there certainly *is* a difference: For the rocket standing on the Earth the potential in the Schrödinger equation is $V = -GmM/r$, resulting in normal quantization as elaborated above. For the rocket accelerating in space, however, $V = 0$ and the energy levels are non-quantized (the neutron being a free particle until it hits the floor of the rocket). So the conclusion is that Newtonian quantum gravity breaks the equivalence principle. Furthermore, to understand why a free-falling object classically accelerates radially downward in, e.g., the Earth's gravitational field, the gravitons must, by conservation of momentum, be emitted in the direction opposite to the acceleration (at least the probability for emission must peak in that direction). Also, the quantum states with given n, l, m are in principle inherently stable, an outside perturbation being needed for the transition rate to be different from zero, just like in atomic physics. For macroscopic bodies this poses no problem as there in that case are abundant backgrounds of both gravitational and non-gravitational disturbances. For an elementary quantum gravity interaction, however, this problem seems much more severe, as the notion of free-fall loses its meaning as the quantum states become practically stable to spontaneous graviton emission. In fact, a bound quantum gravitational object does not fall at all as it is described by a stationary wavefunction, or a superposition of such.

Thus, the difference regarding quantized energy levels for an experiment with neutrons "falling" under the influence of Earth's gravity *with* mirror or *without* (above) shows that Newtonian quantum gravity is dependent on global boundary conditions, where the boundary in principle can lie arbitrarily far away. This comes as no surprise, as the Schrödinger equation models the gravitational interaction as instantaneous, contrasted with the case in general relativity where the behaviour in free fall only depends on the local properties of mass-energy and the resulting space-time curvature (out of which the mirror is not part due to its inherently non-gravitational interaction with the neutron) and causal connection as the gravitational interaction propagates with the speed of light. However, as several experiments on entangled quantum states, starting with Clauser/Freedman and Aspect et al. , seem to be compatible with a non-local connection between quantum objects, this property of the Schrödinger equation does not, at least for the moment, seem to be a serious drawback for a theory of quantum gravity. One could even envisage a "delayed choice" experiment à la Wheeler, where the mirror is removed/inserted before the neutron reaches its position, meaning that we could alter the energy of the gravitons *after* they have been emitted.

12.6.2 Wheeler-DeWitt Quantum Cosmology

In this subsection we will discuss some of the most interesting, profound, and topical speculations - and our stage of knowledge in this beginning of the 121st century... (holocene calendar) - about the earliest moments of the Universe.

"Why are we here?" "Where did it all come from?" These two questions are perhaps the most fundamental to be asked by our species. In recent years, a number of physicists and cosmologists have begun to develop a new description of the ultimate system, the universe as a whole. Although the first question still lies beyond the purview of physics, "quantum cosmology," an amalgam of quantum theory and classical relativistic cosmology, now offers a scientific answer to the second.

Because the underlying physics is still cloudy, it is not clear how (or even whether) one should approach the beginning time of the Universe. In spite of the fact that the underlying physics is not yet well formulated, we will attempt to give the reader a taste for some of the most exciting and potentially important research being pursued at present. The reader should understand that we are fishing in murky waters, and that the ideas we shall discuss here are both highly speculative and not yet unambiguously formulated.

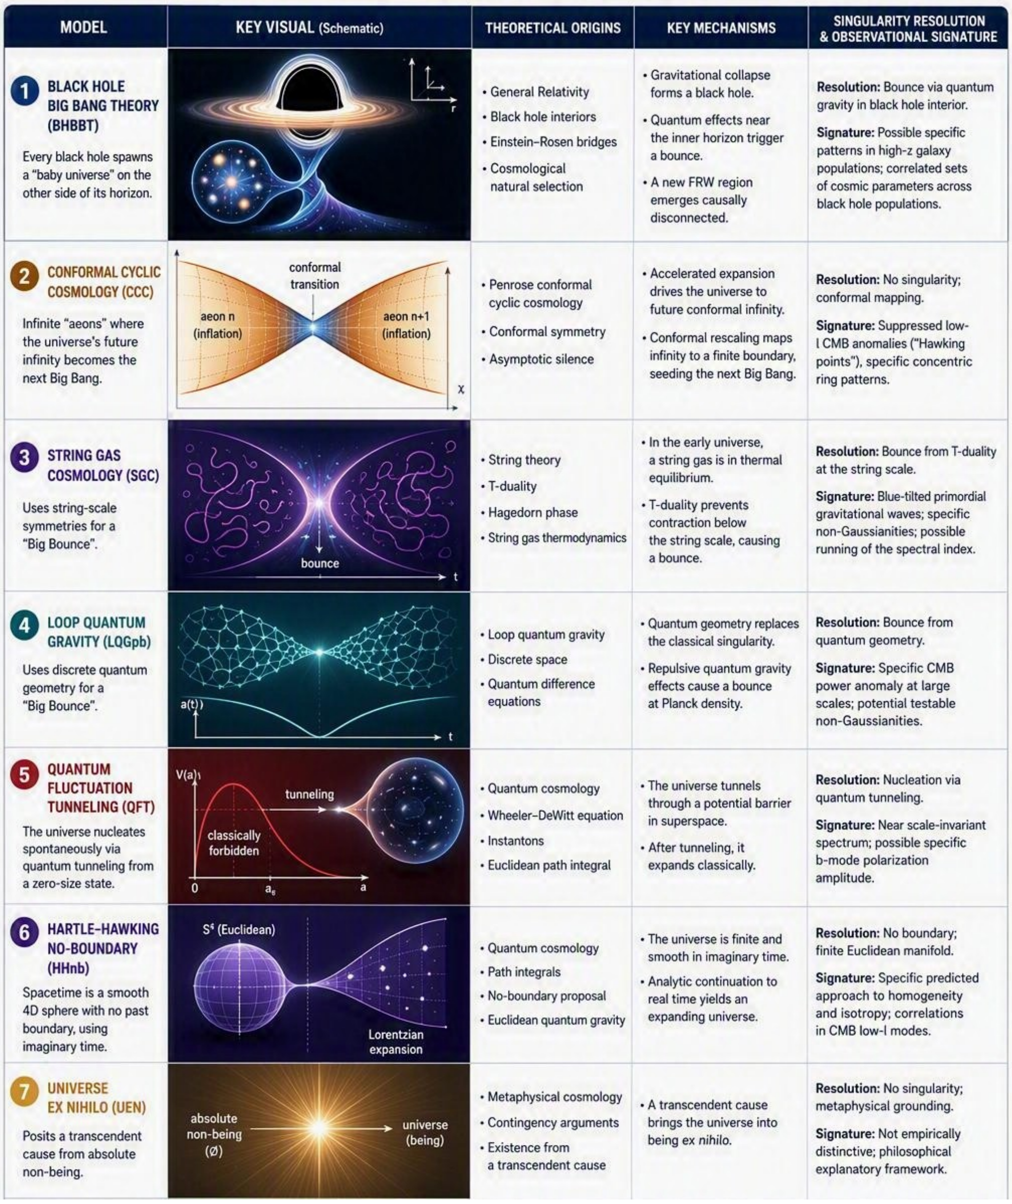
"Quantum cosmology" is the attempt in theoretical physics to develop a quantum theory of the Universe. It employs a particular (and highly speculative) approach to the unification of Quantum Physics and General Relativity that was pioneered by John Wheeler and Bryce DeWitt in the 11960s (holocene calendar). This approach attempts to answer open questions of classical physical cosmology, particularly those related to the first phases of the universe Unfortunately, their theory is difficult to interpret as it does not refer directly to evolution in time, but rather to other properties of the Universe, such as its size. Remarkably, the Wheeler-DeWitt theory can be used to calculate the probability that the Universe came into being from nothing (ex-nihilo), though doing so involves making a number of assumptions. James Hartle and Stephen Hawking attempted this in 11983 (holocene calendar), basing their thinking on the assumption that the Universe should have no boundary in time or space. Others, using different assumptions have found a different answer and it is not clear which, if any, is correct. However it is interesting that one can make progress by assuming that the laws of physics are somehow beyond the Universe itself and can describe its creation. This is in distinct contrast to the philosophy of chaotic inflation, where it is assumed that the laws of physics are very much within the Universe, and may vary from place to place.

> ❞ *Nothing can create something all the time due to the laws of quantum mechanics, and it's fascinatingly interesting!* ❞
>
> Lawrence M. Krauss

quote
12.6:6083.#73

Remark

The Wheeler-DeWitt quantum cosmology model mathematically describes a Universe out of nothing (in the quantum sense of "nothing" obviously!) and without cause (see [238]) like the Vilenkin-Higgs-Coleman-Weinberg model (see [560]). But other models give mathematical possible answers of Universe without cause like the Einstein Cyclic Universe (the Universe always existed and cycles through a sequences of Big-Bang and Big-Crunch so there is no questioning about it's beginning), the Conformal Cyclic Cosmology (the Universe also always existed but finishes with an exponential expansion destructing matter to the states of photons and therefore cancels the concept of time and dimension!), the String Gas Cosmology in which there were cosmic Strings preceding the Big Bang due to Non-singular Ekpyrotic Cosmology, the Hartle-Hawking no-boundary proposal, the Loop Quantum Gravity in which there were spin foams producing a pre-Big-Bang branch to our Universe with Black Holes remnants, the Black Hole Big Bang theory (i.e. cosmic inflation theory) is that matter from a mother universe collapses into a Black Hole that may generate a White Hole giving existence to a new universe, etc.



MODEL	KEY VISUAL (Schematic)	THEORETICAL ORIGINS	KEY MECHANISMS	SINGULARITY RESOLUTION & OBSERVATIONAL SIGNATURE
① **BLACK HOLE BIG BANG THEORY (BHBBT)** Every black hole spawns a "baby universe" on the other side of its horizon.	r	• General Relativity • Black hole interiors • Einstein–Rosen bridges • Cosmological natural selection	• Gravitational collapse forms a black hole. • Quantum effects near the inner horizon trigger a bounce. • A new FRW region emerges causally disconnected.	**Resolution:** Bounce via quantum gravity in black hole interior. **Signature:** Possible specific patterns in high-z galaxy populations; correlated sets of cosmic parameters across black hole populations.
② **CONFORMAL CYCLIC COSMOLOGY (CCC)** Infinite "aeons" where the universe's future infinity becomes the next Big Bang.	conformal transition aeon n (inflation) aeon n+1 (inflation) χ	• Penrose conformal cyclic cosmology • Conformal symmetry • Asymptotic silence	• Accelerated expansion drives the universe to future conformal infinity. • Conformal rescaling maps infinity to a finite boundary, seeding the next Big Bang.	**Resolution:** No singularity; conformal mapping. **Signature:** Suppressed low-l CMB anomalies ("Hawking points"), specific concentric ring patterns.
③ **STRING GAS COSMOLOGY (SGC)** Uses string-scale symmetries for a "Big Bounce".	bounce t	• String theory • T-duality • Hagedorn phase • String gas thermodynamics	• In the early universe, a string gas is in thermal equilibrium. • T-duality prevents contraction below the string scale, causing a bounce.	**Resolution:** Bounce from T-duality at the string scale. **Signature:** Blue-tilted primordial gravitational waves; specific non-Gaussianities; possible running of the spectral index.
④ **LOOP QUANTUM GRAVITY (LQGpb)** Uses discrete quantum geometry for a "Big Bounce".	a(t)) t	• Loop quantum gravity • Discrete space • Quantum difference equations	• Quantum geometry replaces the classical singularity. • Repulsive quantum gravity effects cause a bounce at Planck density.	**Resolution:** Bounce from quantum geometry. **Signature:** Specific CMB power anomaly at large scales; potential testable non-Gaussianities.
⑤ **QUANTUM FLUCTUATION TUNNELING (QFT)** The universe nucleates spontaneously via quantum tunneling from a zero-size state.	V(a) tunneling classically forbidden 0 a_0 a	• Quantum cosmology • Wheeler–DeWitt equation • Instantons • Euclidean path integral	• The universe tunnels through a potential barrier in superspace. • After tunneling, it expands classically.	**Resolution:** Nucleation via quantum tunneling. **Signature:** Near scale-invariant spectrum; possible specific b-mode polarization amplitude.
⑥ **HARTLE–HAWKING NO-BOUNDARY (HHnb)** Spacetime is a smooth 4D sphere with no past boundary, using imaginary time.	S^4 (Euclidean) Lorentzian expansion	• Quantum cosmology • Path integrals • No-boundary proposal • Euclidean quantum gravity	• The universe is finite and smooth in imaginary time. • Analytic continuation to real time yields an expanding universe.	**Resolution:** No boundary; finite Euclidean manifold. **Signature:** Specific predicted approach to homogeneity and isotropy; correlations in CMB low-l modes.
⑦ **UNIVERSE EX NIHILO (UEN)** Posits a transcendent cause from absolute non-being.	absolute non-being (Ø) universe (being)	• Metaphysical cosmology • Contingency arguments • Existence from a transcendent cause	• A transcendent cause brings the universe into being *ex nihilo*.	**Resolution:** No singularity; metaphysical grounding. **Signature:** Not empirically distinctive; philosophical explanatory framework.

The classical cosmology is based on General Relativity which describes the evolution of the Universe very well, as long as we do not approach the Big Bang. It is supposed that General Relativity fails to provide what must be demanded of a final theory of space and time when the conditions are extreme like at the beginning of our Universe. Therefore, a theory is needed that integrates relativity theory and quantum theory. Such an approach is attempted for instance with the Loop Quantum Gravity, the String Theory and the Causal Set Theory (they are "models" and not "theories" in reality but whatever...).

In what follows we will attempt to determine the Wheeler–DeWitt equation that is a field equation. It is part of a theory that attempts to combine mathematically the ideas of Quantum Mechanics and General Relativity, a step towards a theory of Quantum Gravity. As always in this textbook we will start with a naive approach based on the Newtonian case, after we will complexify the method to apply it to FLRW metrics, finally we will generalize to the metric of any minisuperspace metric.

Remark

A universe which originated as a vacuum fluctuation must have as we know a zero total energy. A simple semi-Newtonian argument is that the positive mass-energy of matter is balanced by their negative gravitational potential, to within a factor of order unity. However actual observations of our observable Universe with our actual technologies seems to not corroborate this hypothesis.

12.6.2.1 Wheeler-DeWitt equation for Newtonian Universe

We will use the Lagrangian formalism of Analytical Mechanics and some assumptions to obtain the cosmological differential equations analogous to Friedmann and Einstein equations, obtained from the theory of General Relativity. This method can be used to a Universe constituted of incoherent matter, that is, the cosmologic substratum is comprised of dust. It will help us to understand a more complex model that we will introduce further below for the FLRW Universe.

Quantum Newtonian cosmology is the theoretical framework within which it is possible to find the wave function which predicts the behaviour of the Newtonian universe. This wave function for Newtonian cosmology is obtained in non-relativistic quantum mechanics, and thus, all we need is to solve the Schrödinger equation for the system under consideration.

The kinetic energy for the motion of a galaxy expressed in fixed rectangular coordinates (comoving) is a function only of and, if the galaxy moves in a conservative force field, the potential energy is a function only of $\dot{R}$. Thus, we can write using the notation of Analytical Mechanics:

$$E_c=T=T(\dot{R}) \qquad E_p=U=U(R) \tag{12.6.21}$$

With the usual expressions for the kinetic and gravitational potential energies, the Lagrangian $L(q,\dot{q})$ for the motion of a galaxy of mass m in the expansion is:

$$L(R,\dot{R})=T-U=\frac{1}{2}m\dot{R}^2+\frac{GMm}{R} \tag{12.6.22}$$

where we choose the generalized coordinates $q=R$ and $\dot{q}=\dot{R}$. In the relation above M is the total mass of the universe, that we assume to be distributed in a sphere of radius R.

If we assume that there is a cosmological force on a particle (galaxy) of the gas, given as seen earlier above (page 6015) by:

$$F_\Lambda=\frac{c^2\Lambda mR}{3} \tag{12.6.23}$$

we have an additional potential energy given by:

$$U_\Lambda=-\int F_\Lambda \mathrm{d}R'=-\frac{1}{6}c^2\Lambda mR \tag{12.6.24}$$

This implies that the Lagrangian changes to:

$$L(R,\dot{R})=T-U_{\text{eff}}=T-U-U_\Lambda=\frac{1}{2}m\dot{R}^2+\frac{GMm}{R}+\frac{1}{6}c^2\Lambda mR \tag{12.6.25}$$

Now, using the Euler-Lagrange equation far a conservative system, namely:

$$\frac{\partial L}{\partial q}-\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial \dot{q}}\right)=0 \tag{12.6.26}$$

we have:

$$\begin{gathered}\frac{\partial L}{\partial R}=-\frac{GMm}{R^2}+\frac{1}{3}c^2\Lambda mR\\ \frac{\partial L}{\partial \dot{R}}=m\dot{R}\Rightarrow\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial \dot{q}}\right)=m\ddot{R}\end{gathered} \tag{12.6.27}$$

Substituting the both relations above into the Euler-Lagrange, we get the equation of motion:

$$\ddot{R}=-\frac{GM}{R^2}+\frac{1}{3}c^2\Lambda mR \tag{12.6.28}$$

Since the mass of the sphere is given by:

$$M=\frac{4}{3}\pi R^3\rho \tag{12.6.29}$$

then the equation of motion becomes:

$$\ddot{R}=-\frac{4}{3}\pi G\rho R+\frac{1}{3}c^2\Lambda mR \tag{12.6.30}$$

Therefore, this is the Newtonian cosmological equation for the scale parameter R that governs the universe expansion. This is a nice intermediate result as this equation is analogous to the Einstein Field equations obtained from theory of General Relativity, in the case $P=0$, that is, dust cloud.

According our previous assumption the time is homogeneous within an inertial reference frame. Therefore, the Lagrangian that describes a closed system, i.e., a system not interacting with anything outside the system, cannot depend explicitly on the time. In our case, the Lagrangian is likewise independent of the time, because the system is under the action of a uniform force field. Thus, the constant quantity of the motion is H, the Hamiltonian of the system, which is for recall given by:

$$H=p\dot{q}-L=\left(\frac{\partial L}{\partial \dot{q}}\right)\dot{q}-L \tag{12.6.31}$$

As re-parametrization invariance implies vanishing Hamiltonian (see section Analytical Mechanics page 3182) we must have:

$$H=\left(\frac{\partial L}{\partial \dot{R}}\right)\dot{R}-L=0 \tag{12.6.32}$$

Therefore:

$$H_{\text{Newt.}}=m\dot{R}\dot{R}-\left(\frac{1}{2}m\dot{R}^2+\frac{GMm}{R}+\frac{1}{6}c^2\Lambda mR\right)=0 \tag{12.6.33}$$

Regrouping we get:

$$H_{\text{Newt.}}=\frac{1}{2}m\dot{R}^2-\frac{GMm}{R}-\frac{1}{6}c^2\Lambda mR=0 \tag{12.6.34}$$

Written in term of the momentum:

$$p=\left(\frac{\partial L}{\partial \dot{R}}\right)=m\dot{R} \tag{12.6.35}$$

we get:

$$H_{\text{Newt.}}=\frac{1}{2}\frac{p^2}{m}-\frac{GMm}{R}-\frac{1}{6}c^2\Lambda mR=0 \tag{12.6.36}$$

Let us transform now that latter relation into an Hermitian operator such that we can build something of the form:

$$H\Psi=0 \tag{12.6.37}$$

also often denoted $\hat{H}(x)|\Psi\rangle=0$. Although the symbols $\hat{H}$ and $|\Psi\rangle$ may appear familiar, their interpretation in the Wheeler-DeWitt equation is substantially different from non-relativistic quantum mechanics. $|\Psi\rangle$ is no longer a spatial wave function in the traditional sense of a complex-valued function that is defined on a 3 dimensional space-like surface and normalized to unity. Instead it is a functional of field configurations on all of space-time! This wave function contains all of the information about the geometry and matter content of the universe. $\hat{H}$ is still an operator that acts on the Hilbert space of wave functions, but it is not the same Hilbert space as in the non-relativistic case, and the Hamiltonian no longer determines evolution of the system.

This property is known as "timelessness". The static Cosmos implied by the Wheeler-DeWitt equation $H\Psi=0$ seems quite obvious once one realizes that time is an emergent concept rather than a fundamental one (this theoretical result disturbs even some professional physicists and even some published scientific papers are dedicated only to this topic like [303]). As the Cosmos doesn't have any external thing that can makes it evolve the timelessness implies some violation of conservation laws.

The "problem of time" in present physics substantially consists in the fact that a straightforward quantization of the general relativistic evolution equation and constraints generates for the Universe wave function the Wheeler-De Witt equation, which describes a static Universe! Some physiciscts have considered the fact that there exist states of a system composed by entangled subsystems that are stationary, but one may interpret the component subsystems as evolving: this leads them to suppose that the global state of the universe can be envisaged as one of this static entangled state, whereas the state of the subsystems can evolve. Such system seems to have been verified like presented in [398].

This property suggests that the universe as a whole may be timeless, and what we perceive as time is a local, emergent phenomenon that is not fundamental because as we know from General Relativity there's no universal clock!

Remark

The "universe wave function" is a function of all the possible positions of all the particles in the universe. As we know the wave function of a single particle (without including special properties like the spin) is a function $\psi(x, y, z)$ and the wave function of two particles (still without including special properties like the spin) is $\psi(x1, y2, z1, x2, y2, z2)$. Just bare in mind that the wave function of all the particles of the observable universe is estimated actually to be a wave function of about 10^{80} variables.

quote
12.6:6088.#74

> *When people ask me if a god created the universe, I tell them that the question itself makes no sense. Time didn't exist before the big bang, so there is no time for god to make the universe in. It's like asking directions to the edge of the earth; The Earth is a sphere; it doesn't have an edge; so looking for it is a futile exercise. [...]*

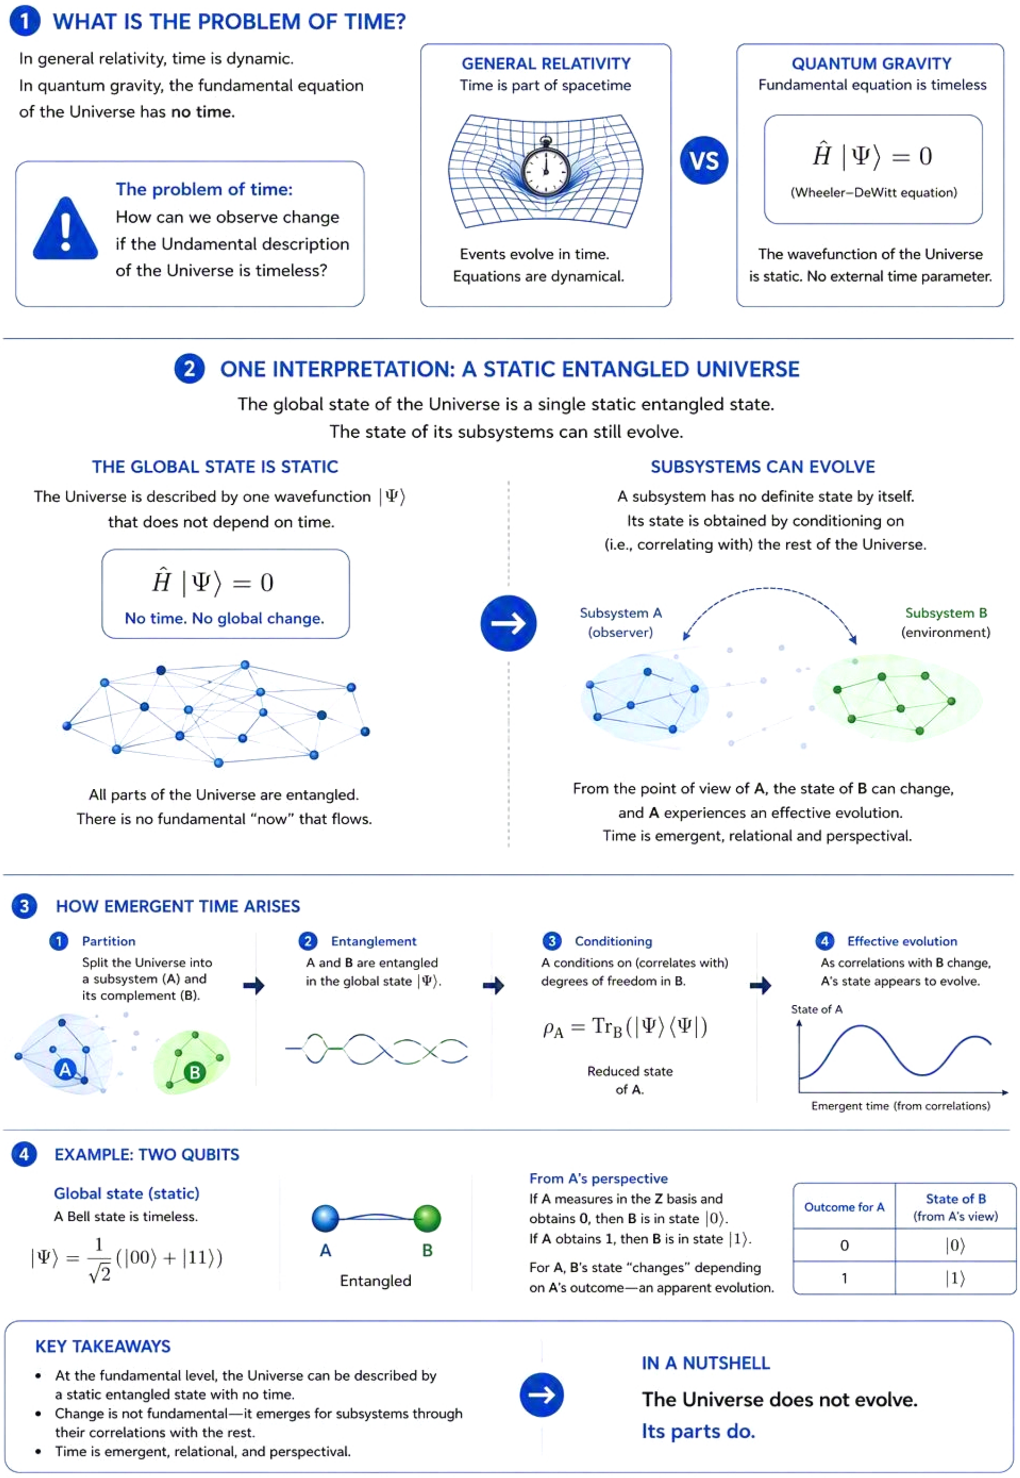
> Stephen Hawking



1 WHAT IS THE PROBLEM OF TIME?

In general relativity, time is dynamic.
In quantum gravity, the fundamental equation of the Universe has **no time.**

The problem of time:
How can we observe change if the Undamental description of the Universe is timeless?

GENERAL RELATIVITY
Time is part of spacetime

Events evolve in time.
Equations are dynamical.

VS

QUANTUM GRAVITY
Fundamental equation is timeless

$$\hat{H}\,|\Psi\rangle = 0$$

(Wheeler–DeWitt equation)

The wavefunction of the Universe is static. No external time parameter.

2 ONE INTERPRETATION: A STATIC ENTANGLED UNIVERSE

The global state of the Universe is a single static entangled state.
The state of its subsystems can still evolve.

THE GLOBAL STATE IS STATIC

The Universe is described by one wavefunction $|\Psi\rangle$ that does not depend on time.

$$\hat{H}\,|\Psi\rangle = 0$$

No time. No global change.

All parts of the Universe are entangled.
There is no fundamental “now” that flows.

SUBSYSTEMS CAN EVOLVE

A subsystem has no definite state by itself.
Its state is obtained by conditioning on (i.e., correlating with) the rest of the Universe.

From the point of view of **A**, the state of **B** can change, and **A** experiences an effective evolution.
Time is emergent, relational and perspectival.

3 HOW EMERGENT TIME ARISES

1. **Partition** — Split the Universe into a subsystem (A) and its complement (B).
2. **Entanglement** — A and B are entangled in the global state $|\Psi\rangle$.
3. **Conditioning** — A conditions on (correlates with) degrees of freedom in B.

$$\rho_{\mathrm{A}} = \mathrm{Tr}_{\mathrm{B}}(|\Psi\rangle\langle\Psi|)$$

Reduced state of A.

4. **Effective evolution** — As correlations with B change, A's state appears to evolve.

4 EXAMPLE: TWO QUBITS

Global state (static)
A Bell state is timeless.

$$|\Psi\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$$

Entangled

From A's perspective
If **A** measures in the **Z** basis and obtains **0**, then **B** is in state $|0\rangle$.
If **A** obtains **1**, then **B** is in state $|1\rangle$.

For **A**, **B**'s state “changes” depending on A's outcome—an apparent evolution.

Outcome for A	State of B (from A's view)
0	$\|0\rangle$
1	$\|1\rangle$

KEY TAKEAWAYS

- At the fundamental level, the Universe can be described by a static entangled state with no time.
- Change is not fundamental—it emerges for subsystems through their correlations with the rest.
- Time is emergent, relational, and perspectival.

IN A NUTSHELL

The Universe does not evolve.
Its parts do.

For this purpose we make the famous replacement:

$$p \to -i\hbar\frac{\partial}{\partial R} \tag{12.6.38}$$

Then the "Hamiltonian operator for a particle (or galaxy or whatever) moving in a Newtonian Universe" is given by :

$$H_{\text{Newt.}}(R) = -\frac{\hbar^2}{2m}\frac{\partial^2}{\partial R^2} - \frac{GMm}{R} - \frac{1}{6}c^2\Lambda m R \tag{12.6.39}$$

Therefore $H(a)\Psi(a)=0$ will be written under the form of the "Wheeler-DeWitt equation for a Newtonian Universe":

$$\boxed{\left\{-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial a^2}-\frac{GMm}{R}-\frac{1}{6}c^2\Lambda mR\right\}\Psi(a)=0} \qquad (12.6.40)$$

where we will consider that the wave function depends only on the scale factor R.

If we rewrite the above relation as:

$$\left\{-\hbar^2\frac{\partial^2}{\partial a^2}+E_p\right\}\Psi(a)=0 \qquad (12.6.41)$$

we recognise here a one-dimensional time-independent Schrödinger where the potential energy is given by:

$$E_p=-\frac{GMm}{R}-\frac{1}{6}c^2\Lambda mR \qquad (12.6.42)$$

12.6.2.2 Wheeler-DeWitt equation for FLRW Universe

Presented below is a derivation of the Wheeler-DeWitt equation in the minisuperspace approximation[79] which also includes matter and radiation and arbitrary values of k.

Let us recall that we have derived earlier (see page 5987) above the following form of the general Friedmann equations assuming a Friedmann-Lemaître-Robertson-Walker (FLRW) Universe:

$$\begin{aligned}H^2=\left(\frac{\dot{a}}{a}\right)^2&=\frac{8\pi G}{3c^2}(\rho+\rho_{\text{vac}})-\frac{kc^2}{a^2}\\ \frac{\ddot{a}}{a}&=\frac{8\pi G}{c^2}\rho_{\text{vac}}-\frac{\dot{a}^2}{a^2}-\frac{kc^2}{a^2}-\frac{8\pi G}{c^2}P\end{aligned} \qquad (12.6.43)$$

Let us also recall the Euler-Lagrange equation for a conservative system (see section Analytical Mechanics page 3169):

$$\frac{\partial L}{\partial q_i}-\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{q}_i}=0 \qquad (12.6.44)$$

Now let suppose we put empirically (trial and error) a density Lagrangian (remember that the Hilbert-Einstein action deals with density Lagrangian!) for the FLRW Universe of the following form[80]:

$$\mathcal{L}=-\kappa a^3\left[\left(\frac{\dot{a}}{a}\right)^2-\frac{kc^2}{a^2}+\frac{8\pi G}{9c^2}(\rho+\rho_{\text{vac}})\right] \qquad (12.6.45)$$

where:

$$\kappa\propto\frac{c^2}{G} \qquad (12.6.46)$$

---

[79] An approximation which is sometimes taken is to only consider the largest wavelength modes of the order of the size of the Universe when studying cosmological models. This is the "minisuperspace approximation".

[80] In facts it can be derived from the Einstein-Hilbert action with matter and cosmological constant and using the FLRW Ricci scalar.

Remark

In some textbooks a simplified version of the above density Lagrangian can be found. First by choosing $k=1$ and distributing $-a^3$ in the square brackets and defining $1/a_0=\frac{8\pi G}{9c^2}(\rho+\rho_{\text{vac}})$:

$$\mathcal{L}=\kappa\left[-\dot{a}^2a+ac^2-\frac{a^3}{a_0}\right]=\kappa\left[-\dot{a}^2a+a\left(c^2-\frac{a^2}{a_0}\right)\right] \tag{12.6.47}$$

and in the worst case where the author write it in natural units, it simplifies to:

$$\mathcal{L}=\kappa'\left[-\dot{a}^2a+a\left(1-\frac{a^2}{a_0'}\right)\right] \tag{12.6.48}$$

With this the Lagrangian density has the unit of energy. Just let check that by rewriting the relation above but expliciting the units:

$$[\text{J}]=\kappa[\text{m}^3]\left[[\text{s}^{-2}]+[\text{s}^{-2}]+[\text{s}^{-2}][\text{s}^{-2}]\right]=\kappa[\text{m}^3\cdot\text{s}^{-2}] \tag{12.6.49}$$

So to transform that into an energy κ must have the units of $[\text{kg}\cdot\text{m}^{-1}]$ and this is exactly the units of $3\pi c^2/4G$ (remember that the units of G are $[\text{m}^3\cdot\text{kg}^{-1}\cdot\text{s}^{-2}]$).

We have for the momentum:

$$p=\frac{\partial\mathcal{L}}{\partial\dot{a}}=-\kappa 2a\dot{a} \tag{12.6.50}$$

And:

$$\frac{\partial\mathcal{L}}{\partial a}=-\kappa\frac{\partial}{\partial a}\left[a\dot{a}^2-kc^2a+a^3\frac{8\pi G}{9c^2}(\rho+\rho_{\text{vac}})\right]=-\frac{\kappa}{k^{3/2}}\left(\dot{a}^2-kc^2+a^2\frac{8\pi G}{3c^2}(\rho+\rho_{\text{vac}})\right) \tag{12.6.51}$$

Substituting into the Euler-Lagrange equation we get:

$$\frac{\partial\mathcal{L}}{\partial a}-\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial\mathcal{L}}{\partial\dot{a}}=-\kappa\left(\dot{a}^2-kc^2+a^2\frac{8\pi G}{3c^2}(\rho+\rho_{\text{vac}})\right)-\frac{\mathrm{d}}{\mathrm{d}t}(-\kappa 2a\dot{a})=0 \tag{12.6.52}$$

i.e. (we see that we can eliminate the unit normalisation constant and the scale factor):

$$-\left(\dot{a}^2-kc^2+a^2\frac{8\pi G}{3c^2}(\rho+\rho_{\text{vac}})\right)+\frac{\mathrm{d}}{\mathrm{d}t}(2a\dot{a})=0 \tag{12.6.53}$$

We assume that there is no time dependant variable (is one of the many plausible weakness of this model). Therefore:

$$-\dot{a}^2+kc^2-a^2\frac{8\pi G}{3c^2}(\rho+\rho_{\text{vac}})=0 \tag{12.6.54}$$

If we divide both side by a^2 and rearrange we get:

$$\left(\frac{\dot{a}}{a}\right)^2=\frac{8\pi G}{3c^2}(\rho+\rho_{\text{vac}})-\frac{kc^2}{a^2} \tag{12.6.55}$$

So we fall back on the velocity equation (12.6.43) and this justifies our initial choice!

Now let us recall the hamiltonien (see section Analytical Mechanics page 3182):

$$H(q_i,p_i)=\sum_{i=1}^{n}\dot{q}_i p_i-L(q_i,\dot{q}_i) \tag{12.6.56}$$

Therefore in the case of one variable:

$$H(q,p)=\dot{q}p-L(q,\dot{q}) \tag{12.6.57}$$

That is written in the current context:

$$\begin{aligned}\mathcal{H}_{\text{FLRW}}(a,p)&=\dot{a}p-\mathcal{L}(a,\dot{a})=\dot{a}(-\kappa 2a\dot{a})-\left[-\kappa a^3\left[\left(\frac{\dot{a}}{a}\right)^2-\frac{kc^2}{a^2}+\frac{8\pi G}{9c^2}(\rho+\rho_{\text{vac}})\right]\right]\\&=\kappa a^3\left[-2\left(\frac{\dot{a}}{a}\right)^2+\left(\frac{\dot{a}}{a}\right)^2-\frac{kc^2}{a^2}+\frac{8\pi G}{9c^2}(\rho+\rho_{\text{vac}})\right]\\&=\kappa a^3\left[-\left(\frac{\dot{a}}{a}\right)^2-\frac{kc^2}{a^2}+\frac{8\pi G}{9c^2}(\rho+\rho_{\text{vac}})\right]\\&=-\kappa a^3\left[\left(\frac{\dot{a}}{a}\right)^2+\frac{kc^2}{a^2}-\frac{8\pi G}{9c^2}(\rho+\rho_{\text{vac}})\right]\end{aligned} \tag{12.6.58}$$

As re-parametrization invariance implies vanishing Hamiltonian (see section Analytical Mechanics page 3182) we have:

$$\mathcal{H}_{\text{FLRW}}(a,p)=-\kappa a^3\left[\left(\frac{\dot{a}}{a}\right)^2+\frac{kc^2}{a^2}-\frac{8\pi G}{9c^2}(\rho+\rho_{\text{vac}})\right]=0 \tag{12.6.59}$$

Written in term of the momentum and dividing both sides by $-\kappa a^3$:

$$p=\frac{\partial\mathcal{L}}{\partial\dot{a}}=-\kappa 2a\dot{a}\Leftrightarrow\left(\frac{\dot{a}}{a}\right)^2=\frac{p^2}{\kappa^2 4a^4}\propto\frac{G^2p^2}{c^4 4a^4} \tag{12.6.60}$$

We get:

$$\mathcal{H}_{\text{FLRW}}(a,p)\propto\frac{G^2p^2}{c^4 4a^4}+\frac{kc^2}{a^2}-\frac{8\pi G}{9c^2}(\rho+\rho_{\text{vac}})=0 \tag{12.6.61}$$

Let us simplify it a bit more:

$$\mathcal{H}_{\text{FLRW}}(a,p)\propto p^2+\frac{4a^2c^2}{G^2}\left[kc^2-\frac{8\pi Ga^2}{9c^2}(\rho+\rho_{\text{vac}})\right]=0 \tag{12.6.62}$$

Let us also transform now that latter relation into an Hermitian operator such that we can build something of the form:

$$\mathcal{H}\Psi=0 \tag{12.6.63}$$

For this purpose we make the famous replacement:

$$p \rightarrow -\mathrm{i}\hbar\frac{\partial}{\partial a} \qquad (12.6.64)$$

Then the "Hamiltonian operator for a particle (or galaxy or whatever) moving in a FLRW Universe" is given by :

$$\mathcal{H}_{\text{FLRW}}(a) \propto -\hbar^2\frac{\partial^2}{\partial a^2}+\frac{4a^2c^2}{G^2}\left[kc^2-\frac{8\pi G a^2}{9c^2}(\rho+\rho_{\text{vac}})\right]=0 \qquad (12.6.65)$$

Therefore $\mathcal{H}(a)\Psi(a)=0$ will be written under the form of the "Wheeler-DeWitt equation for a FLRW Universe":

$$\boxed{\left\{-\hbar^2\frac{\partial^2}{\partial a^2}+\frac{4a^2c^2}{G^2}\left[kc^2-\frac{8\pi G a^2}{9c^2}(\rho+\rho_{\text{vac}})\right]\right\}\Psi(a)=0} \qquad (12.6.66)$$

where we will consider that the wave function depends only on the scale factor a.

Remark

In some papers or textbooks the above relation can be found in the following shape:

$$\left\{\frac{d^2}{da^2}-\frac{9\pi c^4a^2}{4\hbar^2G^2}\left[kc^2-\frac{8\pi G a^2}{3c^2}(\rho+\rho_{vac})\right]\right\}\Psi(a)=0 \qquad (12.6.67)$$

Let us consider the expression for the energy density introduced earlier:

$$\rho=A_\omega a^{-3(\omega+1)} \qquad (12.6.68)$$

where for recall $A_\omega=\rho_{\omega 0}a_0^{3(\omega+1)}$ with $\rho_{\omega 0}$ being the value of ρ_ω at present time, and ω is such that:

$$\omega=\begin{cases}0 \text{ for dust (matter predominance; } \rho_m)\\ \dfrac{1}{3} \text{ for radiation (radiation predominance; } \rho_r)\\ -1 \text{ for de Sitter (false vacuum; } \rho_v)\end{cases} \qquad (12.6.69)$$

The energy density of the vacuum, ρ_{vac}, can be expressed, in terms of the cosmological constant, in the following form:

$$\rho_{\text{vac}}=\frac{\Lambda c^4}{8\pi G} \qquad (12.6.70)$$

Now, substituting all this in the WdW equation above we get:

$$-\hbar^2\frac{\mathrm{d}^2\Psi(a)}{\mathrm{d}a^2}+U_{\text{eff}}(a)\Psi(a)=0 \qquad (12.6.71)$$

where:

$$U_{\text{eff}}(a)=\frac{9\pi^2c^6k}{4G^2}\left[a^2-\frac{1}{k}\left(\frac{\Lambda}{3}a^4+\frac{8\pi G A_\omega}{3c^4}a^{1-3\omega}\right)\right] \qquad (12.6.72)$$

If we rewrite the above relation as:

$$\left\{-\hbar^2\frac{\partial^2}{\partial a^2}+E_p\right\}\Psi(a)=0 \tag{12.6.73}$$

we recognise here a one-dimensional time-independent Schrödinger equation for a particle with $1/2$ of the unit mass and where:

$$E_p \propto \frac{4a^2c^2}{G^2}\left[kc^2-\frac{8\pi Ga^2}{9c^2}(\rho+\rho_{\text{vac}})\right] \tag{12.6.74}$$

Note that for small values of a we can neglect the terms proportional to a^4 and therefore:

$$E_p \propto \frac{4a^2c^2}{G^2}kc^2 \tag{12.6.75}$$

In this case, the solution of the WdW equation is given in terms of Bessel functions (see section Sequences and Series page 1768) and the wave function approaches a constant for $a\rightarrow 0$. On the other hand, for arbitrary values of a, the potential is not so simple, and as a consequence, the solutions of the WdW equation are more complicated and given in terms of Heun functions (see [467]).

Note that when $a=0$ the universe corresponds to a quantum FRW universe with zero radius. In this case, the solution of the WdW equation approaches a constant and describes a state named "nothing[81]" in some literature. This state can be generated by quantum mechanically tunnelling through the potential barrier that appears at $a=a_0\neq 0$. And the reader must really keep in mind that quantum tunnelling can be crudely understood as a quantum effect that result from the Heisenberg uncertainty principle: a temporary upward fluctuation in the particle's energy sends it over the barrier.

Remark

For the readers interested in further reading, we strongly recommend the following references: [559] and [314] and finally [558].

Now let us investigate a very simple special case of:

$$\left\{-\hbar^2\frac{\partial^2}{\partial a^2}+\frac{4a^2c^2}{G^2}\left[kc^2-\frac{8\pi Ga^2}{9c^2}(\rho+\rho_{\text{vac}})\right]\right\}\Psi(a)=0 \tag{12.6.76}$$

Focusing on the potential energy term for $k=+1$ (closed three-sphere Universe) and in natural units:

$$E_p \propto 4a^2\left(1-\frac{8\pi a^2}{9}(\rho+\rho_{\text{vac}})\right) \tag{12.6.77}$$

With a slight change of notation (we discard the factor 4 on the way...):

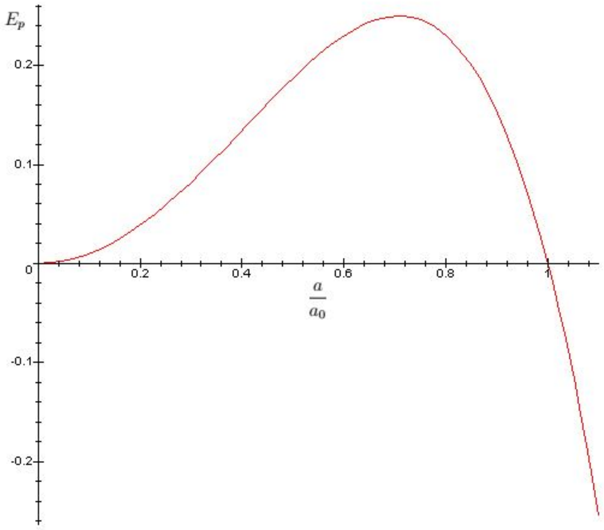
$$E_p \propto a^2\left(1-\frac{a^2}{a_0^2}\right)=4a^2\left(1-\frac{a^2}{a_0^2}\right)=a_0^2\left(\frac{a^2}{a_0^2}-\frac{a^4}{a_0^2}\right)=a_0^2\left[\left(\frac{a}{a_0}\right)^2-\left(\frac{a}{a_0}\right)^4\right] \tag{12.6.78}$$

---

[81] As we already know it from our study of Probabilities and we will see now form the Quantum Physics point of view the nothingness in the philosophical sense is a physical impossibility. So, a scientist who talks about "nothingness" is actually talking about a quantum vacuum.

The shape of the potential is shown in the figure below, where, for convenience. The quantized FRWL universe is thus mathematically equivalent to a simple one-dimensional problem in non-relativistic quantum mechanics-the "particle" at position a represents a universe with that value scale factor.

The region beneath the barrier, $0 < a < a_0$, is classically forbidden to the zero-energy particle; the region $a \geq a_0$ is classically allowed.



The fact that the Big Bang (our Universe) can pop-up from space itself like this is a change of state (or "phase") named a "false vacuum decay". Such a process seems to have been confirmed experimentally at low energies (hopefully...)! For more about such experiments the reader can refer to the papers *False vacuum decay via bubble formation in ferromagnetic superfluids* (see [596]) and *Experimental demonstration of metamaterial "multiverse" in a ferrofluid* (see [502]) where in the latter it is mentioned in the abstract that: «*Thus, thermal fluctuations in a ferrofluid look similar to creation and disappearance of individual Minkowski space-times (universes) in the cosmological multiverse. This theoretical picture is supported by experimental measurements of polarization-dependent optical transmission of a cobalt based ferrofluid at* $1,500$ *[nm]*».

It is worth noting that if our Universe was infinitely old, it would be in a true vacuum. However our Universe has a finite age. At the beginning of it, at the Big Bang, the energy per unit volume was too high so our Universe was neither in the true nor in the false vacuum. Then, as our universe expanded and cooled down, it might have moved to a false vacuum instead of a true one.

Remark

The Wheeler-DeWitt approach to false vacuum decay is often considered more pertinent than the Coleman-De Luccia (CDL) model because it provides a fully quantum-mechanical treatment of the gravitational and scalar field degrees of freedom, whereas the CDL model relies on a semi-classical, Euclidean instanton approximation. While the CDL framework assumes a fixed, classicized background geometry to calculate tunneling rates via a wick-rotated saddle-point evaluation, it breaks down when quantum fluctuations of the metric become large or when the energy barriers approach the Planck scale. By contrast, solving the Wheeler-DeWitt equation the operator constraint equation of canonical quantum gravity, $H\Psi=0$ allows one to determine the wave function of the universe directly, capturing the non-perturbative quantum behavior of space-time itself during the tunneling event and offering a more robust, foundational description of the true quantum-gravitational regime where classical geometry does not exist.

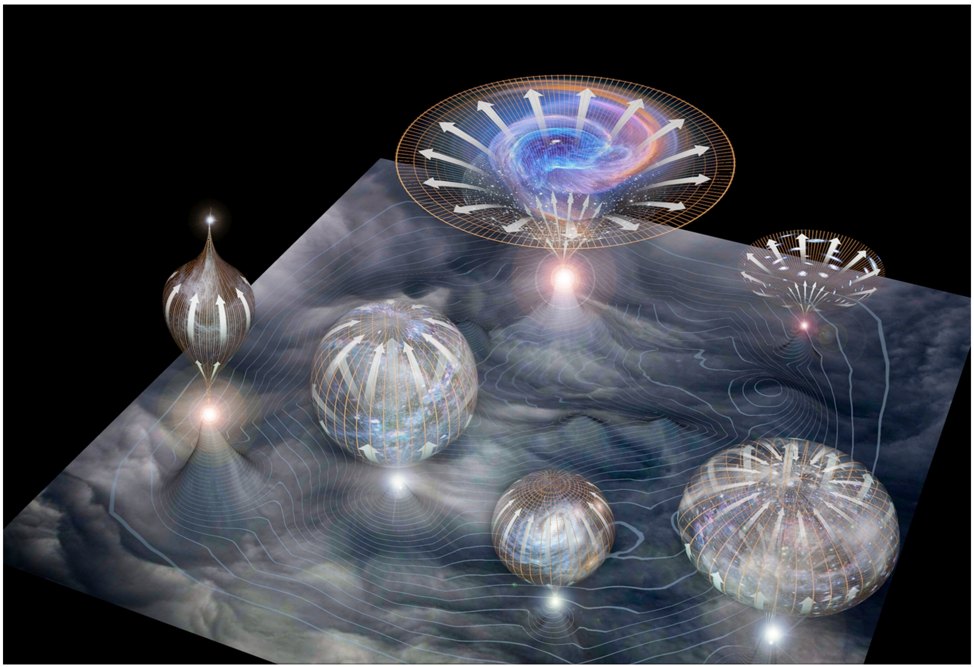


Figure 12.303: **Various universes popping-up from the Cosmos false vacuum (artist: Malcolm Godwin)**

In principle any solution of the Wheeler-DeWitt equation corresponds to a possible quantum state of the universe. It is also clear that the effects of the boundary conditions on the wavefunction will act to severely restrict the class of possible solutions. In ordinary quantum mechanics these are determined by the physical context of the problem and some set of external conditions. In the case of the universe as a whole the situations is less clear, and in many approaches some suitable set of boundary conditions are postulated instead, based on general arguments involving concepts such as simplicity or economy.

Although the above developments sounds like a blatant violation of energy conservation, it is in fact consistent with physics as we know it.

The resolution to the energy paradox lies in the subtle behaviour of gravity. Although it has not been widely appreciated, Newtonian physics unambiguously implies that the energy of a gravitational field is always negative a fact which holds also in General Relativity. The Newtonian argument closely parallels the derivation of the energy density of an electrostatic field, except that the answer has the opposite sign because the force law has the opposite sign: two positive masses attract, while two positive charges repel. The possibility that the negative energy of gravity could balance the positive energy for the matter of the Universe may have been suggested for the first time as early as 11932 (holocene calendar) by Richard Tolman.

So while the energy of matter increases by a factor, the energy of the gravitational field becomes more and more negative to compensate. The total energy - matter plus gravitational - remains constant and very small, and could even be exactly zero. Conservation of energy places no limit on how much the Universe can inflate, as there is no limit to the amount of negative energy that can be stored in the gravitational field.

We will go further in the topic the day we will have a gentle introduction to Heun's differential equations in this textbook.

12.6.3 Why our Universe is a quite massive unpredictable mess

With all the knowledge accumulated so far in fluid mechanics, thermodynamics, electromagnetism, quantum physics, astronomy, astrophysics and cosmogony the reader now can face it!: our (observable) universe is actually messy and also was long time in the past and will likely be for a given time in the future. It is (actually) non-linear, turbulent and chaotic! Our universe isn't "perfect" as some people argue (and by the way... how to these people using this argument quantify "perfectness"...?).

As we already know, Chaos Theory is a branch of physics that describes the evolution of processes that are dependent on initial conditions. Some processes, which at first glance appear to be random, can in fact be based on underlying patterns and interdependencies. In quantum physics however some processes are purely random and without cause as we already know and don't have underlying pattern (i.e. Bell inequalities).

The classic example of a chaotic system is termed as we know the "butterfly effect" (see page 8342): Almost negligible changes in initial conditions can have dramatic and unpredictable effects on the evolution of a chaotic system.

There are several areas of astronomy that benefit from an understanding of Chaos Theory. The obvious one is the gravitational interaction of celestial bodies. Such a system is chaotic,and a tiny error in the positions or velocities of the celestial bodies, or the introduction of small perturbations, means the system is unpredictable in the long term (like most of three body systems, see page).

Weather and climate here on Earth are good examples of chaotic systems (see page 8239). Similarly, features such as the Great Red Spot on Jupiter are also chaotic. Although scientists have a good grasp of fluid dynamics and the forces that result in this massive storm system, its formation and evolution cannot be predicted from these principles.

Most of the processes going on in our Universe are actually (and also for a long time in the future) essentially chaotic. The acceleration of charged particles, the creation of cosmic rays, the structure of magnetic fields, nuclear reactions within stars, chemical reactions in interstellar space, and many more phenomena,are all critically dependent on initial conditions. Ultimately, it would be fair to say that our observable Universe is in its actual state chaotic and therefore unpredictable!

Not only do we have 103 well known list of factors that can make a (business) project fail on Earth (basics of risk management applied by risk managers). Similarly because of various completely random and non-random sources, you can die at any moment, have one of the 160 cancers known so far or one of the $4,200$ genetic anomalies and many other probabilistic stuff that show our body and life on Earth isn't perfect (see table of famous life-event probabilities at page 474).

But we have also bigger natural (random or non-random, not human made) events that can at any day (or at some dates quite well known in the future) completely or significantly eradicate humanity or any other life on Earth or on our whole Solar System for some of them, like:

- Pandemia
- Giant solar flare
- Super-volcano eruption
- Impact with celestial body (rogue planet, rogue star, rogue black hole, asteroids, etc.)
- Increase of the size/temperature of our Sun
- Ejection of planetary nebulae (our Sun death)
- Near-Earth supernova
- Decreasing time of Earth rotation (hence increase of temperature)
- Solar system orbits (chaotic) perturbations
- Extinction of Earth magnetic field
- Important climate change (ozone layer)
- Gamma-ray burst (form quasar, neutron/magnetar star)
- Universe wide quantum vacuum decay
- Space-Time universe big rip
- Universe Big Freeze
- Ecological collapse
- Half-life of particles (weak interaction)
- ...

12.7. String Theory

It must be considered in this section that "String Theory" (and verbatim Superstring Theory) is currently - early 121st century (holocene calendar) - speculative and could not be verified (confirmed) or falsified by experience following the scientific method[82]. We should therefore take with caution the developments that follow and to be the most critical possible!

It is also a speculative theory (we can not even use the word "model" yet...) of unification of the forces that is not new since it soon have over thirty years and is trying to bridge the issues of the standard model of particles and also to unite General Relativity and Quantum Physics (which is not without difficulty since the latter is dependent on the background unlike General Relativity). It is one of the many theories that exist in modern physics and is trying in the early 121st century (holocene calendar) this unification (there are dozens of other more or less known).

Remark

If this subject is covered in the Cosmology chapter and not in the Atomistic one it is only for a pedagogical reason! Indeed, the basic formalism of String Theory is much closer to Relativistic Mechanics (Special and General Relativity) than that of the wave quantum physics or quantum physics fields. It seemed therefore more suited to this day (!), to provide continuity in the mathematical formalism and its interpretation rather than a thematic continuity with a relatively different approach than the usual formalism of quantum physics.

Well, String Theory is a theoretical framework in which the point-like particles of particle physics are replaced by one-dimensional objects named "strings" as its name suggest it... It describes how these strings propagate through space and interact with each other. On distance scales larger than the string scale, a string looks just like an ordinary particle, with its mass, charge, and other properties determined by the vibrational state of the string. In String Theory, one of the many vibrational states of the string corresponds to the (hypothesized) graviton, a quantum mechanical particle that maybe carries gravity. Thus String Theory is a theory of quantum gravity.

String Theory is a broad and varied subject that attempts to address a number of deep questions of fundamental physics. String Theory has been applied to a variety of problems in Black Hole physics, early universe cosmology, nuclear physics, and condensed matter physics, and it has stimulated a number of major developments in pure mathematics. Because String Theory potentially provides a unified description of gravity and particle physics, it is a candidate for a theory of everything, a self-contained mathematical model that describes all fundamental forces and forms of matter. Despite much work on these problems, it is not known to what extent String Theory describes the real world or how much freedom the theory allows to choose the details.

---

[82] Notice that the name is also misleading. "String Theory" is not a theory actually but a "Model". Such a similar vocabulary issue also exist with the "Standard Model" that is not a model anymore since decades but a "Theory"!

Remark

Notice that String theory can recover the Hawking–Bekenstein entropy by providing a microscopic count of Black Hole microstates, something semiclassical gravity alone cannot do. Certain extremal Black Holes are modeled as bound states of D-branes and strings, whose quantum excitations can be counted explicitly; the resulting number of microstates matches the Hawking entropy formula ($S = A/4G$ in natural units) exactly, giving a statistical-mechanical foundation to Hawking's thermodynamic result (see [521]).

String theory has also contributed to important results in superconductivity by providing mathematical tools that help model strongly correlated electrons in high-temperature superconductors, where traditional quasiparticle approaches fail. Using holographic duality (AdS/CFT), physicists map the complex quantum behavior of electrons in a lattice to a simpler gravitational problem in a higher-dimensional spacetime, allowing them to predict how materials transition into superconducting phases and how their resistivity behaves near critical temperatures. This approach has yielded accurate predictions for unusual superconducting materials and clarified how quantum phase transitions occur in systems where electron interactions are too entangled to treat individually.

The undeniable advantage of String Theory, besides the fact that mathematically it is quite indigestible but not really worse than General Relativity, is that it avoids in a certain order... many singularities in the calculations unlike other contemporary theories that consider the objects as points (so zero volume and length...).

The undeniable advantage of String Theory, besides the fact that mathematically it is quite indigestible but not really worse than General Relativity, is that it avoids in a certain order ... many singularities in the calculations unlike other contemporary theories that consider the objects as points (so zero volume and length...).

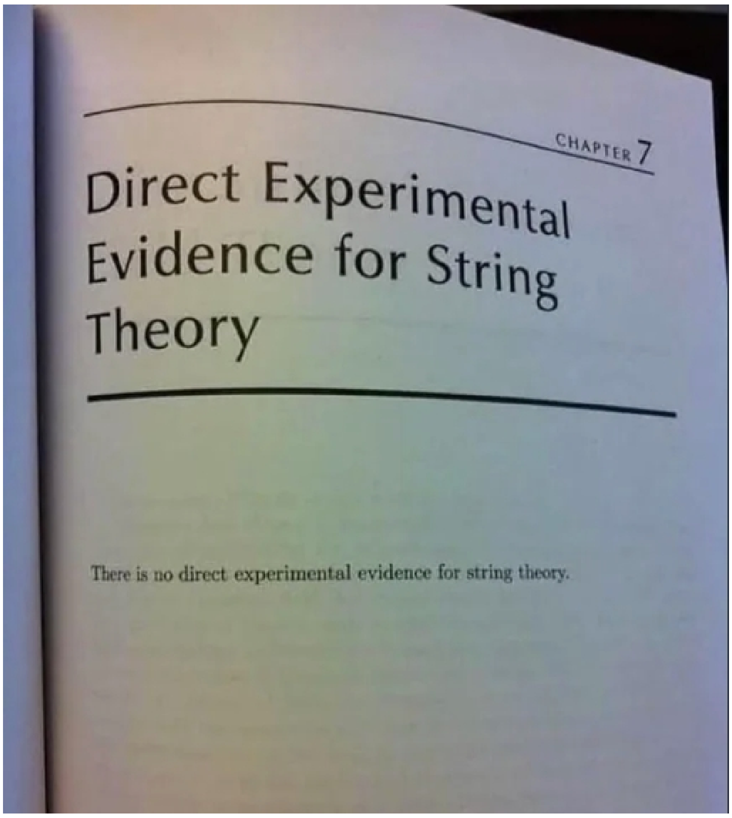
This theory, although aesthetic and remarkable in that it uses for its calculations bases foundations that have over 200 years, is lacking in our opinion to work with successive analogies, as we shall see, with current relativistic and quantum theories. While this is not dramatic in itself, the theory may seem to lose a little of its own autonomy even though the fact it is not. The reader should therefore not be badly surprised in the development that will follow...

The main particularity of String Theory is that his ambition does not stop to this reconciliation, but it claims to successfully unify the four known elementary interactions, we speak therefore about "theory of everything", while staying on two hypothesis/assumptions:

H1. The fundamental building blocks of the universe would not be point particles, but a variety of vibrating string having a given stress in the manner of an elastic. What we perceive as particles with special characteristics (mass, charge, etc.) are merely distinct strings vibrating differently. With this assumption, string theories admit a minimum scale and make it easy to avoid the emergence of some infinite amounts that are inevitable in usual quantum field theories.

H2. The Universe could contain more than three spatial dimensions. Some of them, folded on themselves, being invisible to our scales (by a procedure named "dimensional reduction").

Despite promising first partial promising results and also remarkable rich mathematical background the String Theory remains however incomplete. On the one hand, a multitude of solutions to String Theory equations exist, which poses a selection problem for our Universe and, secondly, even if many similar models were obtained, none of them allows to reproduce accurately the standard model of particle physics...



CHAPTER 7

Direct Experimental Evidence for String Theory

There is no direct experimental evidence for string theory.

That said ... let us begin our initiation:

12.7.1 Wave equation of a transversal string

The aim here will be in a first step to determine the non-relativistic wave equation of a string excited transversely using calculations that we made in the section of Wave Mechanics. Once this work done, we will pass to the study of relativistic strings and see their wave equation, as well as the non-relativistic version, can be assimilated to the current conservation equation we had proved in the section of Electrodynamics.

We begin by recalling the form of the action that we proved in the section of Wave Mechanics for a non-relativistic string (see page 3496):

$$S=\int_{t_1}^{t_2}\mathrm{d}t\int_0^L \mathrm{d}x\mathcal{L}\left(\frac{\partial y}{\partial t},\frac{\partial y}{\partial t}\right) \tag{12.7.1}$$

with:

$$L=\int\limits_0^L\left[\frac{1}{2}\rho\left(\frac{\partial y}{\partial t}\right)^2-\frac{1}{2}F\left(\frac{\partial y}{\partial x}\right)^2\right]\mathrm{d}x=\int\limits_0^L\mathcal{L}\mathrm{d}x \tag{12.7.2}$$

Now, in the same way as we did in thE section of Analytical Mechanics at page 3155 (and in that of Quantum Field Theory), we will define a notation by an analogy to the canonical moments of the string:

$$\mathcal{P}^t:=\frac{\partial\mathcal{L}}{\partial\dot{y}}\qquad\mathcal{P}^x:=\frac{\partial\mathcal{L}}{\partial y'} \tag{12.7.3}$$

with $y'=\partial y/\partial x$. It is simply the derivatives from the Lagrangian density with respectively the first and second argument. More explicitly, we get then directly by doing the calculation (see section Wave Mechanics page 3497):

$$\mathcal{P}^t:=\rho_l\frac{\partial y}{\partial t}\qquad\mathcal{P}^x:=-F\frac{\partial y}{\partial x} \tag{12.7.4}$$

So if we rewrite the variational of the action we obtained in the section of Wave Mechanics with this canonical notation, we get:

$$S=\int\limits_{t_i}^{t_f}\mathrm{d}t\int\limits_0^L\mathrm{d}x\left[\rho_l\frac{\partial y}{\partial t}\frac{\partial(\delta y)}{\partial t}-F\frac{\partial y}{\partial x}\frac{\partial(\delta y)}{\partial x}\right]=\int\limits_{t_i}^{t_f}\mathrm{d}t\int\limits_0^L\mathrm{d}x\left[\frac{\partial\mathcal{L}}{\partial\dot{y}}\delta\dot{y}+\frac{\partial\mathcal{L}}{\partial y'}\delta y'\right] \tag{12.7.5}$$

Making use of the same methods as in the section of Wave Mechanics, our variational can be express after simplification again in the form of three terms:

$$\begin{aligned}\delta S&=\int\limits_0^L\left[\rho_l\frac{\partial y}{\partial t}\delta y\right]\Bigg|_{t_i}^{t_f}\mathrm{d}x+\int\limits_{t_i}^{t_f}\left[-F\frac{\partial y}{\partial x}\delta y\right]\Bigg|_0^L\mathrm{d}t-\int\limits_{t_i}^{t_f}\mathrm{d}t\int\limits_0^L\mathrm{d}x\left(\rho_l\frac{\partial^2 y}{\partial t^2}-F\frac{\partial^2 y}{\partial x^2}\right)\delta y\\&=\int\limits_0^L\left[\mathcal{P}^t\delta y\right]\Big|_{t_i}^{t_f}\mathrm{d}x+\int\limits_{t_i}^{t_f}\left[\mathcal{P}^x\delta y\right]\Big|_0^L\mathrm{d}t-\int\limits_{t_i}^{t_f}\mathrm{d}t\int\limits_0^L\mathrm{d}x\left(\frac{\partial\mathcal{P}^t}{\partial t}+\frac{\partial\mathcal{P}^x}{\partial x}\right)\delta y\end{aligned} \tag{12.7.6}$$

The conditions to find the extreme value (according to the principle of least action) are the same as those seen in the section of Wave Mechanics. Thus, for the third term, we therefore have the wave equation of a transversely excited string with the canonical form given by:

$$\boxed{\frac{\partial\mathcal{P}^t}{\partial t}+\frac{\partial\mathcal{P}^x}{\partial x}=0} \tag{12.7.7}$$

Remark

It obviously should be noted that this form of writing will greatly facilitate our work!

It must be observed (as it is remarkable!) also that as in the section of Analytical Mechanics, the canonical moment $\mathcal{P}^t$ as defined above, coincides perfectly (the hazard makes things well) with the density momentum that we obtained in the section of Wave Mechanics (see page 3500). Indeed:

$$p_y=\int\limits_0^L(\rho_l\mathrm{d}x)\frac{\partial y}{\partial x}=\int\limits_0^L\rho_l\frac{\partial y}{\partial x}\mathrm{d}x=\int\limits_0^L\mathcal{P}^t\mathrm{d}x \tag{12.7.8}$$

Thus, by analogy with Analytical Mechanics (where we recall, the derivative of the Lagrangian with respect to the speed gives the momentum), $\dot{y}$ plays well the role of speed and thus the derivative of the Lagrangian density by this latter gives the momentum density $\mathcal{P}^t$!!!

Remember also another point that has been seen in the section of Wave Mechanics, the extremum of the action ($\delta S=0$) imposes use the Neumann boundary conditions (see page 3499), which leads us to write $\mathcal{P}^x=0$.

Remark

In the context of String Theory to relativistic with more than 3 dimensions, it is possible to generalize the concept of boundary conditions considering the constraints in space like hypersurfaces named Dp-branes with p dimensions. The usual Dirichlet boundary conditions then correspond to the situation where the ends of a strings are constraint by a 0-brane. The Neumann condition for a free string in p dimensions corresponds to a constraint on a Dp-brane.

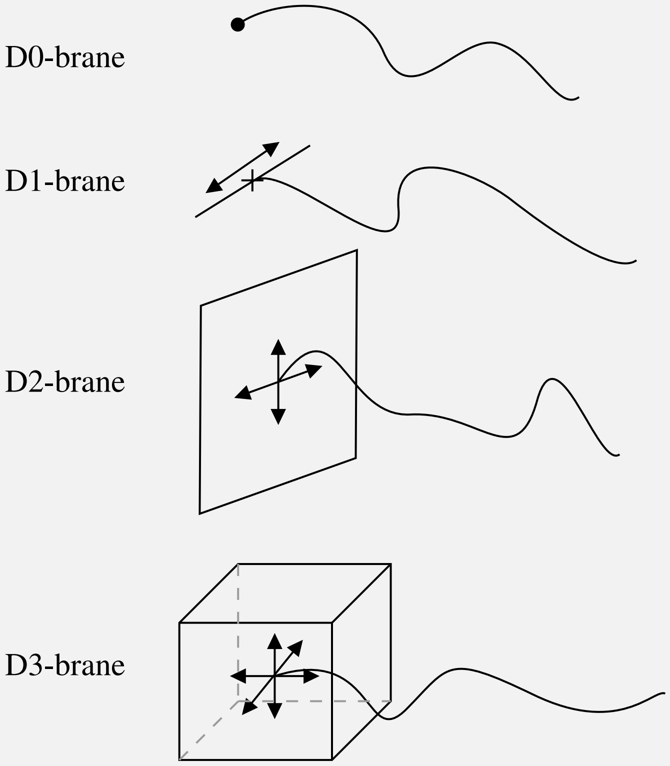


Figure 12.304: **Illustration of Dp-branes**

12.7.2 Non-relativistic Wave equation of a transversal string

We will now determine the action of a relativistic string. We can, to lay the foundations of our study, remember that a point particle draws a line in space-time (each point on the line is marked by a time coordinate and three space coordinates). Therefore, by extension, a string that is a two-dimensional element (if we consider it with no thickness) plots a surface in the space-time.

Thus, just like the line that draw a point particle in space-time is named a "world line" (see section Special Relativity page 5705), the surface traced by a string will by analogy be named a "surface Universe".

A string in a closed space-time Minkowski trace, for example, a tube, while an open string trace a band:

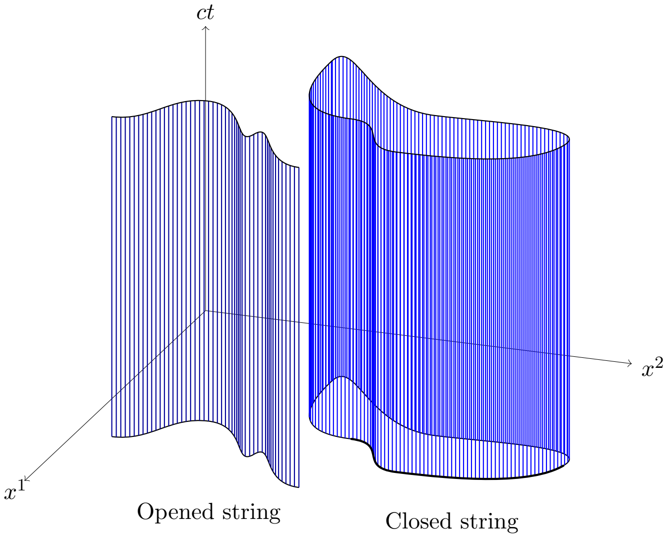

Figure 12.305: Universe surface generated by respectively an opened/closed string (author: Daniel N.)

in the figure above, with two spatial dimensions and one implicit temporal dimension, the string is motionless in our current space. It moves in space-time (as time goes on the vertical axis) but not in space in the example above (it would take an additional spatial component to see such a movement).

Remarks

R1. Remember that the diagram above is in three dimensions while the space-time has four dimensions.

R2. Remember also that the time vector of the orthogonal basis is always perpendicular to all other spatial components (this remark will be useful during our proof of the Nambu-Goto action).

During our proof of the equation of motion in the section of General Relativity (see page 5738), we reparameterized the particle's Universe line with a parameter that was the proper time of the particle t. Indeed, you only have to remember parametric equations that represent curves. For example with Maple™ 4.00b:

```
>with(plots):
>spacecurve([cos(t),sin(t),t],t=0..4*Pi,axes=boxed);
```

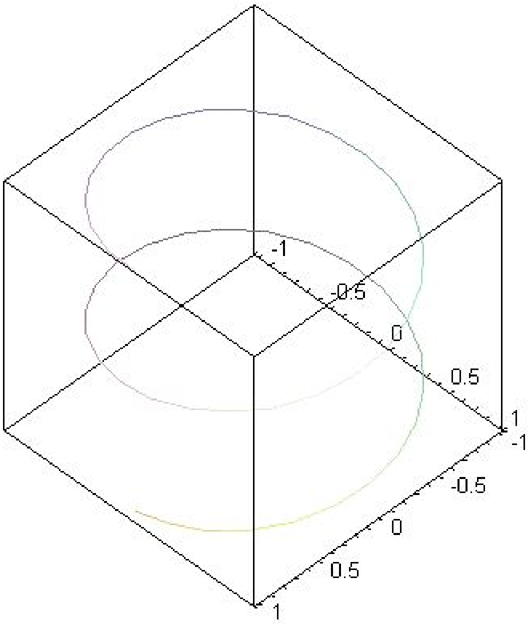

Figure 12.306: **Elementary illustrated refresh of a parametric curve**

and the same procedure is valid for a line in four dimensions (time + space).

We were thus arrived to construct the expression of the action S of it before applying the variational principle.

We will do the same for a relativistic string with the difference that we will re-parametrized the surfaces generated by the strings this time. The constraints we impose are that the chosen parameters will also have to be (in reference to the case of the particle) relativistic invariants.

As we have therefore seen in the section of General Relativity (see page 5738), a world line can be re-parametrized naturally using only one parameter (curvilinear abscissa). A surface in space, however, is a two-dimensional object, we assume by extension that it requires two parameters ζ^1,ζ^2 (one more) to be described completely.

Indeed, we guess, that one of the two parameters will be the proper time (to make the surface evolve in the time), the second parameter will give a "thickness" of what would be only a Universe line if it did not exist. It would be sufficient in a three-dimensional space that the second parameter had, to generate a surface, the dimensions of length but in the four dimension space-time the second parameter must have the units of a surface.

Given a parametrized surface, we can draw on them isolines of the parameters (lines where the two parameters ζ,ζ_2 are constant over the entire surface). These contours cover the surface as a grid (see figure a little bit further below).

The parametric equation of a volume in space requires three parameters as we saw in the section of Analytical Geometry (see page 2800). Thus, if a parametrized area in Euclidean space can be represented by a vector of the type:

$$\vec{f}=\begin{pmatrix} x \\ y \\ z \end{pmatrix} \tag{12.7.9}$$

during a re-parametrization and making use of the tensor notation of Minkowski space-time as seen in the section of General Relativity, we have (by restricting for the moment to the particular case of two spatial dimensions and one of time):

$$\vec{x}=\begin{pmatrix} x^1(\xi^1,\xi^2) \\ x^2(\xi^1,\xi^2) \\ x^3(\xi^1,\xi^2) \end{pmatrix} \tag{12.7.10}$$

Thus, the surface is the image of the parameters (ξ^1,ξ^2). Alternatively, we can see the components (ξ^1,ξ^2) as the time and space coordinates of the surface, at least locally!

We now want to calculate the area of an element of any type of space in the same way as we did for the curvilinear abscissa of any world line in the section of General Relativity. This raises the question of the form of the differential surface element??? Should we take the multiplication of the differential of the two previously selected parameters as being a square, rectangle, circle, or other?

In fact, we will put our choice on a parallelogram! This choice may seem completely arbitrary for now but as we'll see a few lines later, this choice coincides for mathematical reasons with that we name the "induced metric" of the surface itself (rather remarkable result!).

Thus, let us denote by $\mathrm{d}\vec{v}_1$ and $\mathrm{d}\vec{v}_2$ the sides of the parallelogram. They are the image by $\vec{x}$ of the couples $(\xi^1,0)$ and $(0,\xi^2)$ respectively:

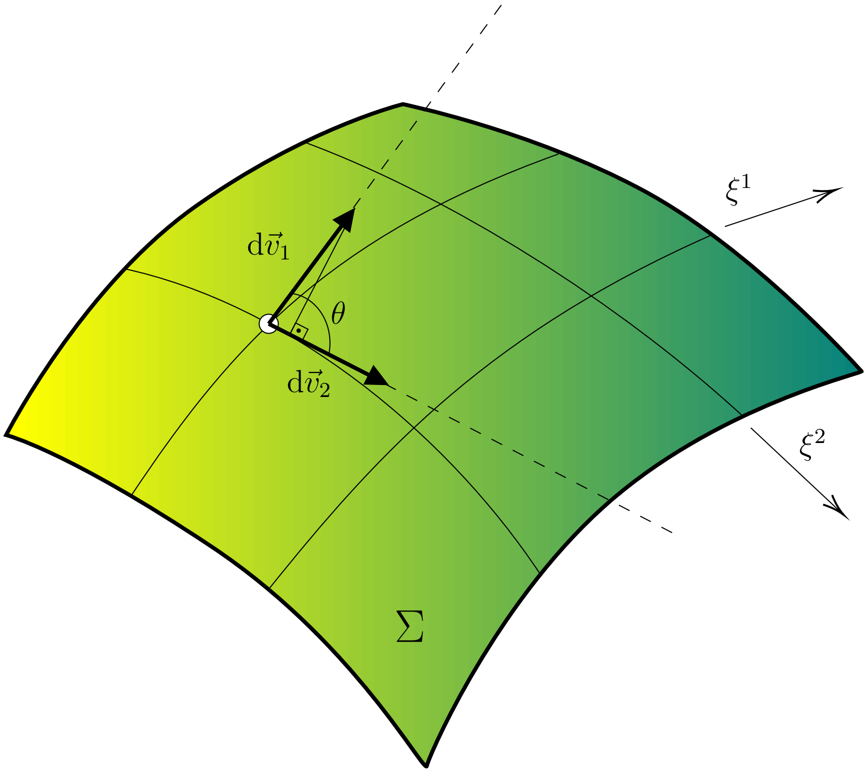

Figure 12.307: **Configuration for the study of an elementary surface element**

Therefore we can write:

$$\frac{\mathrm{d}\vec{v}_1}{\mathrm{d}\xi^1}:=\frac{\partial\vec{x}}{\partial\xi^1},\frac{\mathrm{d}\vec{v}_2}{\mathrm{d}\xi^2}:=\frac{\partial\vec{x}}{\partial\xi^2} \tag{12.7.11}$$

and then:

$$\mathrm{d}\vec{v}_1:=\frac{\partial\vec{x}}{\partial\xi^1}\mathrm{d}\xi^1,\mathrm{d}\vec{v}_2:=\frac{\partial\vec{x}}{\partial\xi^2}\mathrm{d}\xi^2 \tag{12.7.12}$$

Now let us calculate the surface $\mathrm{d}A$ (we will not take the letter S to avoid confusion with the variable representing the action in this section) of the parallelogram (see section Vector Calculus page 1835):

$$\begin{aligned}\mathrm{d}A&=||\mathrm{d}\vec{v}_1||||\mathrm{d}\vec{v}_2||\sin(\theta)=||\mathrm{d}\vec{v}_1||||\mathrm{d}\vec{v}_2||\sqrt{1-\cos^2(\theta)}\\&=\sqrt{||\mathrm{d}\vec{v}_1||^2||\mathrm{d}\vec{v}_2||^2-||\mathrm{d}\vec{v}_1||^2||\mathrm{d}\vec{v}_2||^2\cos^2(\theta)}\end{aligned} \tag{12.7.13}$$

using the dot product, this can be rewritten as:

$$\mathrm{d}A=\sqrt{(\mathrm{d}\vec{v}_1\circ\mathrm{d}\vec{v}_1)(\mathrm{d}\vec{v}_2\circ\mathrm{d}\vec{v}_2)-(\mathrm{d}\vec{v}_1\circ\mathrm{d}\vec{v}_2)^2} \tag{12.7.14}$$

using the previously established relations this can be written:

$$\mathrm{d}A=\mathrm{d}\xi^1\mathrm{d}\xi^2\sqrt{\left(\frac{\partial\vec{x}}{\partial\xi^1}\circ\frac{\partial\vec{x}}{\partial\xi^1}\right)\left(\frac{\partial\vec{x}}{\partial\xi^2}\circ\frac{\partial\vec{x}}{\partial\xi^2}\right)-\left(\frac{\partial\vec{x}}{\partial\xi^1}\circ\frac{\partial\vec{x}}{\partial\xi^2}\right)^2} \tag{12.7.15}$$

the latter relation is the general shape of a surface element of a parametrized pattern. The total surface is obviously given by:

$$A=\int \mathrm{d}\xi^1\mathrm{d}\xi^2\sqrt{\left(\frac{\partial\vec{x}}{\partial\xi^1}\circ\frac{\partial\vec{x}}{\partial\xi^1}\right)\left(\frac{\partial\vec{x}}{\partial\xi^2}\circ\frac{\partial\vec{x}}{\partial\xi^2}\right)-\left(\frac{\partial\vec{x}}{\partial\xi^1}\circ\frac{\partial\vec{x}}{\partial\xi^2}\right)^2} \tag{12.7.16}$$

Just as in the framework of the study of the principle of least action (see section Analytical Mechanics page 3131) we searched the optimum path for a particle browsing a universe line, for a string, we have to search for the optimum of the surface A by minimizing the function $\vec{x}=(\xi^1,\xi^2)$.

This latter form is, however, a little heavy and does not show anything known particularly or is not similar to any form already known in another field of physics. We will see, however that by digging a little bit however it is possible to get something pretty interesting.

Consider now a vector $\mathrm{d}\vec{x}$ and its squared length (norm) given by the scalar product:

$$\mathrm{d}s^2=(\mathrm{d}s)^2=\mathrm{d}\vec{x}\circ\mathrm{d}\vec{x} \tag{12.7.17}$$

Remark

This approach of separating the wave function into the composition of a wave function of the center of mass and the relative movement is also used in the context of the study of poly-electronic atoms, but with one difference: as the nucleus is much more massive than the processing electrons (in approximation ...), the center of mass is assimilated to the nucleus of the atom and the relative motion to the entire electron cloud. This approximate approach is well known under the designation "Born-Oppenheimer approximation".

The vector $\mathrm{d}\vec{x}$ can be expressed in the form of partial derivative terms of $\mathrm{d}\xi^1,\mathrm{d}\xi^2$, such that we get its exact total differential (see section Differential and Integral Calculus page 1466):

$$\mathrm{d}\vec{x}=\frac{\partial\vec{x}}{\partial\xi^1}\mathrm{d}\xi^1+\frac{\partial\vec{x}}{\partial\xi^2}\mathrm{d}\xi^2=\frac{\partial\vec{x}}{\partial\xi^i}\mathrm{d}\xi^i \tag{12.7.18}$$

Thus, the squared length of $\mathrm{d}\vec{x}$ can be expressed in tensor form:

$$\mathrm{d}s^2=\left(\frac{\partial\vec{x}}{\partial\xi^i}\mathrm{d}\xi^i\right)\circ\left(\frac{\partial\vec{x}}{\partial\xi^i}\mathrm{d}\xi^i\right)=\frac{\partial\vec{x}}{\partial\xi^i}\circ\frac{\partial\vec{x}}{\partial\xi^i}\mathrm{d}\xi^i\mathrm{d}\xi^i \tag{12.7.19}$$

what we will note by convention in the future:

$$\mathrm{d}s^2=g_{ij}(\xi)\mathrm{d}\xi^i\mathrm{d}\xi^j \tag{12.7.20}$$

The quantity $g_{ij}(\xi)$ is named the "induced metric of the parametrized area" (because contains a scalar product which quite generally uses a metric... hence the term "induced") and is therefore a matrix of dimension 2×2. It is obvious that the choice of this name comes from the resemblance with the usual metric as we have defined in our study of tensor calculus and from its use in special and General Relativity.

The matrix $g_{ij}(\xi)$ has therefore by design and definition the form:

$$g_{ij}(\xi)=\begin{bmatrix}\dfrac{\partial\vec{x}}{\partial\xi^1}\circ\dfrac{\partial\vec{x}}{\partial\xi^1} & \dfrac{\partial\vec{x}}{\partial\xi^2}\circ\dfrac{\partial\vec{x}}{\partial\xi^2}\\ \dfrac{\partial\vec{x}}{\partial\xi^2}\circ\dfrac{\partial\vec{x}}{\partial\xi^1} & \dfrac{\partial\vec{x}}{\partial\xi^2}\circ\dfrac{\partial\vec{x}}{\partial\xi^2}\end{bmatrix} \tag{12.7.21}$$

Now let us come back to our expression of the surface generated by the string:

$$A=\int \mathrm{d}\xi^1\mathrm{d}\xi^2\sqrt{\left(\dfrac{\partial\vec{x}}{\partial\xi^1}\circ\dfrac{\partial\vec{x}}{\partial\xi^1}\right)\left(\dfrac{\partial\vec{x}}{\partial\xi^2}\circ\dfrac{\partial\vec{x}}{\partial\xi^2}\right)-\left(\dfrac{\partial\vec{x}}{\partial\xi^1}\circ\dfrac{\partial\vec{x}}{\partial\xi^2}\right)^2} \qquad (12.7.22)$$

and let us quickly calculate the determinant (see section Linear Algebra page 1961) of the matrix $g_{ij}(\xi)$:

$$\det(g_{ij}(\xi))=g=g_{11}g_{22}-g_{21}g_{12}=\left(\dfrac{\partial\vec{x}}{\partial\xi^1}\circ\dfrac{\partial\vec{x}}{\partial\xi^1}\right)\left(\dfrac{\partial\vec{x}}{\partial\xi^2}\circ\dfrac{\partial\vec{x}}{\partial\xi^2}\right)-\left(\dfrac{\partial\vec{x}}{\partial\xi^1}\circ\dfrac{\partial\vec{x}}{\partial\xi^1}\right)^2 \qquad (12.7.23)$$

and so what? Well here it is! A can now been expressed as:

$$A=\int \mathrm{d}\xi^1\mathrm{d}\xi^2\sqrt{g} \qquad (12.7.24)$$

Thus, the choice of the parallelogram as elementary surface is best explained here!

Now we will adopt the traditional notations of String Theory in relation to the expression of the surface. Thus, just as the time-space coordinates are described in Special Relativity the space-time four-vector:

$$x^\mu=(x^0,x^1,\ldots,x^d) \qquad (12.7.25)$$

we will describe the surfaces Universe by (we now turn to the notation making use of the four dimensions of space-time):

$$x^\mu(\tau,\sigma)=X^\mu(\tau,\sigma) \qquad (12.7.26)$$

This notation will save us in the future to have to confuse, if the theory leads us there, the traditional space-time coordinates x^μ with the image function of the surface Universe $x^\mu(\tau,\sigma)$ and this especial because physicists being sometimes a little lazy shorten this latter x^μ... hence the choice of the capital letter.

It is then much more appropriate and wise to change the notation.

From now on we will name "string coordinates" the surface Universe described by X^μ.

This small change in notation obviously not change the interpretation of the image of the function. Given a couple (τ,σ) involving proper-time element and surface element of the pre-image, this point is projected onto a surface element of the space-time coordinates of the string:

$$\left(X^0(\tau,\sigma),X^1(\tau,\sigma),\ldots,X^d(\tau,\sigma)\right) \qquad (12.7.27)$$

12.7.2.1 Nambu-Goto Action

The Nambu–Goto action is the simplest invariant action in bosonic String Theory, and is also used in other theories that investigate string-like objects (for example, cosmic strings). It is the starting point of the analysis of zero-thickness (infinitely thin) string behaviour, using the principles of Lagrangian mechanics. Just as the action for a free point particle is proportional to its proper time—i.e., the "length" of its world-line—a relativistic string's action is proportional to the area of the sheet which the string traces as it travels through space-time.

In the case of a Universe surface the parameters are then by convention τ and σ, where as in special and General Relativity, the proper time may be in the range:

$$\tau \in]-\infty,+\infty[\tag{12.7.28}$$

the second can only be positive since this is a surface:

$$\sigma \in]0,\sigma_1[\tag{12.7.29}$$

and the coordinates of this surface corresponding to the parameter space is therefore:

$$X^\mu(\tau,\sigma) \tag{12.7.30}$$

where once again, for recall, the parameter τ is considered as the variable describing the time (there must be one!), and σ the variable describing the spatial extension of a string (that is to say that the condition $\sigma \in]0,\sigma_1[$ involving the finite length of the string).

The parameters (τ,σ) describe therefore a surface in the space of pre-images:

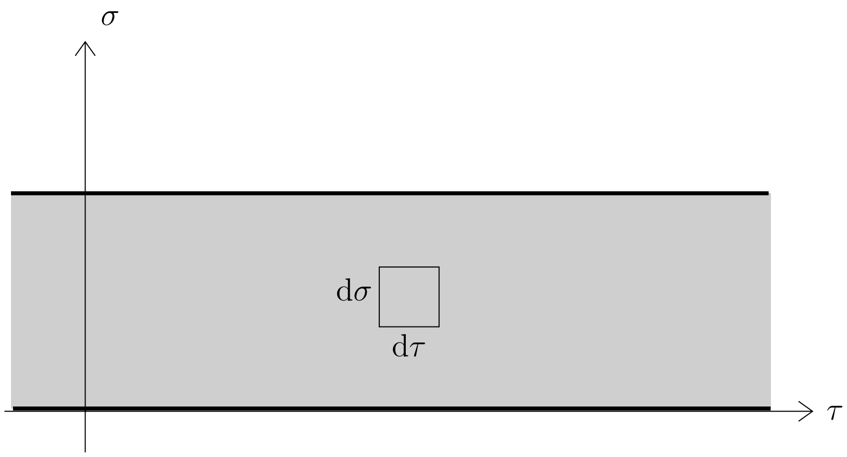

Figure 12.308: **Parametrization of a space-time surface**

The ends of the string have a constant value σ. However, as time passes and that the ends of the string on the Universe surface move we must notice an essential condition of the Universe surface concerning the both ends of an open string:

$$\frac{\partial X^0}{\partial \tau} \neq 0 \tag{12.7.31}$$

Remark

This condition is made on the component X^0 because it corresponds to the component x^0 of the space-time four-vector which is nothing else, in natural units, t (the proper time). Therefore, time passes and is never constant, this is why we impose this derivative as being non-zero.

And using the standard conventions in physics for writing the derivatives with respect to time or space components, we agree to adopt also now the following notations:

$$\dot{X}=\frac{\partial X^\mu}{\partial\tau}\qquad X'=\frac{\partial X^\mu}{\partial\sigma}\tag{12.7.32}$$

since as:

$$X^\mu(\tau,\sigma)=X^\mu(t,\sigma)=(ct,\vec{X}(t,\sigma))\tag{12.7.33}$$

then:

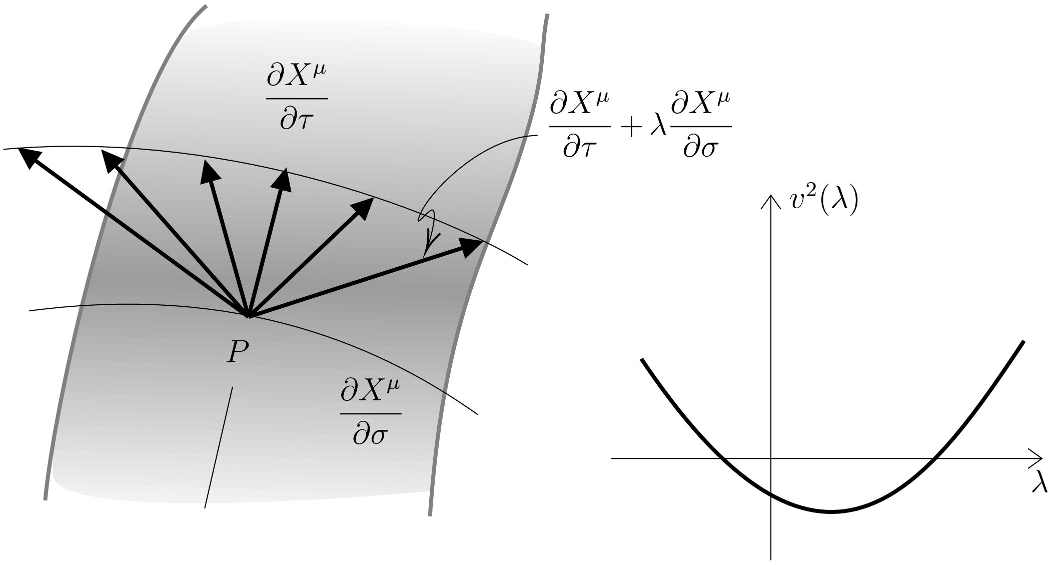
$$\begin{aligned}\frac{\partial X^\mu}{\partial\sigma}&=\left(\frac{\partial X^0}{\partial\sigma},\frac{\partial\vec{X}}{\partial\sigma}\right)=\left(0,\frac{\partial\vec{X}}{\partial\sigma}\right)\\\frac{\partial X^\mu}{\partial\tau}&=\left(\frac{\partial X^0}{\partial t},\frac{\partial\vec{X}}{\partial\tau}\right)=\left(c,\frac{\partial\vec{X}}{\partial t}\right)\end{aligned}\tag{12.7.34}$$

The surface is therefore written:

$$\begin{aligned}A&=\int\mathrm{d}\xi^1\mathrm{d}\xi^2\sqrt{\left(\frac{\partial\vec{x}}{\partial\xi^1}\circ\frac{\partial\vec{x}}{\partial\xi^1}\right)\left(\frac{\partial\vec{x}}{\partial\xi^2}\circ\frac{\partial\vec{x}}{\partial\xi^2}\right)-\left(\frac{\partial\vec{x}}{\partial\xi^1}\circ\frac{\partial\vec{x}}{\partial\xi^2}\right)^2}\\&=\int\mathrm{d}\tau\mathrm{d}\sigma\sqrt{\left(\frac{\partial X^\mu}{\partial\tau}\frac{\partial X_\mu}{\partial\tau}\right)\left(\frac{\partial X^\nu}{\partial\sigma}\frac{\partial X_\nu}{\partial\sigma}\right)-\left(\frac{\partial X^\mu}{\partial\tau}\frac{\partial X_\mu}{\partial\sigma}\right)^2}\\&=\int\mathrm{d}\tau\mathrm{d}\sigma\sqrt{(\dot{X})^2(X')^2-(\dot{X}\circ X')^2}\end{aligned}\tag{12.7.35}$$

However, there is a problem here! Indeed, let us look if the radicand (term under the root) has a tangible physical reality ...

For this, we must first consider the left side of the figure below representing the surface patch described by an open string:



$\frac{\partial X^\mu}{\partial\tau}$
$\frac{\partial X^\mu}{\partial\tau}+\lambda\frac{\partial X^\mu}{\partial\sigma}$
P
$\frac{\partial X^\mu}{\partial\sigma}$
$v^2(\lambda)$
λ

At each point P of this surface patch (assumed differentiable at every point) there are endless tangents, all in the same plane, which we will denote for example by $\vec{v}$ and thus form a surface tangent at P.

Now, as the space in which the surface patch of the string held in a spatial and temporal orthonormal basis, the tangent vectors $\vec{v}$ can then in turn be decomposed into a two-dimensional spatial and temporal local orthogonal base at the point P such that the vectors of the base are two vectors (see our study of surface patches in the section of Differential Geometry at page 2878):

$$\frac{\partial X^\mu}{\partial \tau} \qquad \frac{\partial X^\mu}{\partial \sigma} \tag{12.7.36}$$

all other tangent vectors expressing as a linear combination thereof.

However, a problem remains in our decomposition (...): the unit vectors of the local orthogonal basis at P have units that differ... For this let us add a dimensional factor to the spatial component (this is arbitrary because the conclusion will be the same regardless of the component on which you put the sizing factor) as we did in Special Relativity with the time axis:

$$\frac{\partial X^\mu}{\partial \tau} \qquad \lambda\frac{\partial X^\mu}{\partial \sigma} \tag{12.7.37}$$

This dimensional factor can also be used to get all the tangent vectors such as:

$$v^\mu=\frac{\partial X^\mu}{\partial \tau}+\lambda\frac{\partial X^\mu}{\partial \sigma} \tag{12.7.38}$$

Indeed, if $\lambda\in[-\infty,+\infty]$, then for $\lambda=0$ we get the vector $\partial X^\mu/\partial\tau$ and for $\lambda=+\infty$ the vector $\partial X^\mu/\partial\sigma$. And all intermediate values, we get all the tangent vectors as shown on the left side of the previous figure.

Now, let us recall that we saw in the section of Special Relativity (see page 5707) that there exist according to the curvilinear abscissa:

$$\mathrm{d}s^2=\mathrm{d}x^\nu(\nu_{\mu\nu}\mathrm{d}x^\nu)=\mathrm{d}x^\nu\mathrm{d}x_\nu=c^2\mathrm{d}t^2-\mathrm{d}x^2-\mathrm{d}y^2-\mathrm{d}z^2 \tag{12.7.39}$$

of the Universe line of the light type ($\mathrm{d}s^2$), space ($\mathrm{d}s^2<0$) or time ($\mathrm{d}s^2>0$) if we consider the four-vectors x^μ.

It must be true by analogy the same for the tangent vectors to the surface and given by:

$$v^\mu=\frac{\partial X^\mu}{\partial \tau}+\lambda\frac{\partial X^\mu}{\partial \sigma} \tag{12.7.40}$$

Therefore:

$$v^\mu v_\mu=\lambda^2\left(\frac{\partial X^\mu}{\partial \sigma}\right)^2+2\lambda\left(\frac{\partial X^\mu}{\partial \tau}\circ\frac{\partial X^\mu}{\partial \sigma}\right)+\left(\frac{\partial X^\mu}{\partial \tau}\right)^2 \tag{12.7.41}$$

that corresponds to an equation of the second degree on λ, and that must, to have negative values (Universe surface patch of the type of space) or positive (Universe surface type of the type time) have at least two roots (see the right part of the previous figure). This brings us back to the condition that the discriminant is strictly positive (see section Calculus page 1383):

$$\Delta = b^2 - 4ac = v^\mu v_\mu = 4\left(\frac{\partial X^\mu}{\partial \tau}\circ\frac{\partial X^\mu}{\partial \sigma}\right)^2 - 4\left(\frac{\partial X^\mu}{\partial \sigma}\right)^2\left(\frac{\partial X^\mu}{\partial \tau}\right)^2 > 0 \qquad (12.7.42)$$

Therefore:

$$\left(\frac{\partial X^\mu}{\partial \tau}\circ\frac{\partial X^\mu}{\partial \sigma}\right)^2 - \left(\frac{\partial X^\mu}{\partial \sigma}\right)^2\left(\frac{\partial X^\mu}{\partial \tau}\right)^2 > 0 \qquad (12.7.43)$$

Into condensed form this is equivalent as writing:

$$(\dot{X}\circ X')^2 - (\dot{X})^2(X')^2 > 0 \qquad (12.7.44)$$

The surface must therefore be written as:

$$A = \int \mathrm{d}\tau \mathrm{d}\sigma \sqrt{(\dot{X}\circ X')^2 - (\dot{X})^2(X')^2} \qquad (12.7.45)$$

if we want the radicand has a physical sense.

By analogy with the Lagrangian of General Relativity (see page 5869) we write the latter:

$$\boxed{A = \int \mathrm{d}\tau \mathrm{d}\sigma \sqrt{(\dot{X}\circ X')^2 - (\dot{X})^2(X')^2} = \int \mathrm{d}\Sigma\sqrt{-g}} \qquad (12.7.46)$$

that we will justify a little more robustly further below.

Recall now that the action S of a point particle is proportional to its world line (proper time). Thus by analogy, the action S of string will be proportional to the Universe area:

$$S \propto \int \mathrm{d}A \Leftrightarrow S \propto A \qquad (12.7.47)$$

which gives:

$$S \propto \int \mathrm{d}\tau \mathrm{d}\sigma \sqrt{(\dot{X}\circ X')^2 - (\dot{X})^2(X')^2} \qquad (12.7.48)$$

Which brings us very frequently in the literature to find the action of a string in the following form:

$$S \propto \int \mathrm{d}\tau \mathrm{d}\sigma \mathcal{L}(\sigma,\tau) \qquad (12.7.49)$$

or more stylized:

$$\boxed{\mathcal{S} \propto \int \mathrm{d}\mathcal{A} = \int \mathrm{d}\tau \mathrm{d}\sigma \mathcal{L}(\sigma,\tau) = \int \mathrm{d}\Sigma \mathcal{L}(\sigma,\tau)} \qquad (12.7.50)$$

Relation to compare with the Lagrangian of a free particle (see section Analytical Mechanics page 3170) and with the Lagrangian density of a field (see section Quantum Field Theory page 5172):

$$S(q,\dot{q}) = \int_{t_A}^{t_B} L(q,\dot{q})\mathrm{d}t \quad \text{and} \quad S = \int \mathcal{L}(\Phi^A, \dot{\Phi}^A, \partial_\mu \Phi^A)\mathrm{d}x^4 \qquad (12.7.51)$$

The functional S has for units the one of a surface. This because the X^μ have a unit of length and inside the root each is at the fourth power and the units of τ, $s\sigma$ cancel between the inner root and the differential that are outside it.

Now, by definition of the action, the units that we have to get should match that of energy multiplied by time. That is to say joules [J] or using the international system of units $[\text{kg}\cdot\text{m}^2\cdot s^{-1}]$. For now, we have:

$$\tau:[\text{s}] \qquad \sigma:[\text{m}] \qquad X^\mu=[\text{m}] \qquad A:[\text{m}^2] \tag{12.7.52}$$

To get to the action units we want, then we have to multiply the expression of the surface A by a quantity whose units are $[\text{kg}\cdot\text{s}^{-1}]$. To chose these quantities, we will inspire us from our study of Wave Mechanics. When we worked with (non-relativistic) strings we saw that the properties to be considered were the stress and the velocity of string wave propagation. We'll try to take the following stress/speed ratio:

$$\frac{\text{stress}}{\text{velocity}}=\frac{[\text{N}]}{[\text{m}\cdot\text{s}^{-1}]}=\frac{[\text{kg}\cdot\text{m}\cdot\text{s}^{-1}]}{[\text{m}\cdot\text{s}^{-1}]}=[\text{kg}\cdot\text{s}^{-1}]=\frac{T}{v}=\frac{T_0}{c} \tag{12.7.53}$$

where appears therefore that the stress of the string at rest T_0 and the speed of light c.

Remark

This is similar to the point material physics where in the action we find the rest mass (equivalent to the tension at rest of the string) and the speed of light (see section Special Relativity page 5629).

Thus, the "Nambu-Goto action" can now be written:

$$\boxed{S=-\frac{T_0}{S}\int \mathrm{d}\tau\mathrm{d}\sigma\sqrt{(\dot{X}\circ X')^2-(\dot{X})^2(X')^2}} \tag{12.7.54}$$

Remark

We will prove later why we put a factor "$-$". However, a small analogy with the action of a point particle, for which we also have a "$-$" sign (see section Special Relativity page 5681), can easily be done...

Let us define for what will follow:

$$g_{\alpha\beta}=\frac{\partial X}{\partial\tau}\circ\frac{\partial X}{\partial\sigma}=\frac{\partial X^\mu}{\partial\tau}\frac{\partial X_\mu}{\partial\tau} \tag{12.7.55}$$

What we can also write in matrix form:

$$g_{\alpha\beta}=\begin{bmatrix}(\dot{X})^2 & \dot{X}\circ X'\\ \dot{X}\circ X' & (X')^2\end{bmatrix} \tag{12.7.56}$$

using the determinant of the matrix, it comes:

$$g=\det(g_{\alpha\beta})=(\dot{X})^2(X')^2-(\dot{X}\circ X')^2 \tag{12.7.57}$$

So we can then write the action of a relativistic string in the final following condensed form:

$$\boxed{S=-\frac{T_0}{c}\int \mathrm{d}\tau\mathrm{d}\sigma\sqrt{-g}} \tag{12.7.58}$$

which is nothing else than the "Nambu-Goto condensed form" form of a relativistic string. The latter can also be found in the follow shape in many textbooks:

$$S_{\text{NG}}=-\frac{T_0}{c}\int\sqrt{|\det\left(\partial_\alpha X\partial_\beta X_\mu\right)|}d\tau d\sigma \tag{12.7.59}$$

With the reader has to remember that $\partial_\alpha X^\mu\partial_\beta X_\mu$ is a 2×2 matrix with $\alpha,\beta=0,1$ and $\partial_\alpha=\frac{\partial}{\partial\sigma^\alpha}$ where $\begin{cases}\sigma^0=\tau\\ \sigma^1=\sigma\end{cases}$ are the parameters of the surface.

We will now obtain the equation of motion by varying the action. For this, we will exactly inspire us of the methods seen when determining the non-relativistic wave equation of string in the section of Wave Mechanics (see page 3496).

Thus, we rewrite the Nambu-Goto action by defining a Lagrangian density $\mathcal{L}$ such that:

$$S=-\frac{T_0}{c}\int\mathrm{d}\tau\mathrm{d}\sigma\sqrt{-g}=\int\limits_{\tau_i}^{\tau_f}\mathrm{d}\tau\int\limits_{\sigma_i}^{\sigma_f}\mathrm{d}\sigma\mathcal{L}\left(\frac{\partial X^\mu}{\partial t},\frac{\partial X^\mu}{\partial\sigma}\right)=\int\limits_{\tau_i}^{\tau_f}\mathrm{d}\tau\int\limits_{\sigma_i}^{\sigma_f}\mathrm{d}\sigma\mathcal{L}(\dot{X}^\mu,X'^\mu) \tag{12.7.60}$$

where $\mathcal{L}$ is therefore defined by:

$$\boxed{\mathcal{L}(\dot{X}^\mu,X'^\mu)=-\frac{T_0}{c}\sqrt{(\dot{X}\circ X')^2-(\dot{X})^2(X')^2}} \tag{12.7.61}$$

We will now apply the variational principle on the action in order to get the equation of movement of a string. The development and approximation are perfectly similar to those seen at the beginning of this section for the non-relativistic string. Let us recall that we obtained as Lagrangian density and as an expression of the action:

$$\mathcal{L}=\frac{1}{2}\rho_l\left(\frac{\partial y}{\partial t}\right)^2-\frac{1}{2}F\left(\frac{\partial y}{\partial x}\right)^2 \qquad S=\int\limits_{t_i}^{t_f}\mathrm{d}t\int\limits_0^L\mathrm{d}x\mathcal{L}\left(\frac{\partial y}{\partial t},\frac{\partial y}{\partial x}\right)=\int\limits_{t_i}^{t_f}\mathrm{d}t\int\limits_0^L\mathrm{d}x\mathcal{L}(\dot{y},y') \tag{12.7.62}$$

and that the application of variational gave us:

$$\delta S=\int\limits_{t_i}^{t_f}\mathrm{d}t\int\limits_0^L\mathrm{d}x\left[\rho_l\frac{\partial l}{\partial t}\frac{\partial(\delta y)}{\partial t}-F\frac{\partial y}{\partial x}\frac{\partial(\delta y)}{\partial x}\right] \tag{12.7.63}$$

But what we did not see in the section Wave Mechanics is that the latter relation could easily be written also from the Lagrangian density:

$$\delta S=\int\limits_{t_i}^{t_f}\mathrm{d}t\int\limits_0^L\mathrm{d}x\left[\frac{\partial\mathcal{L}}{\partial\left(\dfrac{\partial y}{\partial t}\right)}\frac{\partial(\delta y)}{\partial t}+\frac{\partial\mathcal{L}}{\partial\left(\dfrac{\partial y}{\partial x}\right)}\frac{\partial(\delta y)}{\partial x}\right]=\int\limits_{t_i}^{t_f}\mathrm{d}t\int\limits_0^L\mathrm{d}x\left[\frac{\partial\mathcal{L}}{\partial\dot{y}}\frac{\partial(\delta y)}{\partial t}+\frac{\partial\mathcal{L}}{\partial y'}\frac{\partial(\delta y)}{\partial x}\right] \tag{12.7.64}$$

Therefore, for the relativistic string, we have an identical form by applying developments in all points similar (even if the Lagrangian density has a different form):

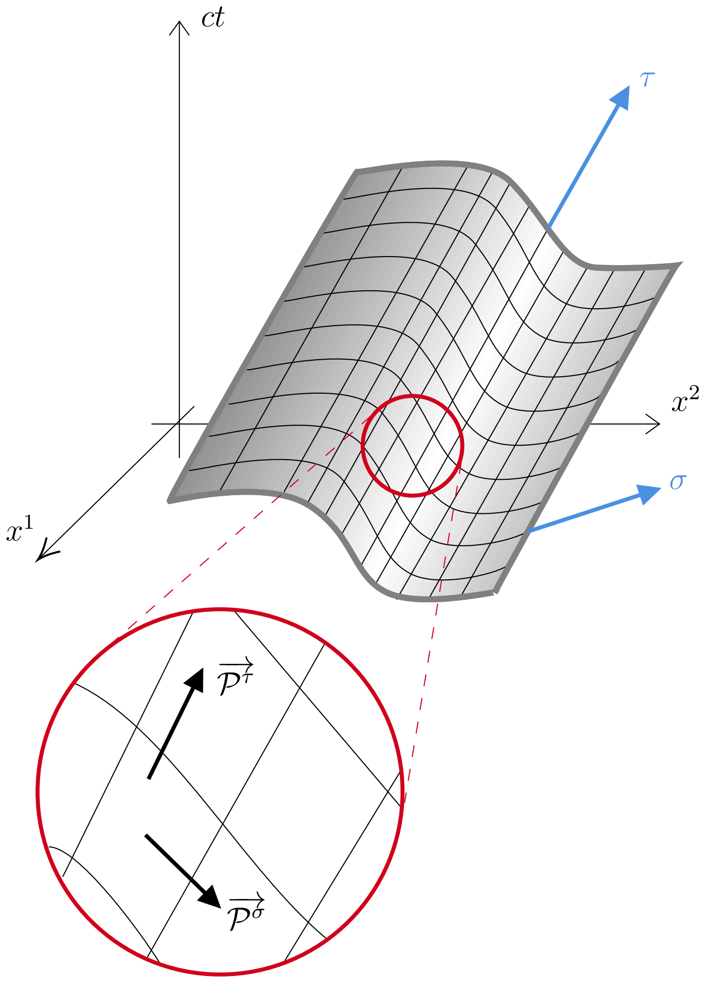
$$\delta S=\int\limits_{\tau_i}^{\tau_f}\mathrm{d}\tau\int\limits_{0}^{\sigma_1}\mathrm{d}\sigma\left[\frac{\partial\mathcal{L}}{\partial\dot{X}^{\mu}}\frac{\partial(\delta X^{\mu})}{\partial\tau}+\frac{\partial\mathcal{L}}{\partial X'^{\mu}}\frac{\partial(\delta X^{\mu})}{\partial\sigma}\right] \tag{12.7.65}$$

and as we did at the beginning of this section for non-relativistic strings, we will introduce the canonical momentum (pulse density/momentum if you prefer) of the string by choosing for the notation:

$$\boxed{\mathcal{P}_{\mu}^{\tau}:=\frac{\partial\mathcal{L}}{\partial\dot{X}^{\mu}}\qquad\mathcal{P}_{\mu}^{\sigma}:=\frac{\partial\mathcal{L}}{\partial\dot{X}'^{\mu}}} \tag{12.7.66}$$

where in the details, we get very easily (it's a simple derivative but if you wish by contacting us, we can detail the developments as always in this textbook) the longitudinal and transverse momentum:

$$\begin{aligned}\mathcal{P}_{\mu}^{\tau}&:=\frac{\partial L}{\partial\dot{X}^{\mu}}=-\frac{T_0}{c}\frac{(\dot{X}\circ X')X'_{\mu}-(X')^2\dot{X}_{\mu}}{\sqrt{(\dot{X}\circ X')^2-(\dot{X})^2(X')^2}}\\ \mathcal{P}_{\mu}^{\sigma}&:=\frac{\partial L}{\partial X'^{\mu}}=-\frac{T_0}{c}\frac{(\dot{X}\circ X')\dot{X}_{\mu}-(\dot{X})^2\dot{X}_{\mu}}{\sqrt{(\dot{X}\circ X')^2-(\dot{X})^2(X')^2}}\end{aligned} \tag{12.7.67}$$



ct
τ
x^2
σ
x^1
$\overrightarrow{\mathcal{P}^{\tau}}$
$\overrightarrow{\mathcal{P}^{\sigma}}$

by making use of this notation, we can then write:

$$\delta S=\int\limits_{\tau_i}^{\tau_f}\mathrm{d}\tau\int\limits_{0}^{\sigma_1}\mathrm{d}\sigma\left[\mathcal{P}_\mu^\tau\frac{\partial(\delta X^\mu)}{\partial\tau}+\mathcal{P}_\mu^\sigma\frac{\partial(\delta X^\mu)}{\partial\sigma}\right] \tag{12.7.68}$$

Making use once again of exactly the same methods as those seen in the section Wave Mechanics, our variational can be written, after simplification, again in the form of three terms:

$$\delta S=\int\limits_{\tau_i}^{\tau_f}\mathrm{d}\tau\int\limits_{0}^{\sigma_1}\mathrm{d}\sigma\left[\frac{\partial}{\partial\tau}(\delta X^\mu P_\mu^\tau)+\frac{\partial}{\partial\sigma}(\delta X^\mu P_\mu^\sigma)-\delta X^\mu\left(\frac{\partial(P_\mu^\tau)}{\partial\tau}+\frac{\partial(P_\mu^\sigma)}{\partial\sigma}\right)\right] \tag{12.7.69}$$

The conditions to find the extremum (according to the principle of least action) remain the same as in Wave Mechanics. Thus, for the third term, we have well the wave equation of a transversely excited string with the following canonical form:

$$\boxed{\frac{\partial(P_\mu^\tau)}{\partial\tau}+\frac{\partial(P_\mu^\sigma)}{\partial\sigma}=0} \tag{12.7.70}$$

As far as we know this equation is horribly difficult to solve but choosing an appropriate parametrization can nevertheless simplify the task.

12.7.3 Lagrangian of a String

Let us recall that we have:

$$\begin{aligned}\frac{\partial X^\mu}{\partial\sigma}&=\left(\frac{\partial X^0}{\partial\sigma},\frac{\partial\vec{X}}{\partial\sigma}\right)=\left(0,\frac{\partial\vec{X}}{\partial\sigma}\right)\\ \frac{\partial X^\mu}{\partial\tau}&=\left(\frac{\partial X^0}{\partial t},\frac{\partial\vec{X}}{\partial\tau}\right)=\left(c,\frac{\partial\vec{X}}{\partial t}\right)\end{aligned} \tag{12.7.71}$$

and that with this choice, we have:

$$
\begin{aligned}
S&=-\frac{T_0}{c}\int \mathrm{d}t\mathrm{d}\sigma\sqrt{(\dot{X}\circ X')^2-(\dot{X})^2(X')^2}\\
&=-\frac{T_0}{c}\int \mathrm{d}t\mathrm{d}\sigma\sqrt{\left(\begin{pmatrix}c\\ \dfrac{\partial\vec{X}}{\partial t}\end{pmatrix}\circ\begin{pmatrix}0\\ -\dfrac{\partial\vec{X}}{\partial\sigma}\end{pmatrix}\right)^2-\begin{pmatrix}c\\ \dfrac{\partial\vec{X}}{\partial t}\end{pmatrix}\circ\begin{pmatrix}c\\ -\dfrac{\partial\vec{X}}{\partial t}\end{pmatrix}\begin{pmatrix}0\\ \dfrac{\partial\vec{X}}{\partial\sigma}\end{pmatrix}\circ\begin{pmatrix}0\\ -\dfrac{\partial\vec{X}}{\partial\sigma}\end{pmatrix}}\\
&=-\frac{T_0}{c}\int \mathrm{d}t\mathrm{d}\sigma\sqrt{\left(\frac{\partial\vec{X}}{\partial t}\circ\left(-\frac{\partial\vec{X}}{\partial\sigma}\right)\right)^2-\left(c^2-\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial\sigma}\right)\left(-\frac{\partial\vec{X}}{\partial\sigma}\circ\frac{\partial\vec{X}}{\partial\sigma}\right)}\\
&=-\frac{T_0}{c}\int \mathrm{d}t\mathrm{d}\sigma\sqrt{(-1)^2\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial\sigma}\right)^2+\left(c^2-\left(\frac{\partial\vec{X}}{\partial t}\right)^2\right)\left(\frac{\partial\vec{X}}{\partial\sigma}\right)^2}\\
&=-\frac{T_0}{c}\int \mathrm{d}t\mathrm{d}\sigma\sqrt{\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial\sigma}\right)^2+\left(c^2-\left(\frac{\partial\vec{X}}{\partial t}\right)^2\right)\left(\frac{\partial\vec{X}}{\partial\sigma}\right)^2}\\
&=-\frac{T_0}{c}\int \mathrm{d}t\mathrm{d}\sigma\sqrt{\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial\sigma}\right)^2+c^2\left(\frac{\partial\vec{X}}{\partial\sigma}\right)^2-\left(\frac{\partial\vec{X}}{\partial t}\right)^2\left(\frac{\partial\vec{X}}{\partial\sigma}\right)^2}
\end{aligned}
\tag{12.7.72}
$$

Now let us use what we have seen in section of Differential Geometry with the Frenet's triad (see page 2863):

$$\vec{T}=\frac{\mathrm{d}\vec{X}}{\mathrm{d}s}\tag{12.7.73}$$

where $\vec{T}$ is the tangent to the Universe surface at a time t at the of a given point. We had also notice in this same section that by definition: where $\vec{T}$ is the tangent to the Universe surface at a time t at the neighbourhood of a given point. We had also notice in this same section that by definition:

$$\vec{T}=\sqrt{\frac{\mathrm{d}\vec{X}}{\mathrm{d}s}\circ\frac{\mathrm{d}\vec{X}}{\mathrm{d}s}}=1\Rightarrow\frac{\mathrm{d}\vec{X}}{\mathrm{d}s}\circ\frac{\mathrm{d}\vec{X}}{\mathrm{d}s}=1\tag{12.7.74}$$

But we can write:

$$\frac{\mathrm{d}\vec{X}}{\mathrm{d}s}\circ\frac{\mathrm{d}\vec{X}}{\mathrm{d}s}=\left(\frac{\mathrm{d}\vec{X}}{\mathrm{d}s}\right)^2=\frac{\mathrm{d}\vec{X}}{\mathrm{d}\sigma}\circ\frac{\mathrm{d}\vec{X}}{\mathrm{d}\sigma}=\frac{\mathrm{d}\vec{X}}{\mathrm{d}\sigma}\circ\frac{\mathrm{d}\vec{X}}{\mathrm{d}\sigma}\left(\frac{\mathrm{d}\sigma}{\mathrm{d}s}\right)^2=\frac{\mathrm{d}\vec{X}}{\mathrm{d}\sigma}\frac{\mathrm{d}\vec{X}}{\mathrm{d}\sigma}\left(\frac{\mathrm{d}\sigma}{\mathrm{d}s}\right)^2=1\tag{12.7.75}$$

where it should be remembered that $\partial\vec{X}/\partial\sigma$ is taken at a fixed time t. As the lines of the surface Universe of constant t describe the string, then $\partial\vec{X}/\partial\sigma$ is tangent to the string.

And as:

$$\frac{\mathrm{d}\vec{X}}{\mathrm{d}s}=\frac{\mathrm{d}\vec{X}}{\mathrm{d}\sigma}\frac{\mathrm{d}\vec{\sigma}}{\mathrm{d}s}\tag{12.7.76}$$

Then $\mathrm{d}\vec{X}/\mathrm{d}s$ is collinear to $\partial\vec{X}/\partial\sigma$ and thus also tangential to the string (information that we did not have a few lines before!). These small discovers being made, let us go back to:

$$\begin{aligned}
S &= -\frac{T_0}{c}\int \mathrm{d}t\mathrm{d}\sigma\sqrt{\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial\sigma}\right)^2+c^2\left(\frac{\partial\vec{X}}{\partial\sigma}\right)^2-\left(\frac{\partial\vec{X}}{\partial t}\right)^2\left(\frac{\partial\vec{X}}{\partial\sigma}\right)^2}\\
&= -\frac{T_0}{c}\int \mathrm{d}t\mathrm{d}\sigma\sqrt{\left(\frac{\mathrm{d}s}{\mathrm{d}\sigma}\right)^2\left[\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)^2+c^2\left(\frac{\partial\vec{X}}{\partial s}\right)^2-\left(\frac{\partial\vec{X}}{\partial t}\right)^2\left(\frac{\partial\vec{X}}{\partial s}\right)^2\right]}\\
&= -\frac{T_0}{c}\int \mathrm{d}t\mathrm{d}\sigma\sqrt{\left(\frac{\mathrm{d}s}{\mathrm{d}\sigma}\right)^2\left[\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)^2+c^2-\left(\frac{\partial\vec{X}}{\partial t}\right)^2\right]}\\
&= -\frac{T_0}{c}\int \mathrm{d}t\mathrm{d}s\sqrt{c^2-\left[\left(\frac{\partial\vec{X}}{\partial t}\right)^2-\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)^2\right]}
\end{aligned}\tag{12.7.77}$$

it already gets a little more interesting!

Now let consider the following figure:

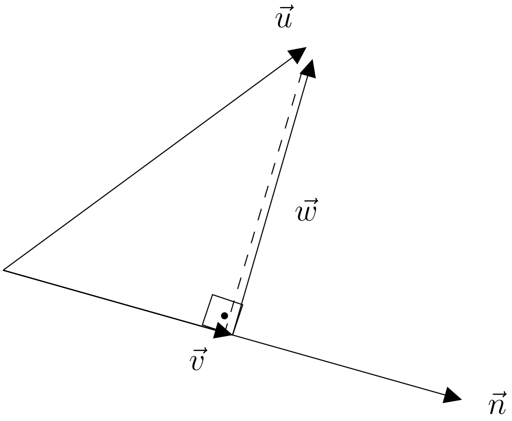


Figure 12.309: **Illustrated recall of the dot product**

where $\vec{u}$ is any vector and $\vec{n}$ a unit (dimensionless) vector and $\vec{v}$, the orthogonal projection of $\vec{u}$ on $\vec{n}$. We then have (see section Vector Calculus page 1821):

$$\vec{u}\circ\vec{n}=\|\vec{u}\|\cdot\|\vec{n}\|\cos(\theta)=(\|\vec{u}\|\cos(\theta))\,\|\vec{n}\|=\|\vec{v}\|\cdot\|\vec{n}\|\tag{12.7.78}$$

Now if we seek for the vector $\vec{v}$ we will have to multiply the whole $\vec{n}$:

$$\vec{v}=(\vec{u}\circ\vec{n})\vec{n}=\|\vec{v}\|\cdot\|\vec{n}\|\vec{n}\tag{12.7.79}$$

Finally, if we seek the expression of the vector $\vec{w}$ it comes immediately:

$$\vec{v}+\vec{w}\Rightarrow\vec{w}=\vec{u}-\vec{v}=\vec{u}-(\vec{u}\circ\vec{n})\vec{n}\tag{12.7.80}$$

Then by similarity, we can write:

$$\vec{w}=\vec{u}-(\vec{u}\circ\vec{n})\vec{n}=\frac{\partial\vec{X}}{\partial t}-\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)\frac{\partial\vec{X}}{\partial s}\tag{12.7.81}$$

where $\vec{w}$ is perpendicular to $\partial\vec{X}/\partial s$ and as the unit of speed. By construction, $\vec{w}$ is therefore the transverse velocity of the speed at a time t t since $\partial\vec{X}/\partial s$ is tangent thereto. We will denote then:

$$\vec{v}_\perp=\frac{\partial\vec{X}}{\partial t}-\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)\frac{\partial\vec{X}}{\partial s}\tag{12.7.82}$$

Let us now take, for future needs, the square norm of this last relation (be careful we process the components of the vectors directly by generalizing the vector notation!):

$$\begin{aligned}\vec{v}_\perp&=\left(\frac{\partial\vec{X}}{\partial t}-\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)\frac{\partial\vec{X}}{\partial s}\right)^2\\&=\left(\frac{\partial\vec{X}}{\partial t}\right)^2-2\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)\left(\frac{\partial\vec{X}}{\partial s}\circ\frac{\partial\vec{X}}{\partial t}\right)+\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)^2\frac{\partial\vec{X}}{\partial s}\circ\frac{\partial\vec{X}}{\partial s}\\&=\left(\frac{\partial\vec{X}}{\partial t}\right)^2-2\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)\left(\frac{\partial\vec{X}}{\partial s}\circ\frac{\partial\vec{X}}{\partial t}\right)+\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)^2\\&=\left(\frac{\partial\vec{X}}{\partial t}\right)^2-2\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)^2+\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)^2\\&=\left(\frac{\partial\vec{X}}{\partial t}\right)^2-\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)^2\end{aligned}\tag{12.7.83}$$

and if we now go back to:

$$\begin{aligned}S&=-\frac{T_0}{c}\int\mathrm{d}t\mathrm{d}s\sqrt{c^2-\left[\left(\frac{\partial\vec{X}}{\partial t}\right)^2-\left(\frac{\partial\vec{X}}{\partial t}\circ\frac{\partial\vec{X}}{\partial s}\right)^2\right]}=\\&=-\frac{T_0}{c}\int\mathrm{d}t\mathrm{d}s\sqrt{c^2-v_\perp^2}\\&=-T_0\int\mathrm{d}t\mathrm{d}s\sqrt{1-\frac{v_\perp^2}{c^2}}\end{aligned}\tag{12.7.84}$$

The associated Lagrangian is then directly (not to be confused with the Lagrangian density!):

$$\boxed{L=-T_0\int\sqrt{1-\frac{v_\perp^2}{c^2}}\mathrm{d}s}\tag{12.7.85}$$

as:

$$S=\int_{t_i}^{t_f}L\mathrm{d}t=\int_{t_i}^{t_f}\mathrm{d}t\int_0^{\sigma_1}\mathrm{d}\sigma\mathcal{L}\tag{12.7.86}$$

The Lagrangian of the prior-previous relation is considered by the specialists in String Theory as a natural generalization of the Lagrangian of the free particle as we get it in the section of Special Relativity and that was for recall given by:

$$L=-mc^2\sqrt{1-\frac{v^2}{c^2}} \tag{12.7.87}$$

13.1. Quantum Chemistry

THROUGHOUT human history, people have tried to convert matter into more useful forms. Our Stone Age ancestors chipped pieces of flint into useful tools and carved wood into statues and toys. These endeavours involved changing the shape of a substance without changing the substance itself. But as our knowledge increased, humans began to change the composition of the substances as well—clay was converted into pottery, hides were cured to make garments, copper ores were transformed into copper tools and weapons, and grain was made into bread.

Humans began to practice chemistry when they learned to control fire and use it to cook, make pottery, and smelt metals. Subsequently, they began to separate and use specific components of matter. A variety of drugs such as aloe, myrrh, and opium were isolated from plants. Dyes, such as indigo and Tyrian purple, were extracted from plant and animal matter. Metals were combined to form alloys - for example, copper and tin were mixed together to make bronze - and more elaborate smelting techniques produced iron. Alkalis were extracted from ashes, and soaps were prepared by combining these alkalis with fats. Alcohol was produced by fermentation and purified by distillation.

Attempts to understand the behaviour of matter extend back for more than 2500 years. As early as the 94th century (holocene calendar), Greek philosophers discussed a system in which water was the basis of all things. You may have heard of the Greek postulate that matter consists of four elements: earth, air, fire, and water. Subsequently, an amalgamation of chemical technologies and philosophical speculations were spread from Egypt, China, and the eastern Mediterranean by alchemists, who endeavoured to transform "base metals" such as lead into "noble metals" like gold, and to develop elixirs to cure disease and extend life.

From alchemy came the historical progressions that led to modern chemistry: the isolation of drugs from natural sources, metallurgy, and the dye industry. Today, chemistry continues to deepen our understanding and improve our ability to harness and control the behaviour of matter. This effort has been so successful that many people do not realize either the central position of chemistry among the sciences or the importance and universality of chemistry in daily life as every other scientific field presented in this textbook do!

Before that the reader goes further in reading this chapter, we want to remind that this textbook deals mainly with applied mathematics and theoretical physics. Thus, we will address in this section only of theoretical chemistry (theoretical quantum chemistry, theoretical thermochemistry, theoretical kinetic chemistry, etc).

This choice follows the changes of chemistry since the years 11980 (holocene calendar): form a largely descriptive science descriptive, it tends to become deductive. That is to say that in addition to experience, calculation methods are constantly growing and particularly since the development of modern computing that greatly helps chemists to numerical modelling.

Theoretical chemistry, also named "physical chemistry" - application of methods from physics to chemistry - is too often seen as a discipline in itself. In fact, under this term any modern chemistry field is included. Thus, the investigation of any problem in advanced chemistry requires the assistance of theoretical chemistry (and this is lucky...) and the chemist must have a thorough knowledge of it. At the level of chemistry teaching as secondary branch, the role of physical chemistry is already evident: the result is an increase in the level of students, increase in the abstraction and therefore a risk in alienating the average student. Finally, the purpose is not to burden the knowledge by incorporating more new elements, but to convert the mode of approach of this discipline by substituting the most often encyclopaedic knowledge statements by rational developments based on only a few assumptions and hypothesis that permits to deduce thanks to mathematics many properties thanks to corollaries.

A good understanding of physical chemistry requires in our point of view necessarily to be familiar with quantum physics (see chapter Atomistic page 4612) to have at least one approach to what an atom is and its different electron orbits before talking about connections, different filling methods of electron orbits, redox, filling layers, and others...

In this sense, we will begin by studying the particular case of the hydrogen atom, which is crucial for the whole that will follow (study of polyelectronic atoms). It is therefore necessary for the reader to browse the next lines with all possible attention and to understand as best as possible the subtleties!

Figure 13.1: **Reminder of atom models evolution**

13.1.1 Infinite three-dimensional rectangular potential

We studied in details in the section of Corpuscular Quantum Physics the Bohr-Sommerfeld hydrogen atom (see page 4648) using the results proved in the section of Special Relativity. This model emerged in a simplistic quantification (but not too much wrong as will discussed later below) of certain properties of matter.

In the section of Wave Quantum Physics, we studied also in details the rectilinear infinite potential well (see page 4796) and the harmonic oscillator (see page 4807) without giving many more examples. Now we will move towards to resolve problems closer to those useful in chemistry with the objective of studying the hydrogen-like atom.

We will now consider a particle moving freely in the three dimensional box below:

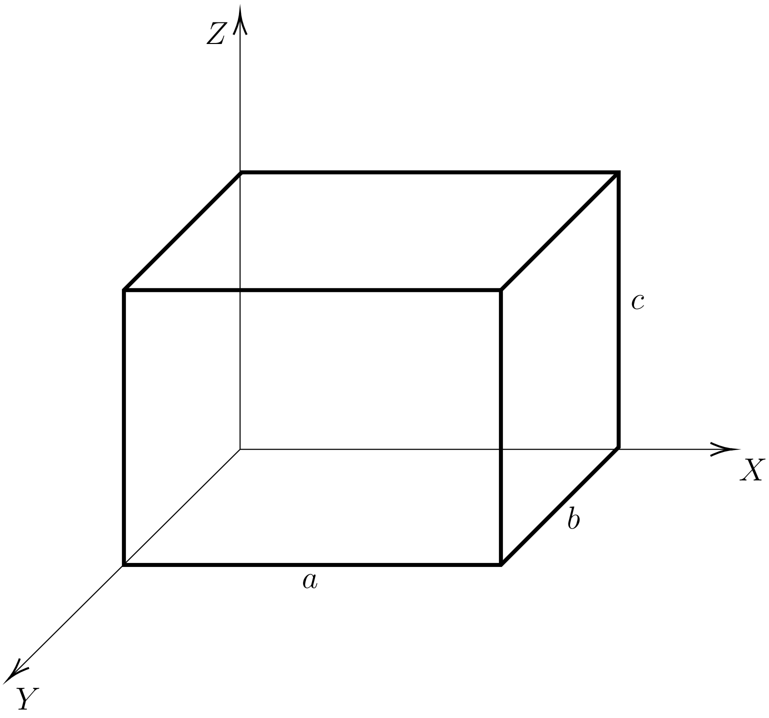

Figure 13.2: **Three dimensional imaginary box in which the particle moves**

The potential electric energy of the system is given by:

$$\begin{aligned} &E_p(x,y,z)=0 && 0<x<a, \quad 0<y<b, \quad 0<z<c, \\ &E_p(x,y,z)=+\infty && \text{everywhere else} \end{aligned} \tag{13.1.1}$$

As in the one-dimensional case (see section Wave Quantum Physics page 4796), the walls of infinite potential prevent the particle from leaving the box, and the wave function is non-zero only for position vector $\vec{r}$ being inside the box. It necessarily vanish when one of the walls is touched. The Schrödinger equation we have to solve is (see section Wave Quantum Physics page 4758):

$$\Delta\Psi+\frac{2m}{\hbar}(E_{\text{tot}}-E_p)\Psi=0 \tag{13.1.2}$$

and boundary conditions are:

$$\begin{gathered}\Psi(x=0,y,z)=\Psi(x=a,y,z)=0\\ \Psi(x,y=0,z)=\Psi(x,y=b,z)=0\\ \Psi(x,y,z=0)=\Psi(x,y,z=c)=0\end{gathered} \tag{13.1.3}$$

Notice that the Hamiltonian can be written as the sum of the Hamiltonian in each axis (we speak of the Hamiltonian operators of course!). So we have:

$$H=H_x+H_y+H_z \tag{13.1.4}$$

where:

$$H_x=\left(\frac{-\hbar^2}{2m}\right)\frac{\partial^2}{\partial^2 x},\quad H_y=\left(\frac{-\hbar^2}{2m}\right)\frac{\partial^2}{\partial^2 y},\quad H_z=\left(\frac{-\hbar^2}{2m}\right)\frac{\partial^2}{\partial^2 z} \tag{13.1.5}$$

Relations that we have proved the origin in details in the section of Wave Quantum Physics of this textbook (see page 4758).

Such a form is named a "separable form": the Hamiltonian is the sum of individual operators H_i each depending only on one variable or degree of freedom q_i. This form reflects the independent nature of the movements described by the variables q_i.

Remember now that the joint probability of two independent events is the product of the individual probabilities of the two events taken separately (see section Probabilities page 480)! We therefore expect that the presence probability density in space (see section Wave Quantum Physics page 4691) with a multidimensional configuration is, in the case where the Hamiltonian is of separable form, a simple individual probability density product. In fact, the separable form of the Hamiltonian permits the separation of variables on the wave function itself!

Let us write the solutions of the Schrödinger equation under the form:

$$\Psi(x,y,z)=\xi(x)\vartheta(y)\zeta(z) \tag{13.1.6}$$

of a product of three factors each depending only of one coordinated.

Substituting this notation in the Schrödinger equation, we get without technical developments (elementary algebra):

$$\vartheta(y)\zeta(z)(H_x\xi(x))+\xi(x)\zeta(z)(H_y\vartheta(y))+\xi(x)\theta(y)(H_z\zeta(z))=(E_{\text{tot}}-E_p)\xi(x)\vartheta(y)\zeta(z) \tag{13.1.7}$$

or, by dividing both sides of this equation by $\xi(x)\vartheta(y)\zeta(z)$:

$$\frac{1}{\xi(x)}(H_x\xi(x))+\frac{1}{\vartheta(y)}(H_y\vartheta(y))+\frac{1}{\zeta(z)}(H_z\zeta(z))=(E_{\text{tot}}-E_p) \tag{13.1.8}$$

which is a much more aesthetic and easier to remember.

This equation requires that the sum of the three terms in the left-hand side is equal to a constant in the context of a conservative system (that is what often interested chemists)! Each of these three terms depending only on one and only one variable, so that their sum is equal to a constant, it is necessary that each term is itself constant! In fact, by taking the derivative of both sides of the above equation with respect to x, for example, we have:

$$\frac{\mathrm{d}\left(\frac{1}{\xi(x)}(H_x\xi(x))\right)}{\mathrm{d}x}=0 \tag{13.1.9}$$

meaning that equation although must be a constant which we will denote equation (as this term expresses an energy). We then have (surprise...):

$$H_x\xi(x)=E_x\xi(x) \tag{13.1.10}$$

Similarly, we get:

$$H_y\theta(y)=E_y\vartheta(y) \quad \text{and} \quad H_z\zeta(z)=E_z\zeta(z) \tag{13.1.11}$$

Notice that each of the separate equations that we have just obtained, for the movement of the particle in the three spatial directions, is a Schrödinger equation in a one-dimensional box. Thus, the three relations previously obtained independently describe each movement in the respective x,y,z directions, limited to the respective ranges:

$$[0,a],[0,b],[0,c] \tag{13.1.12}$$

and must be respectively solved with boundary conditions:

$$\begin{gathered}\xi(0)=\xi(a)=0\\ \theta(0)=\vartheta(b)=0\\ \zeta(0)=\zeta(c)=0\end{gathered} \tag{13.1.13}$$

The results obtained in the section of Wave Quantum Physics when solving the Schrödinger equation in the case of straight wells gave us directly for reminder (see page 4797):

$$\begin{aligned}\xi_\lambda(x)&=\sqrt{\frac{2}{a}}\sin\left(\frac{\lambda\pi x}{a}\right) & E_{x,\lambda}&=\frac{\lambda^2h^2}{8ma^2} &&\text{with}\quad \lambda\in\mathbb{N}^*\\ \vartheta_\mu(y)&=\sqrt{\frac{2}{b}}\sin\left(\frac{\mu\pi y}{b}\right) & E_{y,\mu}&=\frac{\mu^2h^2}{8mb^2} &&\text{with}\quad \mu\in\mathbb{N}^*\\ \zeta_\nu(z)&=\sqrt{\frac{2}{c}}\sin\left(\frac{\nu\pi z}{c}\right) & E_{z,\nu}&=\frac{\nu^2h^2}{8mc^2} &&\text{with}\quad \nu\in\mathbb{N}^*\end{aligned} \tag{13.1.14}$$

In summary the stationary states of the particle in the three-dimensional box are specified by three positive integers quantum numbers λ,μ,ν. The wave function is finally:

$$\boxed{\Psi_{\lambda\mu\nu}=\sqrt{\frac{8}{abc}}\sin\left(\frac{\lambda\pi x}{a}\right)\sin\left(\frac{\mu\pi y}{b}\right)\sin\left(\frac{\nu\pi z}{c}\right)} \tag{13.1.15}$$

and its respective energies (eigenvalues):

$$\boxed{E_{\lambda\mu\nu}=\frac{h^2}{8m}\left(\frac{\lambda^2}{a^2}+\frac{\mu^2}{b^2}+\frac{\nu^2}{c^2}\right)} \tag{13.1.16}$$

The variable separation technique detailed above, is applicable only because the Hamiltonian is in separable form. It comes automatically therefore the three-dimensional probability density $|\Psi(x,y,z)|^2$ is the product of probability density $|\xi_\lambda(x)|^2,|\vartheta_\mu(y)|^2,|\zeta_\nu(z)|^2$, as we had anticipated it. We also notice that the energy of movement in three dimensional space is the sum of energy movements in all three spatial directions: the independence of these three directions or degrees of freedom, implies the additivity of their energy.

13.1.2 Molecular Vibrations

We studied in the Wave Quantum Physics section the harmonic oscillator (see page 4807). Now it is molecular chemistry that we will use all the power of the results obtained during the study of this system.

The harmonic oscillator is a model of molecular vibrations, and is represented by a type of parabolic potential as:

$$E_p = \frac{1}{2}c^{te}x^2 \tag{13.1.17}$$

for a diatomic molecule. But we have proved (see section Wave Mechanics page 3418) that $c^{te} = m\omega_0^2$ so that we finally have for a diatomic molecule:

$$E_p = \frac{m\omega_0^2}{2}x^2 \tag{13.1.18}$$

For a polyatomic molecule, we have verbatim (by the additivity of energy):

$$E_p(q_i) = \frac{1}{2}\sum_i \omega_i^2 q_i^2 \tag{13.1.19}$$

Quantities ω_0 and ω_i are the vibration frequencies (or rather more correctly: the pulsation) of a molecule, diatomic in the first case and polyatomic in the second case. In the first equation, the variable x represents the elongation of the bond between the two atoms A and B (as with a spring) in a diatomic molecule, that is to say $x = R - R_{eq}$, where R is the instantaneous length of this bond, and R_{eq} is its equilibrium value.

In the case of a polyatomic molecule, the potential describing molecular vibrations takes a separable form in terms of summation above only if one considers special variables q_i denoting collective motions of nuclei, and which are named "normal vibration modes".

We also saw in the section of Wave Quantum Physics (see page 4807) that the Hamiltonian of a diatomic molecule (problem of the harmonic oscillator) can be written as

$$H = -\frac{\hbar^2}{2m}\frac{\mathrm{d}^2}{\mathrm{d}x^2} + \frac{m\omega^2}{2}x^2 \tag{13.1.20}$$

For a polyatomic molecule that relationship becomes logically:

$$H = \sum_i \left(-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial q_i^2} + \frac{m\omega^2}{2}q_i^2\right) \tag{13.1.21}$$

The Hamiltonian above is clearly a type of separable form: it is a sum of one-dimensional Hamiltonians, each depending only on a single mode q_i as variable, describing this mode as a unique spring or harmonic unit mass ($m = 1$) oscillator and of pulse oscillation ω_i. Therefore, a separation of variables q_i is possible, reducing the Schrödinger time independent into a number of equations of the same type as that of a one-dimensional harmonic oscillator. So we need just to know the expression of the wave function for a one-dimensional harmonic oscillator, what we already have done in the section of Wave Quantum Physics (see page 4807) where we got:

$$E_n = \hbar\omega\left(n + \frac{1}{2}\right) \quad \text{with} \quad n \in \mathbb{N} \tag{13.1.22}$$

and:

$$\Psi_n = \left(A\sqrt{\pi}n!2^n\right)^{-1/2} e^{-Q^2/2} H_n(Q) \tag{13.1.23}$$

The figure below shows the graph of the first wave functions of the above relation as well as that of their respective presence probability densities. We can see the same modal structures as those specific to functions of a particle in a one-dimensional box:

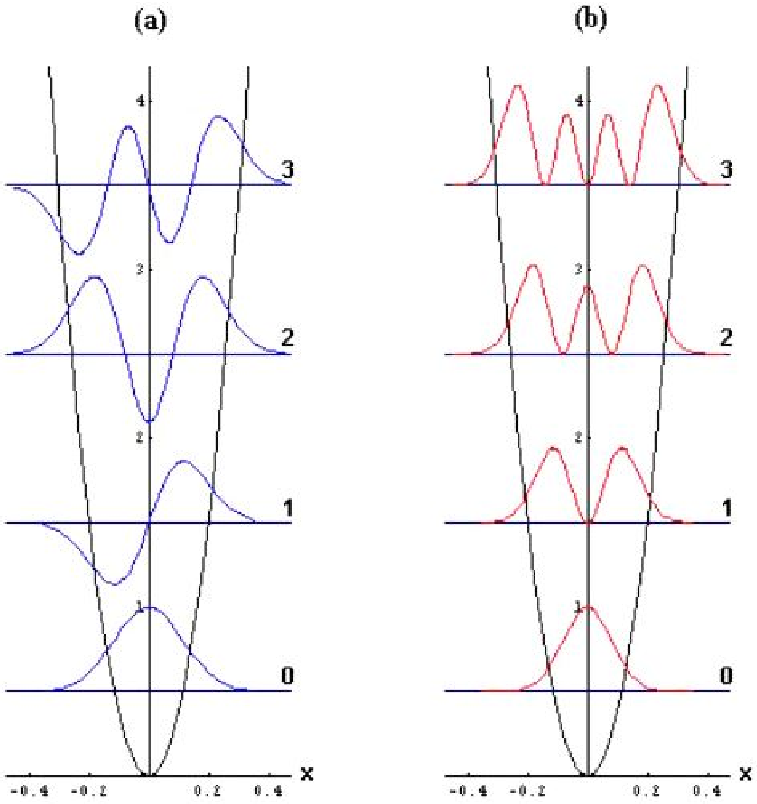

Figure 13.3: **Wave functions and probability density of a one-dimensional harmonic oscillator**

Above the first energy levels of a one-dimensional oscillator with `(a)` their associated eigenfunction, `(b)` the associated probability distribution of presence.

In the limit of very large values of n, the probability distribution approximates more and more of that predicted by classical mechanics, the oscillator lies for the most of the time in the vicinity of the turning points defined by the intersection of potential E_p with the level of n. This trend is illustrated below:

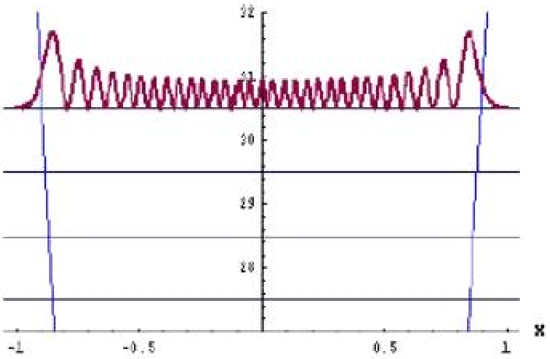

Figure 13.4: Probability density function of a one-dimensional harmonic oscillator for large n

For a polyatomic molecule the expression of quantified energy therefore becomes:

$$\boxed{E_n=\sum_i \hbar\omega_i\left(n_i+\frac{1}{2}\right)} \quad \text{with} \quad n\in\mathbb{N}, \forall i=1,2,3\ldots,n \tag{13.1.24}$$

and eigenfunctions/eigenstates become:

$$\Psi_n(q_i)=(A\sqrt{\pi}n!2^n)^{-1/2}\prod_i H_{n_i}(Q_i)e^{-Q_i^2/2} \tag{13.1.25}$$

with:

$$Q_i=\sqrt{\frac{\omega_i}{\hbar}}q_i \tag{13.1.26}$$

The last two relations are very important because they allow among others to:

- Predict the spectrum of the molecule (spectroscopy)
- To study the energy bands (where does the bands of valence and conduction comes from)
- To locate the bonds between atoms and thus the chemical properties

We will go further into the subject of molecular vibrations later below at page 6205 during our study of molecular vibrations energy levels that will be very important in practice to predict the spectrum of molecules (or respectively their moment of inertia).

13.1.3 Hydrogenoid Atom (Schrödinger model)

We consider here the quantification of a generic system made of two bodies (particles) interacting with each other and moving in a three-dimensional space. We will be prove at first that, even if the separation of dynamic variables describing individually each of the two bodies is impossible, for cons, the overall movement system (the center of mass) and internal movement, also said "relative motion", are separable. In addition, if the potential is centrosymmetric, the internal movement may also be decomposed into a rotational movement and radial movement. The quantification of the rotational movement is intimately connected to that of angular momentum.

Here we focus on the mechanics of an atomic system having only one electron. This is a two-particle system: a nucleus of mass M and charge $+Zq_e$, and an electron of mass m_e and of charge $-q_e$ in the framework of the Schrödinger model (for a more generalized treatment based on Dirac equation see [460]).

The atomic system is described by the following Hamiltonian:

$$\begin{aligned}H&=E_c^{\text{nucleus}}+E_c^{\text{electron}}+E_p^{\text{system}}=\frac{p_N^2}{2M}+\frac{p_e^2}{2m_e}+E_p(\vec{r}_e-\vec{R}_N)\\&=-\frac{\hbar^2}{2M}\nabla_N^2-\frac{\hbar^2}{2m_e}\nabla_e^2+E_p(\vec{r}_e-\vec{R}_N)\end{aligned}\tag{13.1.27}$$

Remember that in the section of Wave Quantum Physics we had proved during our study of functional operators (see page 4714):

$$p=\frac{1}{\mathrm{i}}\hbar\nabla=\frac{1}{\mathrm{i}}\frac{h}{2\pi}\nabla\tag{13.1.28}$$

and remember also that $\vec{r}_e$ and $\vec{R}_n$ are respectively the position vectors of the electron and nucleus in the prior-previous relation.

The potential electric energy being given by (see section Electrostatics page 4005):

$$E_p(\vec{r}_e-\vec{R}_N)=-\frac{Zq_e^2}{4\pi\varepsilon\|\vec{r}_e-\vec{R}_N\|}\tag{13.1.29}$$

The movements of the two particles are correlated because the two charges interact through their mutual electrical field. We can not make a separation between variables $\vec{r}_e$ and $\vec{R}_N$. By cons, a separation of variables is possible with the coordinate of the center of mass (see the definition of the center of mass in the section of Classical Mechanics at page 3213):

$$\vec{R}_{\text{CM}}=\frac{m_e\vec{r}_e+M\vec{R}_N}{m_e+M}\tag{13.1.30}$$

and the relative coordinate of the electron relative to the nucleus:

$$\vec{r}_{\text{rel}}=\vec{r}_e-\vec{R}_N\tag{13.1.31}$$

We get therefore:

$$\vec{p}_{\text{CM}}=\frac{\hbar}{\mathrm{i}}\vec{\nabla}_{\text{CM}}=\frac{\hbar}{\mathrm{i}}\left(\vec{\nabla}_e+\vec{\nabla}_N\right)=\vec{p}_e+\vec{p}_N\tag{13.1.32}$$

and:

$$\vec{p}_{\text{rel}}=\frac{M\vec{p}_e-m_e\vec{p}_N}{m_e+M}\tag{13.1.33}$$

The Hamiltonian in the center of mass repository will therefore be written:

$$H=\frac{p_{\text{CM}}^2}{2M_{\text{tot}}}+\frac{p_{\text{rel}}^2}{2\mu}+E_{\text{tot}}(\vec{r}_{\text{rel}})\tag{13.1.34}$$

where $M_{\text{tot}} = m_e + M$ is the total mass of the system and:

$$\mu = \frac{m_e M}{M_{\text{tot}}} \tag{13.1.35}$$

is its reduced mass.

We clearly see that the Hamiltonian H is this time set in a separable form and we can write it as follows:

$$H = H_{\text{CM}} + H_{\text{rel}} \tag{13.1.36}$$

with:

$$H_{\text{CM}} = \frac{p_{\text{CM}}^2}{2M_{\text{tot}}} \quad \text{and} \quad H_{\text{rel}} = \frac{p_{\text{rel}}^2}{2\mu} + E_{\text{tot}}(\vec{r}_{\text{rel}}) \tag{13.1.37}$$

In terms of the coordinates $\vec{R}_{\text{CM}}$ and $\vec{r}_{\text{rel}}$, the function describing a stationary state of the two-body system is a product of individual wave functions (recall that the joint probability of two events is the product of probabilities), one for the movement of the center of mass and the other for the relative movement:

$$\Psi_{\text{tot}}\left(\vec{R}_{\text{CM}}, \vec{r}_{\text{rel}}\right) = \Psi_{\text{CM}}\left(\vec{R}_{\text{CM}}\right)\Psi_{\text{rel}}\left(\vec{r}_{\text{rel}}\right) \tag{13.1.38}$$

and the energy of this state is the sum of the respective energies of movements:

$$E_{\text{tot}} = E_{\text{CM}} + E_{\text{rel}} \tag{13.1.39}$$

with:

$$H_{\text{CM}}\Psi_{\text{CM}}\left(\vec{R}_{\text{CM}}\right) = E_{\text{CM}}\Psi_{\text{CM}}\left(\vec{R}_{\text{CM}}\right) \quad \text{and} \quad H_{\text{rel}}\Psi_{\text{rel}}\left(\vec{r}_{\text{rel}}\right) = E_{\text{rel}}\Psi_{\text{rel}}\left(\vec{r}_{\text{rel}}\right) \tag{13.1.40}$$

Remark

This approach of separating the wave function into the composition of a wave function of the center of mass and the relative movement is also used in the context of the study of poly-electronic atoms, but with one difference: as the nucleus is much more massive than the processing electrons (in approximation ...), the center of mass is assimilated to the nucleus of the atom and the relative motion to the entire electron cloud[a]. This approximate approach is well known under the designation "Born-Oppenheimer approximation".

---

[a] The electron cloud is the region of negative charge surrounding an atomic nucleus that is associated with an atomic orbital. The region is defined mathematically, describing a region with a high probability of containing electrons. As we know it, the electron cloud model differs from the more simplistic Bohr model, in which electrons orbit the nucleus in much the same way as planets orbit the Sun. In the cloud model, there are regions where an electron may likely be found, but it's theoretically possible for it to be located anywhere, including inside the nucleus.

Where the Hamiltonian appearing in the first of these relations has been defined above as being:

$$H_{\text{CM}} = \frac{p_{\text{CM}}^2}{2M_{\text{tot}}} \tag{13.1.41}$$

This movement is that of a particle of mass M_{tot} in a three-dimensional box of infinite volume. Eigenvalues and eigenfunctions for this movement has already been obtained in our previous study, we will restrict ourselves to the study of separate equation for the relative movement, or internal movement. As no confusion will be possible between different Hamiltonians, we let down, to simplify the notations, the "eel" word in subscript.

With H_{rel} given by the relation that we have proved previously:

$$H_{\text{rel}} = \frac{p_{\text{rel}}^2}{2\mu} + E_p(\vec{r}_{\text{rel}}) \tag{13.1.42}$$

and the relation (as proved above):

$$H_{\text{rel}}\Psi_{\text{rel}}(\vec{r}_{\text{rel}}) = E_{\text{rel}}\Psi_{\text{rel}}(\vec{r}_{\text{rel}}) \tag{13.1.43}$$

then we obtain the Schrödinger equation for the relative motion:

$$\left(\frac{p^2}{2\mu} + E_p(r)\right)\Psi(\vec{r}) = E\Psi(\vec{r}) \tag{13.1.44}$$

or written differently:

$$\left(-\frac{\hbar}{2\mu}\nabla^2 + E_p(r)\right)\Psi(\vec{r}) = E\Psi(\vec{r}) \tag{13.1.45}$$

Notice that in the case where the potential energy E_p is a centrosymmetric source, that is to say it depends only on the length of the position vector $\vec{r}$, and not its orientation, the previous equation, written in Cartesian coordinates, is inseparable. Indeed, in Cartesian coordinates, the length $\vec{r}$ is given by:

$$\|\vec{r}\| = \sqrt{x^2 + y^2 + z^2} \tag{13.1.46}$$

and the potential energy can not be separated into three components, each depending only one of the three variables x, y, z. The Hamiltonian is therefore still not a separable form and so we did not meet our target. However, the above equation is separable at the moment we make a change of coordinates to spherical coordinates. Indeed, in this coordinate system, the potential depends on only on one of the three spherical variables: the radius r. It is independent of the two angles θ and ϕ.

Referring to the result obtained in the study of the Laplace expressions in different coordinate systems, in the section of Vector Calculus, we got for the Laplacian of a scalar field in spherical coordinates the following expression (see page 1899):

$$\vec{\nabla}^2 u = \frac{\partial^2 u}{\partial r^2} + 2\frac{1}{r}\frac{\partial u}{\partial r} + \frac{1}{r^2}\frac{\partial^2 u}{\partial \theta^2} + \frac{\cot(\phi)}{r^2}\frac{\partial u}{\partial \theta} + \frac{1}{r^2\sin^2(\theta)}\frac{\partial^2 u}{\partial \phi^2} \tag{13.1.47}$$

The Hamiltonian:

$$H = -\frac{\hbar}{2\mu}\vec{\nabla}^2 + E_p(\vec{r}) \tag{13.1.48}$$

then becomes (simple distribution and new way to note):

$$\boxed{H = T_r + \frac{L^2}{2\mu r^2}E_p(\vec{r})} \tag{13.1.49}$$

where:

$$\boxed{T_r=-\frac{\hbar}{2\mu}\left(\frac{\partial}{\partial r^2}+2\frac{1}{r}\frac{\partial}{\partial r}\right)=-\frac{\hbar}{2\mu}\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right)} \tag{13.1.50}$$

is the kinetic energy operator for the radial movement of the electron relative to the nucleus, and L^2 is the squared "associated" operator of the angular momentum vector:

$$L^2=-\hbar^2\left[\frac{1}{\sin(\theta)}\frac{\partial}{\partial\theta}\left(\sin(\theta)\frac{\partial}{\partial\theta}\right)+\frac{1}{\sin^2(\theta)}\frac{\partial^2}{\partial\phi^2}\right] \tag{13.1.51}$$

The term:

$$H=\frac{L^2}{2J} \tag{13.1.52}$$

where $J=\mu r^2$ is therefore an energy associated with the angular momentum L (see section Classical Mechanics page 3297 and page 3244).

To understand the nature of this operator L^2 a detour by the notion of rigid rotor will help.

13.1.3.1 Rigid Rotator

If we now consider the case of a system named "rigid rotor" where we neglect ("restrict" would be a more appropriate term ...) the degrees of freedom of oscillation (this is the system that are the study case for linear diatomic or polyatomic molecules), the only coordinates being into play are the angles θ and ϕ which fix the orientation of the rotator.

Thus, in this case r is fixed and we have:

$$T_r=0, E_p(r)=\begin{cases}0 & r=R_e\\ +\infty & r\neq R_e\end{cases} \tag{13.1.53}$$

and in view of the constraints on the potential, it is normally quite easy to understand why the rotator is said to be "rigid". In the above case, the Hamiltonian is reduced to:

$$H=\frac{L^2}{2J}=\frac{L^2}{2\mu r^2} \tag{13.1.54}$$

For the rest, we associate the operator L^2 to the square of an angular momentum, for the simple reason that he has the units of it... Indeed, let us recall that we have prove in the section of Wave Quantum Physics that when the spin is zero (so as part of our study of the hydrogenoid atom here, the spin will not be taken into account in the first instance) and that we are dealing with a single particle then the angular momentum (which we will denote by L instead of b) is given by:

$$L\leqslant\sqrt{l(l+1)}\hbar\Rightarrow L^2\leqslant l(l+1)\hbar^2\quad\text{and}\quad\vec{L}=\hbar\vec{l}\text{ with }l\in\mathbb{N} \tag{13.1.55}$$

where the components of the vector $\vec{l}$ are also natural numbers. By doing this similarity, we can then write the Schrödinger equation in the form:

$$\left[T_r+\frac{l(l+1)\hbar^2}{2\mu r^2}+E_p\right]\Psi=E\Psi \tag{13.1.56}$$

Let us recall that we got in the section of Wave Quantum Physics that (see page 4877):

$$L_x=\frac{\hbar}{\mathrm{i}}(y\partial_z-z\partial_y) \tag{13.1.57}$$

by the vector product.

We go now to rectangular coordinates x,y,z coordinates to spherical coordinates r,θ,ϕ. Remember for this (see section Vector Calculus page 1849) that:

$$\begin{aligned}
r&=\sqrt{x^2+y^2+z^2} \qquad 0<r<+\infty\\
x&=r\sin(\theta)\cos(\phi)\\
y&=r\sin(\theta)\sin(\phi)\\
z&=r\cos(\theta)
\end{aligned} \tag{13.1.58}$$

and that:

$$\begin{aligned}
\theta&=\arccos\left(\frac{z}{\sqrt{x^2+y^2+z^2}}\right) \qquad 0\leq\theta\leq\pi\\
\phi&=\arccos\left(\frac{x}{\sqrt{x^2+y^2}}\right) \qquad 0\leq\phi\leq 2\pi
\end{aligned} \tag{13.1.59}$$

Now let us express the total differentials:

$$\begin{aligned}
\mathrm{d}x&=\sin(\theta)\cos(\phi)\mathrm{d}r+\cos(\theta)\cos(\phi)r\mathrm{d}\theta-r\sin(\theta)\sin(\phi)\mathrm{d}\phi\\
\mathrm{d}y&=\sin(\theta)\sin(\phi)\mathrm{d}r+r\cos(\theta)\sin(\phi)\mathrm{d}\theta+r\sin(\theta)\cos(\phi)\mathrm{d}\phi\\
\mathrm{d}z&=\cos(\theta)\mathrm{d}r-r\sin(\theta)\mathrm{d}\theta
\end{aligned} \tag{13.1.60}$$

These relations can be written as an orthogonal transformation of the total differential $\mathrm{d}r, r\mathrm{d}\theta, r\sin(\theta)\mathrm{d}\phi$ by:

$$\begin{pmatrix}\mathrm{d}x\\ \mathrm{d}y\\ \mathrm{d}z\end{pmatrix}=\begin{bmatrix}\sin(\theta)\cos(\phi) & \cos(\theta)\cos(\phi) & -\sin(\phi)\\ \sin(\theta)\sin(\phi) & \cos(\theta)\sin(\phi) & \cos(\phi)\\ \cos(\theta) & -\sin(\theta) & 0\end{bmatrix}\begin{pmatrix}\mathrm{d}r\\ r\mathrm{d}(\theta)\\ r\sin(\theta)\mathrm{d}\phi\end{pmatrix} \tag{13.1.61}$$

or by the inverse transformation (if required ... it is enough to check that the two transformation matrices multiplied together give the identity matrix):

$$\begin{pmatrix}\mathrm{d}r\\ r\mathrm{d}\theta\\ r\sin(\theta)\mathrm{d}\phi\end{pmatrix}=\begin{bmatrix}\sin(\theta)\cos(\phi) & \sin(\theta)\sin(\phi) & \cos(\phi)\\ \cos(\theta)\cos(\phi) & \cos(\theta)\sin(\phi) & -\sin(\phi)\\ -\sin(\theta) & \cos(\phi) & 0\end{bmatrix}\begin{pmatrix}\mathrm{d}x\\ \mathrm{d}y\\ \mathrm{d}z\end{pmatrix} \tag{13.1.62}$$

It results of this for example:

$$\begin{aligned}
\mathrm{d}r&=\sin(\theta)\cos(\phi)\mathrm{d}x+\sin(\theta)\sin(\phi)\mathrm{d}y+\cos(\theta)\mathrm{d}z\Rightarrow\frac{\partial r}{\partial x}=\sin(\theta)\cos(\phi)\\
r\mathrm{d}\theta&=\cos(\theta)\cos(\phi)\mathrm{d}x+\cos(\theta)\sin(\phi)\mathrm{d}y-\sin(\theta)\mathrm{d}z\Rightarrow\frac{\partial\theta}{\partial x}=\frac{1}{r}\cos(\theta)\cos(\phi)\\
r\sin(\theta)\mathrm{d}\phi&=-\sin(\phi)\mathrm{d}x+\cos(\phi)\mathrm{d}y+0\mathrm{d}z\Rightarrow\frac{\partial\phi}{\partial x}=\cos(\theta)
\end{aligned} \tag{13.1.63}$$

and finally (the method for the second and third lines is the same as for the first!):

$$\begin{aligned}
\frac{\partial}{\partial x}&=\frac{\partial r}{\partial x}\frac{\partial}{\partial r}+\frac{\partial \theta}{\partial x}\frac{\partial}{\partial \theta}+\frac{\partial \varphi}{\partial x}\frac{\partial}{\partial \varphi}=\sin(\theta)\cos(\phi)\frac{\partial}{\partial r}+\cos(\theta)\cos(\phi)\frac{1}{r}\frac{\partial}{\partial \theta}-\frac{\sin(\phi)}{r\sin(\theta)}\frac{\partial}{\partial \varphi}\\
\frac{\partial}{\partial y}&=\frac{\partial r}{\partial y}\frac{\partial}{\partial r}+\frac{\partial \theta}{\partial y}\frac{\partial}{\partial \theta}+\frac{\partial \varphi}{\partial y}\frac{\partial}{\partial \varphi}=\sin(\theta)\sin(\phi)\frac{\partial}{\partial r}+\cos(\theta)\sin(\phi)\frac{1}{r}\frac{\partial}{\partial \theta}+\frac{\cos(\phi)}{r\sin(\theta)}\frac{\partial}{\partial \varphi}\\
\frac{\partial}{\partial z}&=\frac{\partial r}{\partial z}\frac{\partial}{\partial r}+\frac{\partial \theta}{\partial z}\frac{\partial}{\partial \theta}+\frac{\partial \varphi}{\partial z}\frac{\partial}{\partial \varphi}=\cos(\theta)\frac{\partial}{\partial r}-\frac{\sin(\theta)}{r}\frac{\partial}{\partial \theta}
\end{aligned} \tag{13.1.64}$$

Thus, taking into account these relations, we get for example, in the case of the operator:

$$L_x=-\frac{\hbar}{\mathrm{i}}(y\partial_z-z\partial_y) \tag{13.1.65}$$

the following developments:

$$\begin{aligned}
y\frac{\partial}{\partial z}-z\frac{\partial}{\partial y}=&\,y\left(\cos(\theta)\frac{\partial}{\partial r}-\frac{\sin(\theta)}{r}\frac{\partial}{\partial \theta}\right)-z\left(\sin(\theta)\sin(\phi)\frac{\partial}{\partial r}+\frac{\cos(\theta)\sin(\phi)}{r}\frac{\partial}{\partial \theta}+\frac{\cos(\phi)}{r\sin(\theta)}\frac{\partial}{\partial \phi}\right)\\
&=r\sin(\theta)\sin(\phi)\left(\cos(\theta)\frac{\partial}{\partial r}-\frac{\sin(\theta)}{r}\frac{\partial}{\partial \theta}\right)\\
&-r\cos(\theta)\left(\sin(\theta)\sin(\phi)\frac{\partial}{\partial r}+\frac{\cos(\theta)\sin(\phi)}{r}\frac{\partial}{\partial \theta}+\frac{\cos(\phi)}{r\sin(\theta)}\frac{\partial}{\partial \phi}\right)\\
&=r\sin(\theta)\sin(\phi)\left(-\frac{\sin(\theta)}{r}\frac{\partial}{\partial \theta}\right)-r\cos(\theta)\left(\frac{\cos(\theta)\sin(\phi)}{r}\frac{\partial}{\partial \theta}+\frac{\cos(\phi)}{r\sin(\theta)}\frac{\partial}{\partial \phi}\right)\\
&=\sin(\theta)\sin(\phi)\left(-\frac{\sin(\theta)}{r}\frac{\partial}{\partial \theta}\right))-\cos(\theta)\left(\cos(\theta)\sin(\phi)\frac{\partial}{\partial \theta}+\frac{\cos(\phi)}{\sin(\theta)}\frac{\partial}{\partial \phi}\right)\\
&=(-\sin(\theta)\sin(\theta)\sin(\phi)-\cos(\theta)\cos(\theta)\sin(\phi))\frac{\partial}{\partial \theta}-\cos(\theta)\left(\frac{\cos(\phi)}{\sin(\theta)}\frac{\partial}{\partial \phi}\right)\\
&=-\sin(\phi)\frac{\partial}{\partial \theta}-\cot(\theta)\cos(\phi)\frac{\partial}{\partial \phi}
\end{aligned} \tag{13.1.66}$$

which gives the following result:

$$L_x=-\mathrm{i}\hbar(\sin(\phi)\partial_\theta-\cot(\theta)\cos(\phi)\partial_\phi) \tag{13.1.67}$$

By doing the same with:

$$L_y=\frac{\hbar}{\mathrm{i}}(z\partial_x-x\partial_z)=-\mathrm{i}\hbar(z\partial_x-x\partial_z) \tag{13.1.68}$$

and processing with the same developments:

$$\begin{aligned}
z\frac{\partial}{\partial x}-x\frac{\partial}{\partial z}&=z\left(\sin(\theta)\cos(\phi)\frac{\partial}{\partial r}+\frac{\cos(\theta)\cos(\phi)}{r}\frac{\partial}{\partial\theta}-\frac{\sin(\phi)}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)-x\left(\cos(\theta)\frac{\partial}{\partial r}-\frac{\sin(\theta)}{r}\frac{\partial}{\partial\theta}\right)\\
&=r\cos(\theta)\left(\sin(\theta)\cos(\phi)\frac{\partial}{\partial r}+\frac{\cos(\theta)\cos(\phi)}{r}\frac{\partial}{\partial\theta}-\frac{\sin(\phi)}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)\\
&-r\sin(\theta)\cos(\phi)\left(\cos(\theta)\frac{\partial}{\partial r}-\frac{\sin(\theta)}{r}\frac{\partial}{\partial\theta}\right)\\
&=r\cos(\theta)\left(\frac{\cos(\theta)\cos(\phi)}{r}\frac{\partial}{\partial\theta}-\frac{\sin(\phi)}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)-r\sin(\theta)\cos(\phi)\left(-\frac{\sin(\theta)}{r}\frac{\partial}{\partial\theta}\right)\\
&=\cos(\theta)\left(\cos(\theta)\cos(\phi)\frac{\partial}{\partial\theta}-\frac{\sin(\phi)}{\sin(\theta)}\frac{\partial}{\partial\phi}\right)-\sin(\theta)\cos(\phi)\left(-\sin(\theta)\frac{\partial}{\partial\theta}\right)\\
&=(\cos(\theta)\cos(\theta)\cos(\phi)+\sin(\theta)\cos(\phi)\sin(\theta))\frac{\partial}{\partial\theta}-\cos(\theta)\frac{\sin(\phi)}{\sin(\theta)}\frac{\partial}{\partial\phi}\\
&=\cos(\phi)(\cos^2(\theta)+\sin^2(\theta))\frac{\partial}{\partial\theta}-\sin(\phi)\cot(\theta)\frac{\partial}{\partial\phi}\\
&=\cos(\phi)\frac{\partial}{\partial\theta}-\sin(\phi)\cot(\theta)\frac{\partial}{\partial\phi}
\end{aligned}\tag{13.1.69}$$

we get the following result:

$$L_y=-\mathrm{i}\hbar\left(\cos(\phi)\partial_\theta-\sin(\phi)\cot(\theta)\partial_\phi\right)\tag{13.1.70}$$

And for finish with:

$$L_z=\frac{\hbar}{\mathrm{i}}(x\partial_y-y\partial_x)=-\mathrm{i}\hbar(x\partial_y-y\partial_x)\tag{13.1.71}$$

and again processing the same developments:

$$\begin{aligned}
x\frac{\partial}{\partial y}-y\frac{\partial}{\partial x}&=x\left(\sin(\theta)\sin(\phi)\frac{\partial}{\partial r}+\frac{\cos(\theta)\sin(\phi)}{r}\frac{\partial}{\partial\theta}+\frac{\cos(\phi)}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)\\
&-y\left(\sin(\theta)\cos(\phi)\frac{\partial}{\partial r}+\frac{\cos(\theta)\cos(\phi)}{r}\frac{\partial}{\partial\theta}-\frac{\sin(\phi)}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)\\
&=r\sin(\theta)\cos(\phi)\left(\sin(\theta)\sin(\phi)\frac{\partial}{\partial r}+\frac{\cos(\theta)\sin(\phi)}{r}\frac{\partial}{\partial\theta}+\frac{\cos(\phi)}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)\\
&-r\sin(\theta)\sin(\phi)\left(\sin(\theta)\cos(\phi)\frac{\partial}{\partial r}+\frac{\cos(\theta)\cos(\phi)}{r}\frac{\partial}{\partial\theta}-\frac{\sin(\phi)}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)\\
&=r\sin(\theta)\cos(\phi)\left(\frac{\cos(\theta)\sin(\phi}{2}\frac{\partial}{\partial\theta}+\frac{\cos(\phi)}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)\\
&-r\sin(\theta)\sin(\phi)\left(\frac{\cos(\theta)\cos(\phi)}{r}\frac{\partial}{\partial\theta}-\frac{\sin(\phi)}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)\\
&=r\sin(\theta)\cos(\phi)\left(\frac{\cos(\phi)}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)-r\sin(\theta)\sin(\phi)\left(-\frac{\sin(\phi)}{r\sin(\theta)}\frac{\partial}{\partial\phi}\right)\\
&=\cos^2(\phi)\frac{\partial}{\partial\phi}+\sin^2(\phi)\frac{\partial}{\partial\phi}=\frac{\partial}{\partial\phi}
\end{aligned}\tag{13.1.72}$$

we get the following result:

$$L_z=-\mathrm{i}\hbar\partial_\phi\tag{13.1.73}$$

Finally, we have only little freedom for the movement of our rigid rotor (as it is very rigid ...) and we can write for the Schrödinger equation:

$$H_{\text{rot}} = \frac{L^2}{2J} \Rightarrow H_{\text{rot}}\Psi = E\Psi \tag{13.1.74}$$

where H_{rot} is for recall, seen as the functional linear operator, and the total energy E as its corresponding eigenvector.

Therefore, we can write that angular momentum operator is given by (we change the notation so to not confuse subsequently operator and eigenvalue according to the comments we made during the statement of the postulates of Wave Quantum Physics in the corresponding section):

$$\hat{L}_z = -\mathrm{i}\hbar\partial_\phi \tag{13.1.75}$$

Thus, the eigenfunctions $\Phi(\phi)$ of $\hat{L}_z$ are solutions of the equation to the eigenvalues and eigenfunctions:

$$\boxed{\hat{L}_z\Phi(\phi) = L_z\Phi(\phi)} \tag{13.1.76}$$

that is to say the differential equation:

$$\boxed{-\mathrm{i}\hbar\partial_\varphi\Phi(\varphi) = L_z\Phi(\phi)} \tag{13.1.77}$$

where L_z is obviously the eigenvalue of $\hat{L}_z$. A simple solution to this differential would be:

$$\Phi(\phi) = ce^{\frac{\mathrm{i}}{\hbar}L_z\phi} \tag{13.1.78}$$

with for uniformity condition, depending on the properties of complex number (see section Numbers page 243):

$$\Phi(\phi + 2\pi) = \Phi(\phi) \tag{13.1.79}$$

This mathematical condition imposes the obvious and remarkable following quantification:

$$L_z = \hbar m_l \quad \text{with} \quad m_l = 0, \pm 1, \pm 2, \ldots \tag{13.1.80}$$

where (recall) m_l is the magnetic quantum number.

Knowing that (see section Corpuscular Quantum Physics page 4668):

$$-l \leqslant m_l \leqslant +l \tag{13.1.81}$$

We can write:

$$L_z = \hbar l \tag{13.1.82}$$

Therefore, we falls back on the result(s) that we get in the section of Corpuscular Quantum Physics and Wave Quantum Physics (see page 4877):

$$b_z = \hbar l \Rightarrow \vec{b} = \hbar\vec{l} \tag{13.1.83}$$

Which is quite satisfactory, even remarkable and enjoyable (to not say it ...).

Thus, the measurement of one of the components of the angular momentum, provides always a multiple of $\hbar$ which appears therefore as a natural unit of angular momentum.

The common eigenfunctions (!!!) to the operators $\hat{L}^2$ and $\hat{L}_z$ are in a more general framework necessarily of the form (method of separation of variables):

$$R(r)\Phi(\phi)\Theta(\theta) \tag{13.1.84}$$

As the rotator is rigid, we have $R(r) = c^{te}$. This factor will eliminate itself in the equation of eigenvalues and eigenfunctions that we will determine further below. So we don't need to take it into account if we want! Finally, we can write thanks to previous developments:

$$\Phi(\varphi)\Theta(\theta) = e^{\mathrm{i}m_l\phi}\Theta(\theta) \tag{13.1.85}$$

Which brings us to the following equation of the eigenvalues and eigenfunctions:

$$\hat{L}^2\Phi(\phi)\Theta(\theta) = L^2 e^{\mathrm{i}m_l\phi}\Theta(\theta) \tag{13.1.86}$$

That is to say:

$$\boxed{-\hbar^2\left[\frac{1}{\sin(\theta)}\frac{\partial}{\partial\theta}\left(\sin(\theta)\frac{\partial}{\partial\theta}\right)+\frac{1}{\sin^2(\theta)}\frac{\partial^2}{\partial\phi^2}\right]\Phi(\phi)\Theta(\theta) = L^2 e^{\mathrm{i}m_l\varphi}\Theta(\theta)} \tag{13.1.87}$$

Therefore:

$$\begin{aligned}
&-\hbar^2\left(\frac{1}{\sin(\theta)}\frac{\partial}{\partial\theta}\left(\sin(\theta)\frac{\partial\left(e^{\mathrm{i}m_l\phi\Theta(\theta)}\right)}{\partial\theta}\right)+\frac{1}{\sin^2(\theta)}\frac{\partial^2\left(e^{\mathrm{i}m_l\phi}\Theta(\theta)\right)}{\partial\phi^2}\right) = L^2 e^{\mathrm{i}m_l\phi}\Theta(\theta)\\
&-\hbar^2\left(\begin{array}{c}\dfrac{1}{\sin(\theta)}\dfrac{\partial}{\partial\theta}\left(\sin(\theta)\Theta(\theta)\underbrace{\dfrac{\partial(e^{m_l\phi})}{\partial\theta}}_{=0}+\sin(\theta)e^{\mathrm{i}m_l\phi}\dfrac{\partial\Theta(\theta)}{\partial\theta}\right)\\ +\dfrac{1}{\sin^2(\theta)}e^{\mathrm{i}m_l\phi}\underbrace{\dfrac{\partial^2\Theta(\theta)}{\partial\phi^2}}_{=0}+\dfrac{1}{\sin^2(\theta)}\Theta(\theta)\dfrac{\partial^2\left(e^{\mathrm{i}m_l\phi}\right)}{\partial\phi^2}\end{array}\right) = L^2 e^{\mathrm{i}m_l\phi}\Theta(\theta)\\
&-\hbar^2\left(\frac{1}{\sin(\theta)}\frac{\partial}{\partial\theta}\sin(\theta)e^{\mathrm{i}m_l\phi}\frac{\partial\Theta(\theta)}{\partial\theta}+\frac{1}{\sin^2(\theta)}\Theta(\theta)\frac{\partial^2\left(e^{\mathrm{i}m_l\phi}\right)}{\partial\phi^2}\right) = L^2 e^{\mathrm{i}m_l\phi}\Theta(\theta)\\
&-\hbar^2\left(\cancel{e^{\mathrm{i}m_l\phi}}\frac{1}{\sin(\theta)}\frac{\partial}{\partial\theta}\sin(\theta)\frac{\partial\Theta(\theta)}{\partial\theta}+\frac{1}{\sin^2(\theta)}\Theta(\theta)(\mathrm{i}m_l)^2\cancel{e^{\mathrm{i}m_l\phi}}\right) = L^2\cancel{e^{\mathrm{i}m_l\phi}}\Theta(\theta)\\
&-\hbar^2\left(\frac{1}{\sin(\theta)}\frac{\partial}{\partial\theta}\sin(\theta)\frac{\partial\Theta(\theta)}{\partial\theta}+\frac{\Theta(\theta)m_l^2}{\sin^2(\theta)}\right) = L^2\Theta(\theta)
\end{aligned} \tag{13.1.88}$$

By putting:

$$\xi = \cos(\theta) \Rightarrow \frac{\partial\xi}{\partial\theta} = -\sin(\theta) \Rightarrow \partial\theta = -\frac{\partial\xi}{\sin(\theta)} \tag{13.1.89}$$

and therefore:

$$\cos^2(\theta)+\sin^2(\theta) = 1 \Rightarrow \xi^2+\sin^2(\theta) = 1 \Rightarrow = 1-\xi^2 \tag{13.1.90}$$

we get a "Fuchs" like differential equation given by:

$$\begin{aligned}
&-\hbar^2\left(\frac{1}{\sin(\theta)}\frac{\partial}{\partial\theta}\sin(\theta)\frac{\partial\Theta(\theta)}{\partial\theta}+\frac{\Theta(\theta)m_l^2}{\sin^2(\theta)}\right)=L^2\Theta(\theta)\Rightarrow\\
&-\hbar^2\left(\frac{1}{\cancel{\sin(\theta)}}\frac{\partial}{-\frac{\partial\xi}{\cancel{\sin(\theta)}}}\sin(\theta)\frac{\partial\Theta(\xi)}{-\frac{-\partial\xi}{\sin(\theta)}}+\frac{\Theta(\xi)m_l^2}{\sin^2(\theta)}\right)-L^2\Theta(\xi)=0\\
&-\hbar^2\left(\frac{\partial}{\partial\xi}\sin^2(\theta)\frac{\partial\Theta(\xi)}{\partial\xi}-\frac{\Theta(\xi)m_l^2}{\sin^2(\theta)}\right)-L^2\Theta(\xi)=0\\
&\left(\frac{\partial}{\partial\xi}(1-\xi^2)\frac{\partial\Theta(\xi)}{\partial\xi}-\frac{\Theta(\xi)m_l^2}{1-\xi^2}\right)-\frac{L^2}{\hbar}\Theta(\xi)=0\\
&\left(\frac{\partial}{\partial\xi}(1-\xi^2)\frac{\partial\Theta(\xi)}{\partial\xi}\right)-\left(\frac{L^2}{\hbar}-\frac{m_l^2}{1-\xi^2}\right)\Theta(\xi)=0\\
&\left(\frac{\partial(1-\xi^2)}{\partial\xi}+(1-\xi^2)\frac{\partial}{\partial\xi}\frac{\partial\Theta(\xi)}{\partial\xi}\right)-\left(\frac{L^2}{\hbar}-\frac{m_l^2}{1-\xi^2}\right)\Theta(\xi)=0\\
&\left(-2\xi\Theta'(\xi)+(1-\xi^2)\Theta''(\xi)\right)-\left(\frac{L^2}{\hbar}-\frac{m_l^2}{1-\xi^2}\right)\Theta(\xi)=0
\end{aligned}\tag{13.1.91}$$

Therefore we get finally:

$$\Theta''(\xi)-\frac{2\xi\Theta'(\xi)}{1-\xi^2}+\left(\frac{L^2}{\hbar^2}-\frac{m_l^2}{1-\xi^2}\right)\frac{\Theta(\xi)}{1-\xi^2}=0\tag{13.1.92}$$

Whose coefficients have poles (singularities) in $\xi=\pm1$. But, let us recall that we have:

$$L^2=\hbar^2l(l+1)\Rightarrow\frac{L^2}{\hbar^2}=l(l+1)\tag{13.1.93}$$

So that we often find the previous differential equation in the following form in the books after elementary algebra factorization of some terms:

$$\frac{\mathrm{d}}{\mathrm{d}\xi}\left[(1-\xi^2)\frac{\mathrm{d}\Theta(\xi)}{\mathrm{d}\xi}\right]+\left[l(l+1)-\frac{m_l^2}{1-\xi^2}\right]\Theta(\xi)=0\tag{13.1.94}$$

That is obviously also often written in the literature:

$$\frac{1}{\sin(\theta)}\left[\sin(\theta)\frac{\mathrm{d}\Theta}{\mathrm{d}\theta}\right]+\left[l(l+1)-\frac{m_l^2}{\sin^2(\theta)}\right]\Theta=0\tag{13.1.95}$$

A non-trivial solution being, assuming we know Fuchs differential equations (...), what it is customary to name the "associated Legendre polynomials" (although this is not strictly speaking a polynomial ....) because containing partly Legendre polynomials (see section Calculus page 1400):

$$\boxed{P_{m_l,l}=\Theta(\xi)=\frac{1}{2^l l!}(1-\xi^2)^{\frac{m_l}{2}}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}\xi^{m_l+l}}(1-\xi^2)^l}\tag{13.1.96}$$

that you can check by injecting this solution in prior-previous differential equation.

...Following the request of a reader here is an example of verification before continuing:

The $m_l=l=0$ is immediate. Then let us consider the case where $m_l=l=1$:

$$\frac{\mathrm{d}}{\mathrm{d}\xi}\left[(1-\xi^2)\frac{\mathrm{d}\Theta(\xi)}{\mathrm{d}\xi}\right]+\left[1(1+1)-\frac{1^2}{1-\xi^2}\right]\Theta(\xi)=0 \tag{13.1.97}$$

Thus:

$$\frac{\mathrm{d}}{\mathrm{d}\xi}\left[(1-\xi^2)\frac{\mathrm{d}\Theta(\xi)}{\mathrm{d}\xi}\right]+\left[\frac{1-2\xi^2}{1-\xi^2}\right]\Theta(\xi)=0 \tag{13.1.98}$$

And we inject in it the associated Lagrange polynomial:

$$\frac{\mathrm{d}}{\mathrm{d}\xi}\left[(1-\xi^2)\frac{\mathrm{d}\sqrt{1-\xi^2}}{\mathrm{d}\xi}\right]+\left[\frac{1-2\xi^2}{1-\xi^2}\right]\sqrt{1-\xi^2}=0 \tag{13.1.99}$$

Therefore:

$$\frac{\mathrm{d}}{\mathrm{d}\xi}\left[-(1-\xi^2)\frac{\xi}{\sqrt{1-\xi^2}}\right]+\left[\frac{1-2\xi^2}{1-\xi^2}\right]\sqrt{1-\xi^2}=0 \tag{13.1.100}$$

Which give after a small simplification:

$$\frac{\mathrm{d}}{\mathrm{d}\xi}\left[-\sqrt{1-\xi^2}\xi\right]+\left[\frac{1-2\xi^2}{1-\xi^2}\right]\sqrt{1-\xi^2}=0 \tag{13.1.101}$$

By derivating:

$$\frac{\xi^2}{\sqrt{1-\xi^2}}-\sqrt{1-\xi^2}+\left[\frac{1-2\xi^2}{1-\xi^2}\right]\sqrt{1-\xi^2}=0 \tag{13.1.102}$$

Let's focus on the left part to see what it is equal to by putting everything to a common denominator:

$$\frac{\xi^2(1-\xi^2)-\sqrt{1-\xi^2}\sqrt{1-\xi^2}(1-\xi^2)+(1-2\xi^2)\sqrt{1-xi^2}\sqrt{1-\xi^2}}{\sqrt{1-\xi^2}(1-\xi^2)} \tag{13.1.103}$$

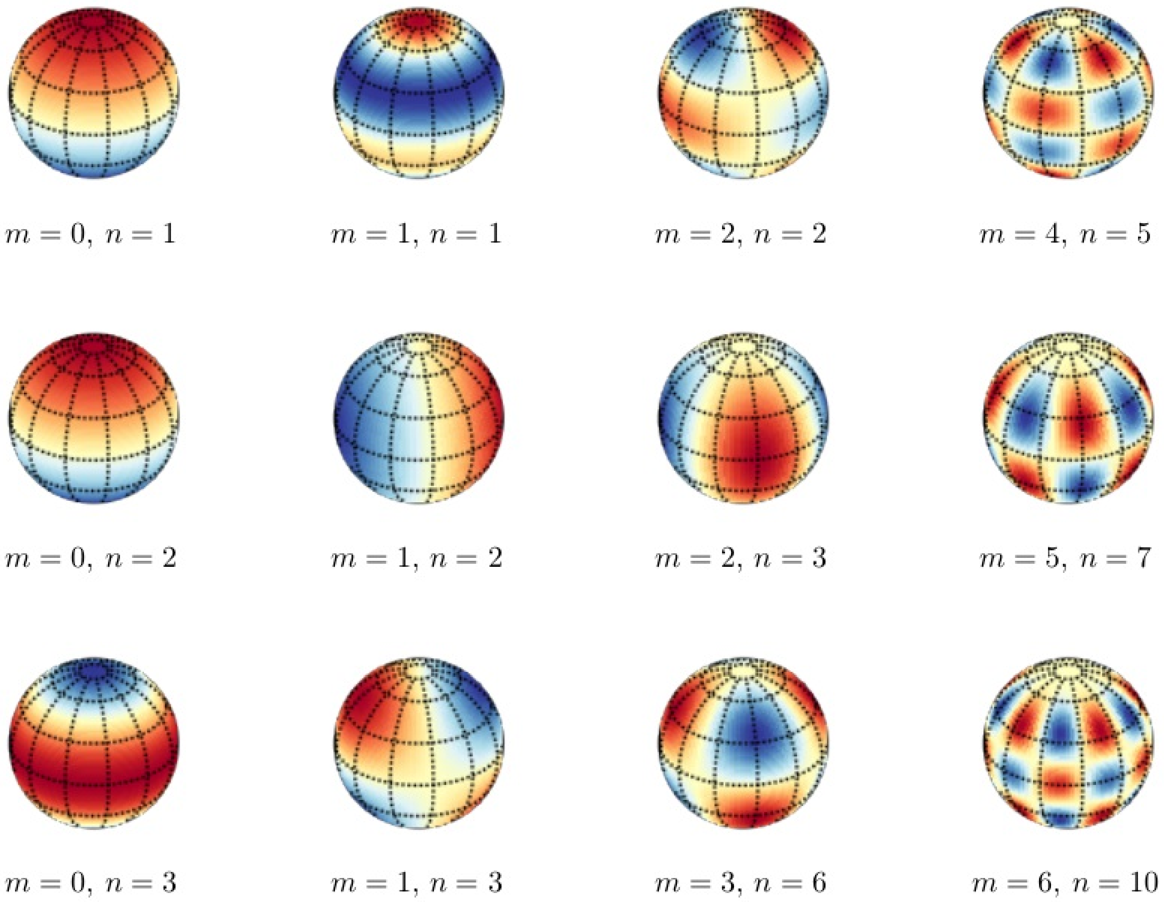
By simplifying the numerator, it should be zero. Let us see this by simplifying a first time:

$$\xi^2(1-\xi^2)-(1-\xi^2)^2+(1-2\xi^2)(1-\xi^2) \tag{13.1.104}$$

by distributing:

$$\xi^2-\xi^4-1+2\xi^2-\xi^4+1-\xi^2-2\xi^2+2\xi^4 \tag{13.1.105}$$

Which is indeed equal to zero!!!



$m = 0,\ n = 1$ $m = 1,\ n = 1$ $m = 2,\ n = 2$ $m = 4,\ n = 5$

$m = 0,\ n = 2$ $m = 1,\ n = 2$ $m = 2,\ n = 3$ $m = 5,\ n = 7$

$m = 0,\ n = 3$ $m = 1,\ n = 3$ $m = 3,\ n = 6$ $m = 6,\ n = 10$

Figure 13.5: Legendre spherical harmonics plot

With the corresponding MATLAB® 2013a script[1] (we give the script here as it is not given in the MATLAB® companion book) provided on Internet by Sanjay Sekaran (big thanks!):

```
theta = 0:pi/40:pi;                  % polar angle
phi = 0:pi/20:2*pi;                  % azimuth angle

[phi,theta] = meshgrid(phi,theta);   % define the grid

degree = 0;

So finally, we have common eigen functions (because remember that the Legendre polynomials are orthogonal to each other) that will be:

$$Y_{m_l,l}(\theta,\phi)=N_{m_l,l}P_{m_l,l}(\xi)e^{\mathrm{i}m_l\phi} \tag{13.1.106}$$

Remark

There is no need to make complicated calculations to determine the normalization factor of the exponential, as in the context of an integration over all space, the three factors of $Y_{m_l,l}(\theta,\phi)$ are independent of each other. Thus the integral is the product of the integrals (see section Differential and Integral Calculus page 1497).

Finally, we must find $N_{m_l,l}$ such that:

$$\boxed{\int|Y_{m_l,l}(\theta,\phi)|^2\mathrm{d}\Omega=\int Y_{m_l,l}(\theta,\phi)\bar{Y}_{m_l,l}(\theta,\phi)\mathrm{d}\Omega=1} \tag{13.1.107}$$

and we will see (what we will prove just below) that:

$$\boxed{N_{m_l,l}=\sqrt{\frac{(2l+1)(l-m_l)!}{2(l+m_l)!}}} \tag{13.1.108}$$

In summary, we write (we should rather say "we will write"...):

$$\boxed{Y_{m_l,l}(\theta,\phi)=\frac{1}{\sqrt{2\pi}}\sqrt{\frac{(2l+1)(l-m_l)!}{2(l+m_l)!}}\frac{1}{2^l l!}(1-\xi^2)^{\frac{m_l}{2}}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}\xi^{m_l+l}}(1-\xi^2)^l e^{\mathrm{i}m_l\phi}} \tag{13.1.109}$$

where we have omitted the factor $(-1)^l$ since in any case this term in the module of this function this term multiplies himself and then gives $(-1)^{2l}=1$.

Let us check now the framed previous boxed relation (warning this is a bit long and it is advisable to read it several times):

We consider the functions defined by:

$$Y_{m_l,l}(\theta,\phi)=\frac{N_{l,m}}{\sqrt{2\pi}}P_{m_l,l}(\cos\theta)e^{\mathrm{i}m\phi} \tag{13.1.110}$$

where:

$$P_{m_l,l}(x)=\frac{1}{2^l l!}(1-x^2)^{m_l/2}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}x^{m_l+l}}(1-x^2)^l \tag{13.1.111}$$

with:

$$l\in\mathbb{N},-l\leq m_l\leq l \quad \text{and} \quad \theta\in[0,\pi],\phi\in[0,2\pi[\tag{13.1.112}$$

The aim will therefore be to prove that these functions are orthogonal first and then find the constants $N_{m_l,l}$ such that $||Y_{m_l,l}||$. In short we will have to roll up the sleeves... of our brain...

First, let us prove for future needs that:

$$\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}\left((1-x^2)^{m_l}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}x^{m_l+l}}(1-x^2)^l\right)=(-1)^{m_l}\frac{(l+m_l)!}{(l-m_l)!}\frac{\mathrm{d}^l}{\mathrm{d}x^l}(1-x^2)^l \tag{13.1.113}$$

Proof 13.0.1. If and only if $l=m_l=0$ the equality is obvious. Let us suppose that $l\geq 1$ (thus the general case outside the obvious previous case) and given P a real polynomial of degree $\leq l-1$.

Let us put:

$$Z(x):=(1-x^2)^{m_l}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}x^{m_l+l}}(1-x^2)^l \tag{13.1.114}$$

Let us prove (functional dot product):

$$\left\langle \frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z\middle|P\right\rangle=0 \tag{13.1.115}$$

in $\mathcal{C}(x\in[-1,1],\mathbb{R})$.

Indeed, let us recall that we made the change of variable:

$$x=\cos(\theta),-\pi\leq\theta\leq+\pi\Rightarrow -1\leq x\leq +1 \tag{13.1.116}$$

Integrating by parts, we get:

$$\left\langle \frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z\middle|P\right\rangle = \int\limits_{-1}^{1}\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z(x)P(x)\mathrm{d}x = \frac{\mathrm{d}^{m_l-1}}{\mathrm{d}x^{m_l-1}}Z(x)P(x)\mathrm{d}x\bigg|_{-1}^{1} - \int\limits_{-1}^{1}\frac{\mathrm{d}^{m_l-1}}{\mathrm{d}x^{m_l-1}}Z(x)\frac{\mathrm{d}}{\mathrm{d}x}P(x)\mathrm{d}x \tag{13.1.117}$$

let us notice that for any $0 \leq j \leq m_l - 1$, $\dfrac{\mathrm{d}^j}{\mathrm{d}x^j}Z(x)$ is equal to zero in $x = \pm 1$ that is to say:

$$\frac{\mathrm{d}^j}{\mathrm{d}x^j}Z(-1) = \frac{\mathrm{d}^j}{\mathrm{d}x^j}Z(1) = 0 \tag{13.1.118}$$

Therefore (by extension), the above relation simplifies to:

$$\left\langle \frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z\middle|P\right\rangle = -\int\limits_{-1}^{1}\frac{\mathrm{d}^{m_l-1}}{\mathrm{d}x^{m_l-1}}Z(x)\frac{\mathrm{d}}{\mathrm{d}x}P(x)\mathrm{d}x \tag{13.1.119}$$

After m_l integration by parts equation, we get:

$$\left\langle \frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z\middle|P\right\rangle = (-1)^{m_l}\int\limits_{-1}^{1}Z(x)\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P(x)\mathrm{d}x \tag{13.1.120}$$

If $\deg(P) < m_l$ then the above expression shows that trivially:

$$\left\langle \frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z\middle|P\right\rangle = 0 \tag{13.1.121}$$

If $\deg(P) \geq m_l$ then by putting:

$$h(x) := (1-x^2)^{m_l}\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P(x) \tag{13.1.122}$$

We get:

$$\begin{aligned}\left\langle \frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z\middle|P\right\rangle &= (-1)^{m_l}\int\limits_{-1}^{1}(1-x^2)^{m_l}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}x^{m_l+l}}(1-x^2)^l\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P(x)\mathrm{d}x\\ &= (-1)^{m_l}\int\limits_{-1}^{1}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}x^{m_l+l}}(1-x^2)^l h(x)\mathrm{d}x\end{aligned} \tag{13.1.123}$$

let us notice once again that $\dfrac{\mathrm{d}^j}{\mathrm{d}x^j}h(x)$ vanishes in $x = \pm 1$ for any $j \leq m_l - 1$, that is say:

$$\frac{\mathrm{d}^j}{\mathrm{d}x^j}h(-1) = \frac{\mathrm{d}^j}{\mathrm{d}x^j}h(1) = 0 \tag{13.1.124}$$

By integrating by parts $m_l$the previous expression, we find:

$$\left\langle \frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z\middle|P\right\rangle = \int\limits_{-1}^{1}\frac{\mathrm{d}^l}{\mathrm{d}x^l}(1-x^2)^l\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}h(x)\mathrm{d}x \tag{13.1.125}$$

but h is a polynomial of degree $m_l+\deg(P)$.

Indeed, the first factor is of degree $2m$ and the m_lth derivative of $P(x)$" is of degree $P-m_l$, therefore:

$$2m_l+P-m_l=m_l+P=m_l+\deg(P) \tag{13.1.126}$$

So $\dfrac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}h(x)$ is a polynomial of degree $\deg(P)\leq l-1$ and knowing that $\dfrac{\mathrm{d}^l}{\mathrm{d}x^l}(1-x^2)^l$ is to a given constant equal to the l-th Legendre polynomial (see section Calculus page 1400) we then have:

$$\left\langle \frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z \middle| P\right\rangle=\int\limits_{-1}^{1}\frac{\mathrm{d}^l}{\mathrm{d}x^l}(1-x^2)^l\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}h(x)\mathrm{d}x=0 \tag{13.1.127}$$

So we have just proved that $\dfrac{\mathrm{d}m_l}{\mathrm{d}x_l^m}$ is orthogonal to any polynomial of degree $\leq l-1$.

■ Q.E.D.

$\dfrac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z$ is a polynomial of degree l (its just enough to check for some values) so therefore let us search if there is a constant $c^{te}\in\mathbb{R}$ such that:

$$\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z=c^{te}\frac{\mathrm{d}^l}{\mathrm{d}x^l}(1-x^2)^l \tag{13.1.128}$$

with for recall:

$$Z(x):=(1-x^2)^{m_l}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}x^{m_l+l}}(1-x^2)^l \tag{13.1.129}$$

We can determine the constant c^{te} by comparing the dominant coefficients of the polynomials:

$$\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z \quad \text{and} \quad \frac{\mathrm{d}^l}{\mathrm{d}x^l}(1-x^2)^l \tag{13.1.130}$$

The dominant coefficient of $\dfrac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}Z$ is:

$$(-1)^{l+m_l}\frac{(2l)!}{(l-m_l)!}\frac{(l+m_l)!}{l!} \tag{13.1.131}$$

and the dominant coefficient of $\dfrac{\mathrm{d}^l}{\mathrm{d}x^l}(1-x^2)^l$ is:

$$(-1)^l\frac{(2l)!}{l!} \tag{13.1.132}$$

Therefore:

$$(-1)^{l+m_l}\frac{(2l)!}{(l-m_l)!}\frac{(l+m_l)!}{l!}=c^{te}(-1)^l\frac{(2l)!}{l!} \tag{13.1.133}$$

That is to say:

$$c^{te}=(-1)^{m_l}\frac{(l+m_l)!}{(l-m_l)!} \tag{13.1.134}$$

So we would have for $l \geq m_l \geq 0$ (we integrate parts we integrate as many times as necessary to the left and right - necessarily - to achieve this result):

$$Z(x)=(1-x^2)^{m_l}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}x^{m_l+l}}(1-x^2)^l=(-1)^{m_l}\frac{(l+m_l)!}{(l-m_l)!}\frac{\mathrm{d}^{l-m_l}}{\mathrm{d}x^{l-m_l}}(1-x^2)^l \tag{13.1.135}$$

Now let us establish a remarkable relation that should perhaps exist between $P_{-m_l,l}$ and $P_{m_l,l}$ (and which will be useful to us later). Let us assume for this $0 \leq m_l \leq l$ and remember that at the base:

$$P_{m_l,l}(x)=\frac{1}{2^l l!}(1-x^2)^{m_l/2}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}x^{m_l+l}}(1-x^2)^l \tag{13.1.136}$$

So that brings us to write (nothing special):

$$P_{-m_l,l}(x)=\frac{1}{2^l l!}(1-x^2)^{-m_l/2}\underbrace{\left[\frac{\mathrm{d}^{l-m_l}}{\mathrm{d}x^{l-m_l}}(1-x^2)^l\right]}_{\text{replaced by the result obtained above}} \tag{13.1.137}$$

By the previous results ($(-1)^{m_l}=(-1)^{-m_l}$):

$$\begin{gathered}(1-x^2)^{m_l}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}x^{m_l+l}}(1-x^2)^l=(-1)^{m_l}\frac{(l+m_l)!}{(l-m_l)!}\frac{\mathrm{d}^{l-m_l}}{\mathrm{d}x^{l-m_l}}(1-x^2)^l\\ \Rightarrow\frac{\mathrm{d}^{l-m_l}}{\mathrm{d}x^{l-m_l}}(1-x^2)^l=(-1)^{m_l}\frac{(l-m_l)!}{(l+m_l)!}(1-x^2)^{m_l}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}x^{m_l+l}}(1-x^2)^l\end{gathered} \tag{13.1.138}$$

this leads us to write:

$$\begin{aligned}P_{-m_l,l}(x)&=\frac{(-1)^{m_l}}{2^l l!}\frac{(l-m_l)!}{(l+m_l)!}(1-x^2)^{-m_l/2}(1-x^2)^{m_l}\frac{\mathrm{d}^{l+m_l}}{\mathrm{d}x^{l+m_l}}(1-x^2)^l\\ &=\frac{(-1)^{m_l}}{2^l l!}\frac{(l-m_l)!}{(l+m_l)!}(1-x^2)^{m_l/2}\frac{\mathrm{d}^{l+m_l}}{\mathrm{d}x^{l+m_l}}(1-x^2)^l=\\ &=(-1)^{m_l}\frac{(l-m_l)!}{(l+m_l)!}P_{m_l,l}(x)\end{aligned} \tag{13.1.139}$$

Therefore we get:

$$P_{-m_l,l}(x)=(-1)^{m_l}\frac{(l-m_l)!}{(l+m_l)!}P_{m_l,l} \tag{13.1.140}$$

First, let us prove that:

$$\int\limits_{-1}^{1}P_l(x)x^l\mathrm{d}x=\frac{(l!)^2}{(2l+1)!}2^{l+1} \tag{13.1.141}$$

where P_l is the n-th Legendre polynomial (hence the origin of the name of "associated Legendre polynomial" ...).

Proof 13.0.2. First, we have proved that the Legendre polynomials satisfy the following recurrence relation (see section Calculus page 1400):

$$(n+1)P_{n+1}(x)=(2n+1)xP_n(x)-nP_{n-1}(x) \tag{13.1.142}$$

for $n\geq 1$. Multiplying the above equation by x^{n-1} and integrating, we get:

$$(n+1)\int\limits_{-1}^{1}P_{n+1}(x)x^{n-1}\mathrm{d}x=(2n+1)\int\limits_{-1}^{1}P_n(x)x^n\mathrm{d}x-n\int\limits_{-1}^{1}P_{n-1}(x)x^{n-1}\mathrm{d}x \tag{13.1.143}$$

But:

$$\int\limits_{-1}^{1}P_{n+1}(x)x^{n-1}\mathrm{d}x=0 \tag{13.1.144}$$

Let us recall that the P_{n+1} polynomials form an orthogonal basis of which the polynomials that generate it are of increasing degree from 0 to n, so a lower order polynomial - expressed in a sub vector space - will always be perpendicular to the vectors (polynomials) generating the higher dimensions. So if we take the example of $\mathbb{R}^3$ generated by the basis $(\vec{e}_1,\vec{e}_2,\vec{e}_3)$, then a vector $\vec{v}$ expressed by the linear combination of $(\vec{e}_1,\vec{e}_2)$ will always be perpendicular to $\vec{e}_3$ and therefore a zero scalar product with it.

And therefore it follows:

$$\int\limits_{-1}^{1}P_n(x)x^n\mathrm{d}x=\frac{n}{2n+1}\int\limits_{-1}^{1}P_{n-1}(x)x^{n-1}\mathrm{d}x \tag{13.1.145}$$

Let us put:

$$S_n=\int\limits_{-1}^{1}P_n(x)x^n\mathrm{d}x \tag{13.1.146}$$

The previous expression becomes (remember $P_0(x)=1$):

$$S_n=\frac{n}{2n+1}S_{n-1}\quad\text{with}\quad S_0=S_n=\int\limits_{-1}^{1}P_0(x)x^0\mathrm{d}x=\int\limits_{-1}^{1}1\mathrm{d}x=2 \tag{13.1.147}$$

Thus by induction:

$$S_n=\frac{n}{2n+1}S_{n-1}=2\cdot\frac{1}{3}\cdot\frac{2}{5}\cdot\frac{3}{7}\cdot\ldots\cdot\frac{n}{2n+1}=\frac{2}{1}\cdot\frac{1}{3}\cdot\frac{2}{5}\cdot\frac{3}{7}\cdot\ldots\cdot\frac{n}{2n+1} \tag{13.1.148}$$

Furthermore as:

$$1\cdot 2\cdot 3\cdot 4\cdot\ldots\cdot n=n! \tag{13.1.149}$$

We then have for the prior-previous relation the denominator which can obviously be rewritten:

$$1\cdot 3\cdot 5\cdot 7\cdot\ldots\cdot(2n+1)=\frac{(2n+1)!}{2\cdot 4\cdot 6\cdot\ldots\cdot(2n)} \tag{13.1.150}$$

Then we have:

$$2\cdot 4\cdot 6\cdot \ldots \cdot (2n)=\prod_{j=1}^{n}2j=2^n n! \tag{13.1.151}$$

So in the end we can simplify the denominator as follows:

$$1\cdot 3\cdot 5\cdot \ldots \cdot (2n+1)=\frac{(2n+1)!}{2\cdot 4\cdot 6\cdot \ldots \cdot (2n)}=\frac{(2n+1)!}{2^n n!} \tag{13.1.152}$$

and:

$$S_n=2\cdot\frac{1}{3}\cdot\frac{2}{5}\cdot\frac{3}{7}\cdot \ldots \cdot \frac{n}{2n+1}=2^{n+1}\frac{(n!)^2}{(2n+1)!} \tag{13.1.153}$$

So we have well proved that (just in case ... you would not follow anymore the initial target ...) that:

$$\int_{-1}^{1}P_l(x)x^l\mathrm{d}x=\frac{(l!)^2}{(2l+1)!}2^{l+1} \tag{13.1.154}$$

■ Q.E.D.

Let us attack us finally to what interests us. That is to say, prove that:

$$\langle Y_{m_l,l}|Y_{j,k}\rangle=\begin{cases}\dfrac{2N_{m_l,l}^2}{2l+1}\dfrac{(l+m_l)!}{(l-m_l)!} & \text{if}\quad m_l=j \text{ and } l=k\\ 0 & \text{otherwise}\end{cases} \tag{13.1.155}$$

Proof 13.0.3. If $m_l\neq j$ then:

$$\langle Y_{m_l,l}|Y_{j,k}\rangle=\frac{N_{m_l,l}N_{j,k}}{2\pi}\int_0^{\pi}\int_0^{2\pi}P_{m,l}(\cos\theta)P_{j,k}(\cos\theta)\mathrm{e}^{\mathrm{i}\phi(m_l-j)}\mathrm{d}\Omega=0 \tag{13.1.156}$$

where:

$$\mathrm{d}\Omega=\sin(\theta)\mathrm{d}\theta\mathrm{d}\phi \tag{13.1.157}$$

Remark

Let us recall that the Jacobian in spherical coordinates is $r^2\sin(\theta)$ (see section Differential and Integral Calculus page 1528) and as the integrated function above is not dependent on r, we have take out the term $r^2\mathrm{d}r$ of this integral (by cons we will meet again the same term in the function $R(r)$ present in the Schrödinger equation).

And with:

$$\int_0^{2\pi}e^{\mathrm{i}\phi(m_l-j)}\mathrm{d}\phi=0 \tag{13.1.158}$$

If $l>k$ and $m_l=j$ then the dot product of:

$$\langle Y_{m_l,l}|Y_{m_l,k}\rangle=N_{m_l,l}N_{m_l,k}\int\limits_0^\pi P_{m_l,l}(\cos\theta)P_{m_l,k}(\cos\theta)\sin(\theta)\mathrm{d}\theta \tag{13.1.159}$$

is simplified to:

$$\langle Y_{m_l,l}|Y_{j,k}\rangle=N_{m_l,l}N_{j,k}\int\limits_0^\pi P_{m_l,l}(\cos\theta)P_{j,k}(\cos\theta)\sin(\theta)\mathrm{d}\theta \tag{13.1.160}$$

By doing the change of variable $x=\cos(\theta)$ we get:

$$\langle Y_{m_l,l}|Y_{j,k}\rangle=N_{m_l,l}N_{j,k}\int\limits_{-1}^1 P_{m,l}(x)P_{j,k}(x)\mathrm{d}x \tag{13.1.161}$$

Let us suppose that $m_l\geq 0$:

$$P_{m,l}(x)=\frac{1}{2^l l!}(1-x^2)^{m_l/2}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}x^{m_l+l}}(1-x^2)^l=(-1)^l(1-x^2)^{m_l/2}\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P_l(x) \tag{13.1.162}$$

where $P_l(x)$ is the n-th Legendre polynomial. Thus the expression of the dot product becomes:

$$\langle Y_{m_l,l}|Y_{j,k}\rangle=(-1)^{l+k}N_{m_l,l}N_{j,k}\int\limits_{-1}^1(1-x^2)^{m_l}\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P_l(x)\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P_k(x)\mathrm{d}x \tag{13.1.163}$$

If we put:

$$h(x):=(1-x^2)^{m_l}\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P_k(x) \tag{13.1.164}$$

then the relation becomes:

$$\langle Y_{m_l,l}|Y_{j,k}\rangle=(-1)^{l+k}N_{m_l,l}N_{j,k}\int\limits_{-1}^1\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P_l(x)h(x)\mathrm{d}x \tag{13.1.165}$$

Integrating by parts m times the expression above we get:

$$\langle Y_{m_l,l}|Y_{j,k}\rangle=(-1)^{l+k+m_l}N_{m_l,l}N_{j,k}\int\limits_{-1}^1 P_l(x)\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}h(x)\mathrm{d}x \tag{13.1.166}$$

But $\dfrac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}h(x)$ is a polynomial of degree k. Knowing that $l>k$, the latter integral is zero for the same reasons as those mentioned above. Therefore:

$$\langle Y_{m_l,l}|Y_{j,k}\rangle=0 \tag{13.1.167}$$

If $m_l<$ then we have proved that:

$$P_{-m_l,l}(x)=(-1)^{m_l}\frac{(l-m_l)!}{(l+m_l)!}P_{m_l,l} \tag{13.1.168}$$

and therefore:

$$\langle Y_{m_l,l}|Y_{j,k}\rangle = C\int\limits_{-1}^{1} P_{-m_l,l}(x)P_{-j,k}(x)\mathrm{d}x = 0 \tag{13.1.169}$$

as $-m_l \geq 0$.

It only remains to us to treat the case $m_l = j, l = k$. Let us suppose again that $m_l \geq 0$. So as before we have:

$$P_{m_l,l}(x) = (-1)^l(1-x^2)^{m_l/2}\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P_l(x) \tag{13.1.170}$$

and:

$$\langle Y_{m_l,l}|Y_{m_l,l}\rangle = N_{m_l,l}^2\int\limits_{-1}^{1} P_{m_l,l}(x)^2\mathrm{d}x = N_{m_l,l}^2\int\limits_{-1}^{1}(1-x^2)^{m_l}\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P_l(x)\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P_l(x)\mathrm{d}x \tag{13.1.171}$$

Let us put:

$$h(x) := (1-x^2)^{m_l}\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P_l(x) \tag{13.1.172}$$

The relation then becomes:

$$\langle Y_{m_l,l}|Y_{m_l,l}\rangle = N_{m_l,l}^2\int\limits_{-1}^{1}\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}P_l(x)h(x)\mathrm{d}x \tag{13.1.173}$$

By integrating m times by parts, we find:

$$\langle Y_{m_l,l}|Y_{m_l,l}\rangle = N_{m_l,l}^2(-1)^{m_l}\int\limits_{-1}^{1}P_l(x)\frac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}h(x)\mathrm{d}x \tag{13.1.174}$$

$\dfrac{\mathrm{d}^{m_l}}{\mathrm{d}x^{m_l}}h(x)$ is a polynomial of degree l which dominant coefficient is equal to:

$$(-1)^{m_l}\frac{(2l)!}{(l!)^2 2^l}\frac{(l+m_l)!}{(l-m_l)!} \tag{13.1.175}$$

P_l being orthogonal to any polynomial of degree strictly less that l, the expression can be written:

$$\langle Y_{m_l,l}|Y_{m_l,l}\rangle = N_{m_l,l}^2\frac{(2l)!}{(l!)^2 2^l}\frac{(l+m_l)!}{(l-m_l)!}\int\limits_{-1}^{1}P_l(x)x^l\mathrm{d}x \tag{13.1.176}$$

But, we have proved that:

$$\int\limits_{-1}^{1}P_l(x)x^l\mathrm{d}x = \frac{(l!)^2}{(2l+1)!}2^{l+1} \tag{13.1.177}$$

therefore:

$$\langle Y_{m_l,l}|Y_{m_l,l}\rangle = N_{m_l,l}^2\frac{(2l)!}{(l!)^2 2^l}\frac{(l+m_l)!}{(l-m_l)!}\frac{(l!)^2}{(2l+1)!}2^{l+1} = \frac{2N_{m_l,l}^2}{2l+1}\frac{(l+m_l)!}{(l-m_l)!} \tag{13.1.178}$$

If $m_l \leq 0$ we know that we get the result.

■ Q.E.D.

Finally this result gives us also the normalization condition:

$$\langle Y_{m_l,l}|Y_{m_l,l}\rangle=\frac{2N^2_{m_l,l}}{2l+1}\frac{(l+m_l)!}{(l-m_l)!}=1\quad\Rightarrow\quad N_{m_l,l}=\sqrt{\frac{(2l+1)(l-m_l)!}{2(l+m_l)!}}\tag{13.1.179}$$

And so finally:

$$Y_{m_l,l}(\theta,\phi)=\frac{N_{m_l,l}}{\sqrt{2\pi}}P_{m_l,l}(\cos(\theta))e^{\mathrm{i}m\phi}\tag{13.1.180}$$

is indeed an orthonormal family. Either explicitly (we reintroduce the factor $(-1)^l$):

$$\boxed{Y_{m_l,\phi}=\sqrt{\frac{(2l+1)(l-m_l)!}{4\pi(l+m_l)!}}\frac{(-1)^l}{2^l\cdot l!}(1-\cos^2(\theta))^{m_l/2}\frac{\mathrm{d}^{m_l+l}}{\mathrm{d}\cos(\theta)^{m_l+l}}\left(1-\cos^2(\theta)\right)^l e^{\mathrm{i}m_l\phi}}\tag{13.1.181}$$

Finally, after this highly mathematical interlude (but instructive for the methodology of approach), we see (which is logical) that to each value of l correspond therefore $2l+1$ eigenfunctions $Y_{m_l,l}(\theta,\phi)$. We also say that the value $\hbar l(l+1)$ is $2l+1$ times degenerated since:

$$\begin{gathered}\hat{L}^2Y_{m_l,l}(\theta,\phi)=L^2Y_{m_l,l}(\theta,\phi)\\ \Updownarrow\\ \hat{L}^2Y_{m_l,l}(\theta,\phi)=\hbar^2l(l+1)Y_{m_l,l}(\theta,\phi)\end{gathered}\tag{13.1.182}$$

Here are some values of the function $Y_{m_l,l}(\theta,\phi)$ (here below denoted $Y_l^{m_l}(\theta,\phi)$) that generates what we commonly name "spherical harmonics"[2]. Some of these formulas give the "Cartesian" version (useful for some softwares that doesn't manage directly plots in spherical coordinates...). This assumes x, y, z, and r are related to θ and ϕ through the usual spherical-to-Cartesian coordinate transformation (see section Vector Calculus page 1849):

$$\begin{cases}x=r\sin(\theta)\cos(\phi)\\ y=r\sin(\theta)\sin(\phi)\\ z=r\cos(\theta)\end{cases}\tag{13.1.183}$$

So let's start!:

$$Y_0^0(\theta,\phi)=\frac{1}{2}\sqrt{\frac{1}{\pi}}\tag{13.1.184}$$

$$\begin{aligned}Y_1^{-1}(\theta,\phi)=&\quad\frac{1}{2}\sqrt{\frac{3}{2\pi}}e^{-\mathrm{i}\phi}\sin(\theta)&=&\quad\frac{1}{2}\sqrt{\frac{3}{2\pi}}\frac{(x-\mathrm{i}y)}{r}\\ Y_1^0(\theta,\phi)=&\quad\frac{1}{2}\sqrt{\frac{3}{\pi}}\cos(\theta)&=&\quad\frac{1}{2}\sqrt{\frac{3}{\pi}}\frac{z}{r}\\ Y_1^1(\theta,\phi)=&\;-\frac{1}{2}\sqrt{\frac{3}{2\pi}}e^{\mathrm{i}\phi}\sin(\theta)&=&\;-\frac{1}{2}\sqrt{\frac{3}{2\pi}}\frac{(x+\mathrm{i}y)}{r}\end{aligned}\tag{13.1.185}$$

---

Let's see some plots of these beautiful spherical harmonics that can be obtained with Maple™ 4.00b[3] by using the following command (this is the $Y_2^{-1}(\theta,\phi)$ spherical harmonic function above):

---

[3] For the `R` equivalent code, the reader can refer to the `R` companion book

```
>plot3d(Re(-sqrt(15/(8*Pi))*(sin(theta)*cos(theta)*exp(-I*phi)))^2,phi=0..2*Pi,
theta=0..Pi, coords=spherical,scaling=constrained,numpoints=5000,axes=frame);
```

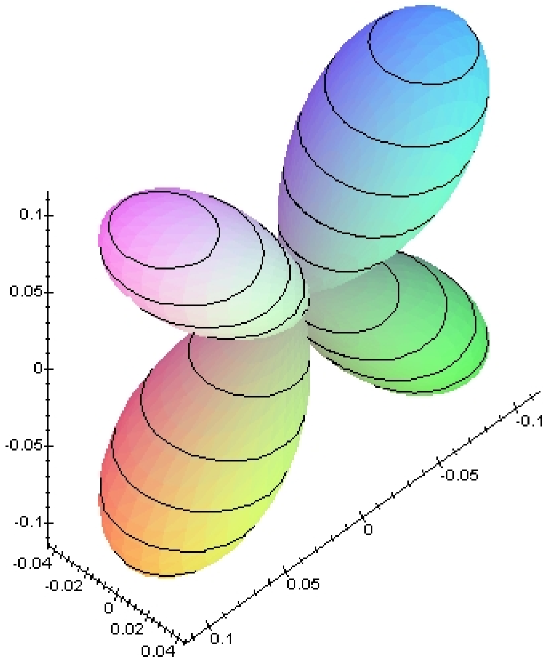

Figure 13.6: Plot of the spherical harmonics $Y_{1,2}$

- $Y_{0,0}$ (corresponding to $n=1$!) gives a sphere (constant value regardless θ,ϕ) which the probability density can be represented by the following "photographic card" or "density map" (the density in a given state is represented by the density of light spotted on a dark background):

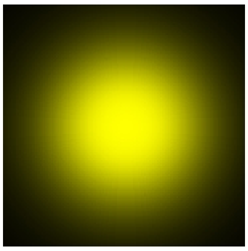

Figure 13.7: $1s$ density map

Representing the possible $1s$ orbits.

- $Y_{0,1},Y_{1,1},Y_{-1,1}$ give (for $n=2$ at least!):

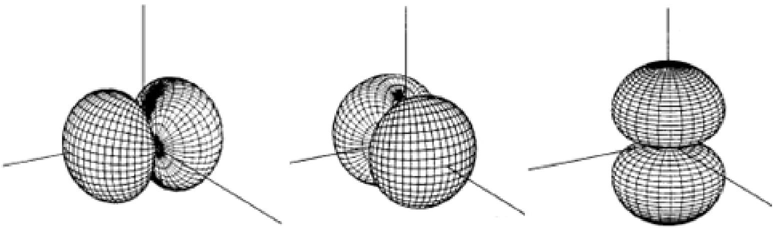

Figure 13.8: $2p$ orbitals (spherical harmonics)

Which represents the possible $2p$ orbits, the probability density function can be represented by its density and isodensity maps:

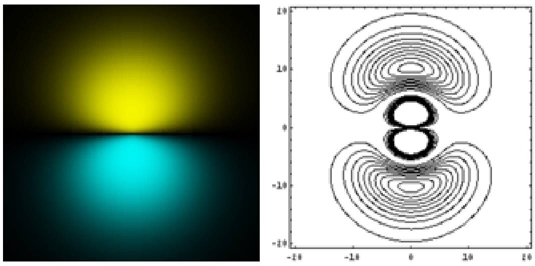

Figure 13.9: $2p$ **density map**

- $Y_{-2,2}, Y_{-1,2}, Y_{1,2}, Y_{2,2}, Y_{0,2}$ give (for $n = 3$ at least!):

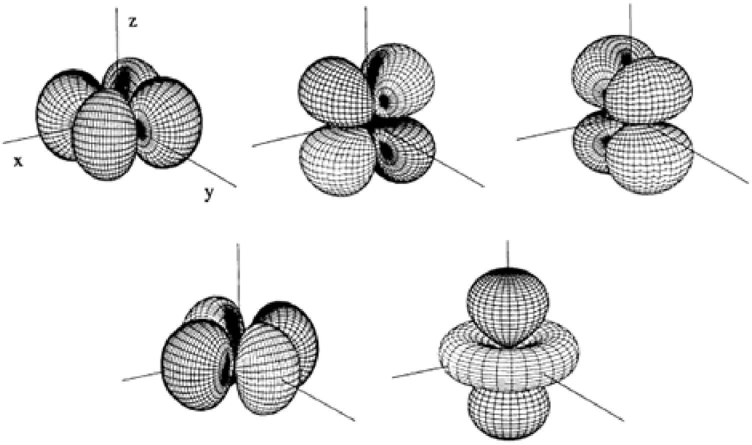

Figure 13.10: $3d$ **orbitals (spherical harmonics)**

Representing 5 possible $3d$ centrosymmetric orbits, which the probability density can be represented by (the last two maps represent $Y_{0,2}$) the following density maps:

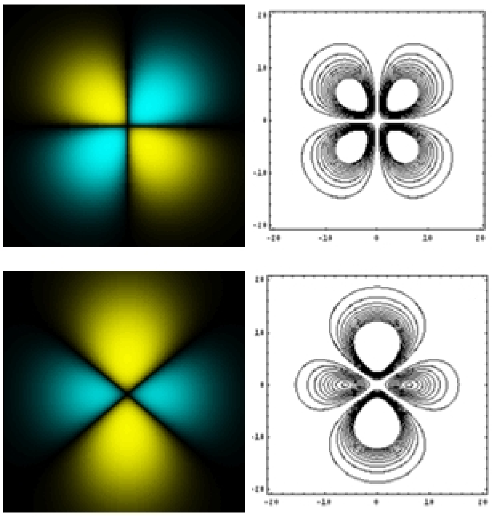

Figure 13.11: $3d$ **density map**

- $Y_{-3,3}, Y_{-2,3}, Y_{-1,3}, Y_{1,3}, Y_{2,3}, Y_{3,3}, Y_{0,3}$ give (for $n = 4$ at least!):

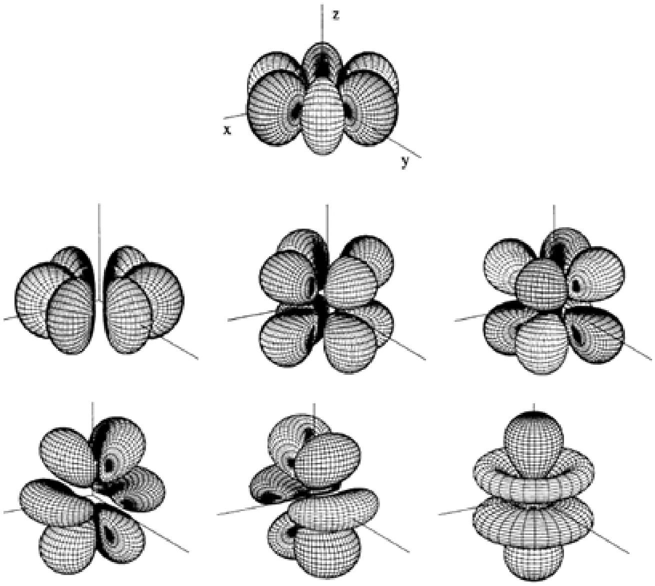

Figure 13.12: $3d$ orbitals (spherical harmonics)

Representing 7 possible $3f$ anti-centrosymmetric orbits, which the probability density can be represented by (in the order: $Y_{0,3}, Y_{\pm 1,3}, Y_{\pm 2,3}, Y_{\pm 3,3}$) the following density maps:

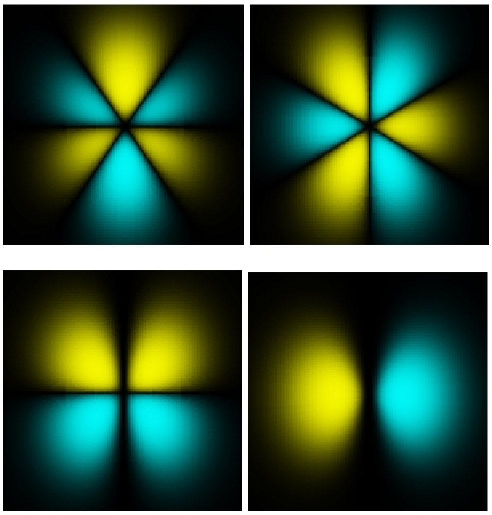

Figure 13.13: $4f$ density map

Or in a much better quality (from top-left to bottom right we have $Y_0^0, Y_1^{-1}, Y_1^0, Y_1^1, Y_2^{-2}, Y_2^{-1}, Y_2^0, Y_2^1, Y_2^2, Y_3^0$):

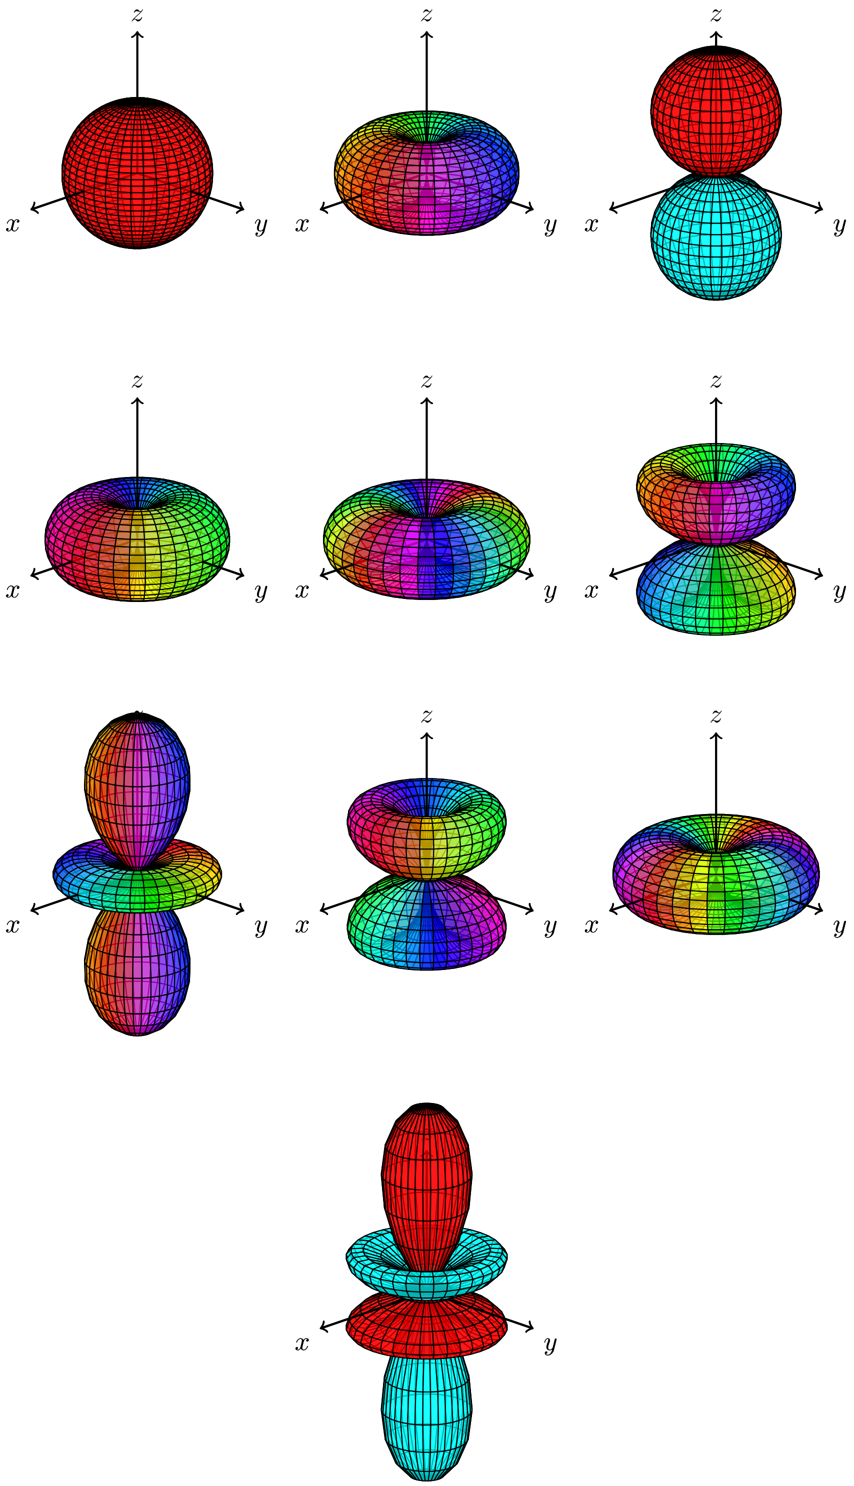

Figure 13.14: **3d orbitals (spherical harmonics) made with TikZ (author: Jeff Hein)**

The above results thus lead us to write:

$$\Psi(r,\theta,\phi)=R(r)\Phi(\phi)\Theta(\theta)=R(r)Y_{m_l,l}(\theta,\phi) \qquad (13.1.195)$$

Substituting this in the Schrödinger equation:

$$\left[T_r+\frac{l(l+1)\hbar^2}{2\mu r}+E_p\right]\Psi=E\Psi \qquad (13.1.196)$$

We get ($T_r = 0$ in the rigid rotor but $\neq 0$ in the case of the hydrogen atom):

$$\left[T_r + \frac{l(l+1)\hbar^2}{2\mu r} + E_p\right] R(r)Y_{m_l,l}(\theta,\phi) = ER(r)Y_{m_l,l}(\theta,\phi) \tag{13.1.197}$$

As there is in this relation no operator which acts on $Y_{m_l,l}(\theta,\phi)$, we can simplify to obtain:

$$\left[T_r + \frac{l(l+1)\hbar^2}{2\mu r} + E_p\right] R(r) = ER(r) \tag{13.1.198}$$

which we see in the general case of the isolated atom that energy levels are no longer dependent of m_l (due to the spherical symmetry of the potential). Then we say that the levels corresponding to the same values of n and of l are all merged whatever the values of m_l.

In the case where E_p derived from the $1/r$ Coulomb potential , this radial equation leads us to a normalizing solution of $R(r)$ (different from zero then...) only for values of the energy corresponding to the following quantization law (well ... what a coincidence, we fall back on the expression proved in the old models of Corpuscular Quantum Physics at page 4632!):

$$E_n = -hcR_H\frac{Z^2}{n^2} \tag{13.1.199}$$

where R_H is the Rydberg constant as we determined in the section of Corpuscular Quantum Physics. Thus, in this case the energy levels corresponding to the same values of n are all merged regardless of the value of l.

Remember that from the beginning we assume a rigid rotator with $R(r) = c^{te}$. And what if we consider now the non-rigid version?

13.1.3.2 Non-Rigid Rotator

Let us remind that we started from:

$$\left(-\frac{\hbar}{2\mu}\nabla^2 + E_p(r)\right)\Psi(\vec{r}) = E\Psi(\vec{r}) \tag{13.1.200}$$

Or more explicitly:

$$\left(-\frac{\hbar}{2\mu}\nabla^2 - \frac{Ze^2}{4\pi\varepsilon_0 r}\right)\Psi(\vec{r}) = E\Psi(\vec{r}) \tag{13.1.201}$$

Therefore in polar coordinates:

$$-\frac{\hbar^2}{2\mu}\left[\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial\Psi}{\partial r}\right) + \frac{1}{r^2\sin(\theta)}\frac{\partial}{\partial\theta}\left(\sin(\theta)\frac{\partial\Psi}{\partial\theta}\right) + \frac{1}{r^2\sin^2(\theta)}\frac{\partial^2\psi}{\partial\phi^2}\right] - \frac{Ze^2}{4\pi\varepsilon_0 r}\Psi = E\Psi \tag{13.1.202}$$

Both LHS and RHS contain a term linear in Ψ, so combine:

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial\Psi}{\partial r}\right) + \frac{1}{r^2\sin(\theta)}\frac{\partial}{\partial\theta}\left(\sin(\theta)\frac{\partial\Psi}{\partial\theta}\right) + \frac{1}{r^2\sin^2(\theta)}\frac{\partial^2\Psi}{\partial\phi^2} + \frac{2\mu}{\hbar^2}\left(E + \frac{Ze^2}{4\pi\varepsilon_0 r}\right)\Psi = 0 \tag{13.1.203}$$

Using the separation of variables idea, we assume a product solution of a radial and an angular function:

$$\Psi(r,\theta,\phi)=R(r)Y(\theta,\phi) \tag{13.1.204}$$

Since Y does not depend on r, we can move it in front of the radial derivative:

$$\frac{\partial\Psi}{\partial r}=\frac{\partial}{\partial r}RY=Y\frac{\mathrm{d}R}{\mathrm{d}r} \tag{13.1.205}$$

and, similarly, R does not depend on the angular variables. Thus replace Ψ and the differentials:

$$\frac{Y}{r^2}\frac{\mathrm{d}}{\mathrm{d}r}\left(r^2\frac{\mathrm{d}R}{\mathrm{d}r}\right)+\frac{R}{r^2\sin(\theta)}\frac{\partial}{\partial\theta}\left(\sin(\theta)\frac{\partial Y}{\partial\theta}\right)+\frac{R}{r^2\sin^2(\theta)}\frac{\partial^2 Y}{\partial\phi^2}+\frac{2\mu}{\hbar^2}\left(E+\frac{Ze^2}{4\pi\varepsilon_0 r}\right)RY=0 \tag{13.1.206}$$

We multiply by r^2 and divide by RY to separate the radial and angular terms:

$$\frac{1}{R}\frac{\mathrm{d}}{\mathrm{d}r}\left(r^2\frac{\mathrm{d}R}{\mathrm{d}r}\right)+\frac{1}{Y\sin(\theta)}\frac{\partial}{\partial\theta}\left(\sin(\theta)\frac{\partial Y}{\partial\theta}\right)+\frac{1}{Y\sin^2(\theta)}\frac{\partial^2 Y}{\partial\phi^2}+\frac{2\mu r^2}{\hbar^2}\left(E+\frac{Ze^2}{4\pi\varepsilon_0 r}\right)=0 \tag{13.1.207}$$

The first and fourth terms depend on r only, the middle terms depend on the angles only. They can only balance each other for all points in space if the radial and angular terms are the same constant but with opposite sign.

Therefore, we can separate into a radial equation:

$$\frac{\mathrm{d}}{\mathrm{d}r}\left(r^2\frac{\mathrm{d}R}{\mathrm{d}r}\right)+\frac{2\mu r^2}{\hbar^2}\left(E+\frac{Ze^2}{4\pi\varepsilon_0 r}\right)R-AR=0 \tag{13.1.208}$$

and an angular equation:

$$\frac{1}{\sin(\theta)}\frac{\partial}{\partial\theta}\left(\sin(\theta)\frac{\partial Y}{\partial\theta}\right)+\frac{1}{\sin^2(\theta)}\frac{\partial^2 Y}{\partial\phi^2}+AY=0 \tag{13.1.209}$$

where A is the separation constant.

The angular part still contains terms depending on both θ and ϕ. Another separation of variables is needed.

We'll replace Y by a product of single-variable functions:

$$Y(\theta,\phi)=\Theta(\theta)\Phi(\phi) \tag{13.1.210}$$

And we just see earlier what it took us to! However let us continue because we would like to know the value of A!

Replacing Y and the differentials, we have:

$$\frac{\Phi}{\sin(\theta)}\frac{\mathrm{d}}{\mathrm{d}\theta}\left(\sin(\theta)\frac{\mathrm{d}\Theta}{\mathrm{d}\theta}\right)+\frac{\Theta}{\sin^2(\theta)}\frac{\mathrm{d}^2\Phi}{\mathrm{d}\phi^2}+A\Phi\Theta=0 \tag{13.1.211}$$

Isolating variables in separate terms:

$$\frac{\sin(\theta)}{\Theta}\frac{\mathrm{d}}{\mathrm{d}\theta}\left(\sin(\theta)\frac{\mathrm{d}\Theta}{\mathrm{d}\theta}\right)+\frac{1}{\Phi}\frac{\mathrm{d}^2\Phi}{\mathrm{d}\phi^2}+A\sin^2(\theta)=0 \tag{13.1.212}$$

With B as separation constant, we have a polar part:

$$\frac{\sin(\theta)}{\Theta}\frac{\mathrm{d}}{\mathrm{d}\theta}\left(\sin(\theta)\frac{\mathrm{d}\Theta}{\mathrm{d}\theta}\right)+A\sin^2(\theta)-B=0 \tag{13.1.213}$$

where B is another separation constant! Rearranging we get:

$$\frac{1}{\sin(\theta)}\frac{\mathrm{d}}{\mathrm{d}\theta}\left(\sin(\theta)\frac{\mathrm{d}\Theta}{\mathrm{d}\theta}\right)+\left(A-\frac{B^2}{\sin^2(\theta)}\right)\Theta=0 \tag{13.1.214}$$

And here we recognize something known to us. We already proved earlier (see page 6140):

$$\frac{1}{\sin(\theta)}\left[\sin(\theta)\frac{\mathrm{d}\Theta}{\mathrm{d}\theta}\right]+\left[l(l+1)-\frac{m_l^2}{\sin^2(\theta)}\right]\Theta=0 \tag{13.1.215}$$

So we can immediately associate $A=l(l+1)$ and $B=m_l$. Great!

That means now we can write the radial equation as:

$$\frac{\mathrm{d}}{\mathrm{d}r}\left(r^2\frac{\mathrm{d}R}{\mathrm{d}r}\right)+\frac{2\mu r^2}{\hbar^2}\left(E+\frac{Ze^2}{4\pi\epsilon_0 r}\right)R-l(l+1)R=0 \tag{13.1.216}$$

We apply the product rule to the first term:

$$r^2\frac{\mathrm{d}^2R}{\mathrm{d}r^2}+2r\frac{\mathrm{d}R}{\mathrm{d}r}+\frac{2\mu r^2}{\hbar^2}\left(E+\frac{Ze^2}{4\pi\epsilon_0 r}\right)R-l(l+1)R=0 \tag{13.1.217}$$

and divide by r^2:

$$\frac{\mathrm{d}^2R}{\mathrm{d}r^2}+\frac{2}{r}\frac{\mathrm{d}R}{\mathrm{d}r}+\left(\frac{2\mu}{\hbar^2}\left(E+\frac{Ze^2}{4\pi\epsilon_0 r}\right)-\frac{l\,(l+1)}{r^2}\right)R=0 \tag{13.1.218}$$

We can't solve this straight away, but for very large r, the highlighted terms are forced to zero because they go reciprocal with r.

That leaves us with an asymptotic equation:

$$\frac{\mathrm{d}^2R_\infty}{\mathrm{d}r^2}+\frac{2\mu E}{\hbar^2}R_\infty=0 \tag{13.1.219}$$

which is another ordinary differential equation with constant coefficients. Having for solution (see section Differential and Integral Calculus page 1610):

$$R_\infty=C_1\exp\left(\mathrm{i}\sqrt{\frac{2\mu E}{\hbar^2}}r\right)+C_2\exp\left(-\mathrm{i}\sqrt{\frac{2\mu E}{\hbar^2}}r\right) \tag{13.1.220}$$

It makes sense to use as the zero point of potential energy the energy of a free electron, i.e. in this asymptotic case, $E\rightarrow 0$ for an electron far away from the nucleus, as it is practically free.

Since the presence of the positive charge in the nucleus stabilises the atom, we must look for solutions where E becomes negative as the electron comes closer to the nucleus. These two conditions are met if we choose $C_2 = 0$ and use the fact that $E < 0$ to get rid of the imaginary unit.

The asymptotic solution is then:

$$R_\infty = C_2 e^{-\sqrt{-\frac{2\mu E}{\hbar^2}}r} \tag{13.1.221}$$

For bound states, $R \to 0$ as $r \to +\infty$, and R is finite at the origin, $r = 0$. We do not consider continuum states with positive energy. Only when the latter are included do hydrogen wave functions form a complete set.

By use of the abbreviations (resulting from rescaling r to the dimensionless radial variable ρ):

$$\rho = \alpha r \quad \text{with} \quad \alpha^2 = -\frac{8\mu E}{\hbar^2}, \quad E < 0, \quad \lambda = \frac{\mu Z e^2}{2\pi\varepsilon_0 \alpha \hbar^2} \tag{13.1.222}$$

the equation:

$$\frac{\mathrm{d}^2 R}{\mathrm{d}r^2} + \frac{2}{r}\frac{\mathrm{d}R}{\mathrm{d}r} + \left(\frac{2\mu}{\hbar^2}\left(E + \frac{Ze^2}{4\pi\epsilon_0 r}\right) - \frac{l\,(l+1)}{r^2}\right) R = 0 \tag{13.1.223}$$

becomes:

$$\frac{1}{\rho^2}\frac{d}{d\rho}\left(\rho^2 \frac{d\chi(\rho)}{d\rho}\right) + \left(\frac{\lambda}{\rho} - \frac{1}{4} - \frac{l(l+1)}{\rho^2}\right)\chi(\rho) = 0 \tag{13.1.224}$$

where $\chi(\rho) = R(\rho/\alpha)$. A comparison with the differential equation introduced during our study of Laguerre polynomials in the section of Calculus page 1414 for $\Phi_n^k(x)$ (with a small change in the notation):

$$\frac{\mathrm{d}^2 \Phi_j^k(x)}{\mathrm{d}x^2} + \left(-\frac{1}{4} + \frac{2j+k+1}{2x} - \frac{k^2-1}{4x^2}\right)\Phi_j^k(x) = 0 \tag{13.1.225}$$

shows that the previous relation is satisfied by:

$$\rho\chi(\rho) = e^{-\rho/2}\rho^{l+1} L_{n-l-1}^{2l+1}(\rho) \tag{13.1.226}$$

in which k is replaced by $2l+1$ (as $(k^2-1)/4 = l(l+1)$) and j by $\lambda - l - 1$, upon using:

$$\frac{1}{\rho^2}\frac{\mathrm{d}}{\mathrm{d}\rho}\rho^2\frac{\mathrm{d}\chi}{d\rho} = \frac{1}{\rho}\frac{\mathrm{d}^2}{\mathrm{d}\rho^2}(\rho\chi) \tag{13.1.227}$$

We must restrict the parameter λ by requiring it to be an integer $n, n = 1, 2, 3, \ldots$. This is necessary because the Laguerre function of non-integral n would diverge as $\rho^n e^\rho$, which is unacceptable for our physical problem, in which:

$$\lim_{r \to +\infty} R(r) = 0 \tag{13.1.228}$$

This restriction on λ, imposed by our boundary condition, has the effect of quantizing the energy!

The comparison of the two ordinary differential equations above gives us the eigenenergies of the hydrogen atom, but require some development. Since $k=2l+1$:

$$\frac{2j+k+1}{2}=\frac{2j+(2l+1)+1}{2}=j+l+1 \tag{13.1.229}$$

From the discussion on associated Laguerre polynomials, the indices j and k are non-negative. The sum $j+l+1$ can, therefore, assume any integer values of 1 or greater. We are going to rename it n, or:

$$n:=j+l+1 \tag{13.1.230}$$

The new integer index n is known as the "principal quantum number". Using the principal quantum number, we can deduce the eigenenergies of the hydrogen atom. Indeed we have comparing again the two ordinary differential equations:

$$\lambda=\frac{\mu Ze^2}{2\pi\varepsilon_0\alpha\hbar^2}=\frac{2j+k+1}{2}=j+l+1=n \tag{13.1.231}$$

Squaring:

$$\left(\frac{\mu Ze^2}{2\pi\varepsilon_0\alpha\hbar^2}\right)^2=n^2 \tag{13.1.232}$$

and simplifying plus rearranging by injecting again α leads us to:

$$E_n=-\frac{Z^2\mu}{2n^2\hbar^2}\left(\frac{e^2}{4\pi\varepsilon_0}\right)^2=-\frac{Z^2\hbar^2}{2\mu n^2}\left(\frac{\mu e^2}{4\pi\varepsilon_0\hbar^2}\right)^2=-\frac{Z^2\hbar^2}{2\mu n^2r_0^2}=\frac{Z^2\cdot 13.6\,[\text{eV}]}{n^2} \tag{13.1.233}$$

where r_0 is the Bohr radius given for reminder by:

$$r_0=\frac{4\pi\varepsilon_0\hbar^2}{\mu e^2} \tag{13.1.234}$$

Now coming back to:

$$\rho\chi(\rho)=e^{-\rho/2}\rho^{l+1}L_{n-l-1}^{2l+1}(\rho) \tag{13.1.235}$$

Let us explicit it:

$$\begin{aligned}\sqrt{-\frac{8\mu E_n}{\hbar^2}}rR_{n,l}(r)&=e^{-\alpha r/2}(\alpha r)^{l+1}L_{n-l-1}^{2l+1}(\alpha r)\\&=e^{-\sqrt{-\frac{8\mu E_n}{\hbar^2}}r/2}\left(\sqrt{-\frac{8\mu E_n}{\hbar^2}}r\right)^{l+1}L_{n-l-1}^{2l+1}\left(\sqrt{-\frac{8\mu E_n}{\hbar^2}}r\right)\end{aligned} \tag{13.1.236}$$

Using:

$$E_n=-\frac{Z^2\hbar^2}{2\mu n^2r_0^2}\Rightarrow\sqrt{-\frac{8\mu E_n}{\hbar^2}}=\sqrt{\frac{4Z^2}{n^2r_0^2}}=\frac{2Z}{nr_0} \tag{13.1.237}$$

Therefore:

$$\left(\frac{2Z}{nr_0}\right)rR_{nl}(r)=e^{-2Zr/2nr_0}\left(\frac{2Z}{nr_0}r\right)^{l+1}L_{n-l-1}^{2l+1}\left(\frac{2Z}{nr_0}r\right) \tag{13.1.238}$$

After simplifying a bit and rearranging:

$$R_{nl}(r)=\frac{nr_0}{2Zr}e^{-Zr/nr_0}\left(\frac{2Z}{nr_0}r\right)^{l+1}L_{n-l-1}^{2l+1}\left(\frac{2Z}{nr_0}r\right)=e^{-Zr/nr_0}\left(\frac{2Z}{nr_0}r\right)^{l}L_{n-l-1}^{2l+1}\left(\frac{2Z}{nr_0}r\right) \tag{13.1.239}$$

Finally adding a normalization constant[4]:

$$R_{nl}(r)=A\left(\frac{2Z}{nr_0}r\right)^{l}L_{n-l-1}^{2l+1}\left(\frac{2Z}{nr_0}r\right)e^{-Zr/nr_0} \tag{13.1.240}$$

For a given value of the principal quantum number n (recall that we saw in the section of Corpuscular Quantum Physics at page 4667 that $l\leq n-1$), it is possible to verify that there are several solutions to the function $R(r)$ according to the value of the azimuthal quantum number l. Hence the identification of the solutions by the pair (n,l). We denote them $R_{n,l}(r)$. These are real functions of the variable r (it is just enough to check ... because if they work then they satisfy the Schrödinger equation, we will make an example a little further below):

$$\begin{aligned}
R_{10}(r)&=\left(\frac{Z}{a_0}\right)^{3/2}2e^{-(Zr/a_0)}\\
R_{20}(r)&=\left(\frac{Z}{a_0}\right)^{3/2}\frac{1}{2\sqrt{2}}\left(2-\frac{Zr}{a_0}\right)e^{-(Zr/2a_0)}\\
R_{21}(r)&=\left(\frac{Z}{a_0}\right)^{3/2}\frac{1}{2\sqrt{6}}\frac{Zr}{a_0}e^{-(Zr/2a_0)}\\
R_{30}(r)&=\left(\frac{Z}{a_0}\right)^{3/2}\frac{1}{9\sqrt{3}}\left(6-\frac{4Zr}{a_0}+\frac{4Z^2r^2}{9a_0^2}\right)e^{-(Zr/3a_0)}\\
R_{31}(r)&=\left(\frac{Z}{a_0}\right)^{3/2}\frac{1}{9\sqrt{6}}\left(\frac{8Zr}{3a_0}+\frac{4Z^2r^2}{9a_0^2}\right)e^{-(Zr/3a_0)}\\
R_{32}(r)&=\left(\frac{Z}{a_0}\right)^{3/2}\frac{1}{9\sqrt{30}}\left(\frac{4Z^2r^2}{9a_0^2}\right)e^{-(Zr/3a_0)}
\end{aligned} \tag{13.1.241}$$

where (beware some books give this value in natural units!):

$$a_0=4\pi\varepsilon_0\frac{\hbar^2}{\mu e^2}\qquad\text{or}\qquad\frac{\hbar^2}{\mu e^2} \tag{13.1.242}$$

is as we know the equivalent of the Bohr radius (for the reduced mass) that we have determined in the section of Corpuscular Quantum Physics with the difference that here we have a reduced mass instead of a single mass.

---

[4] Derive or even check that the normalization constant is the right one takes between five to ten pages so we will do that in the future when we will have the time to write a lot of LaTeX...

However let us see if our Schrödinger equation is satisfied (taking $n=1, l=0$ for example):

$$\begin{aligned}
&\left[T_r+\frac{l(l+1)\hbar^2}{2\mu r}+E_p\right]R(r)=E_1R(r)\\
&\left[-\frac{\hbar^2}{2\mu r^2}\partial_r(r^2\partial_r)-\frac{Ze^2}{4\pi\varepsilon_0 r}\right]\left(\frac{Z}{r_0}\right)^{3/2}2e^{-(Zr/r_0)}=E_1\left(\frac{Z}{r_0}\right)^{3/2}2e^{-(Zr/r_0)}\\
&-\frac{\hbar^2}{2\mu r^2}\partial_r\left(r^2\partial_r e^{-(Zr/r_0)}\right)-\frac{Ze^2}{4\pi\varepsilon_0 r}e^{-(Zr/r_0)}=E_1e^{-(Zr/r_0)}\\
&-\frac{\hbar^2}{2\mu r^2}\partial_r\left(-\frac{Zr^2}{r_0}e^{-(Zr/r_0)}\right)-\frac{Ze^2}{4\pi\varepsilon_0 r}e^{-(Zr/r_0)}=E_1e^{-(Zr/r_0)}\\
&-\frac{\hbar^2}{2\mu r^2}\left(-\frac{2Zr}{r_0}+\frac{Z^2r^2}{r_0^2}\right)e^{-(Zr/r_0)}-\frac{Ze^2}{4\pi\varepsilon_0 r}e^{-(Zr/r_0)}=E_1e^{-(Zr/r_0)}\\
&-\frac{\hbar^2}{2\mu r^2}\left(-\frac{2Zr}{4\pi\varepsilon_0\frac{\hbar^2}{\mu e^2}}+\frac{Z^2r^2}{\left(4\pi\varepsilon_0\frac{\hbar^2}{\mu e^2}\right)^2}\right)-\frac{Ze^2}{4\pi\varepsilon_0 r}=E_1\\
&\frac{Ze^2}{4\pi\varepsilon_0 r}-\frac{\hbar^2Z^2}{2\mu\left(4\pi\varepsilon_0\frac{\hbar^2}{\mu e^2}\right)^2}-\frac{Ze^2}{4\pi\varepsilon_0 r}=E_1\\
&-\frac{1}{(4\pi\varepsilon_0)^2}\frac{Z^2\mu e^2}{2\hbar^2}=-\frac{1}{16\pi^2\varepsilon_0^2}\frac{Z^2\mu e^4}{\frac{2h^2}{4\pi^2}}=-Z^2\frac{\mu e^4}{8\varepsilon_0^2h^2}=-hcR_HZ^2=E_1
\end{aligned}\tag{13.1.243}$$

Which corresponds well to the expected result!

Which graphically gives us the radial part $R_{n,l}(r)$:

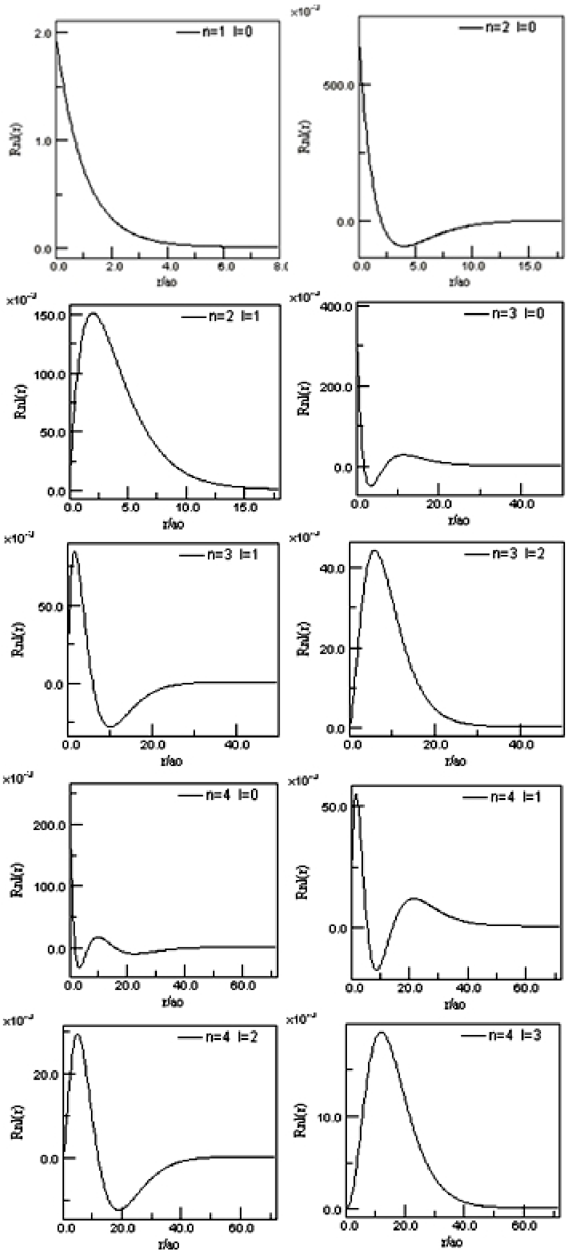

Figure 13.15: **Plot of a few radial functions** $R_{n,l}(r)$

Let us study a little more in detail the radial function in the case of the hydrogen atom!:

In the case of the atomic orbital $1s$ (!special case but we could do the same calculations as the following with all other orbital!) we have for the hydrogen atom:

$$R_{10}(r)=\left(\frac{Z}{r_0}\right)^{3/2}2e^{-Zr/r_0}=\left(\frac{1}{r_0}\right)^{3/2}2e^{-r/r_0}=\frac{2}{r_0^{3/2}}e^{-r/r_0} \quad (13.1.244)$$

where r_0 is the Bohr radius given for reminder by:

$$r_0=\frac{4\pi\varepsilon_0\hbar^2}{\mu e^2} \quad (13.1.245)$$

and:

$$\mu = \frac{m_e M}{M_{\text{tot}}} \tag{13.1.246}$$

is its reduced mass.

Notice there is a non-null probability for the electron to be at the center of atom ($r=0$), as we have:

$$R_{10}(0) = \frac{2}{r_0^{3/2}} = \frac{2}{\left(\dfrac{4\pi\varepsilon_0\hbar^2 M_{\text{tot}}}{m_e M e^2}\right)^{3/2}} \neq 0 \tag{13.1.247}$$

So it is well a decreasing exponential function as shown in the graphic above. Before continuing let us recall that (see section Wave Quantum Physics page 4691) :

$$\int\limits_{\infty} |\Psi|^2 \mathrm{d}V = \int\limits_{\infty} |\Psi|^2 \mathrm{d}x\mathrm{d}y\mathrm{d}z = 1 \tag{13.1.248}$$

But, in spherical coordinates (see the beginning of this section):

$$\mathrm{d}x\mathrm{d}y\mathrm{d}z = r^2 \mathrm{d}r \sin(\theta)\mathrm{d}\theta\mathrm{d}\phi \tag{13.1.249}$$

It then comes as we have seen earlier above:

$$\begin{aligned}\int\limits_{\infty} |\Psi|^2 \mathrm{d}x\mathrm{d}y\mathrm{d}z &= \int\limits_{\infty} |\Psi(r,\theta,\phi)|^2 r^2 \mathrm{d}r \sin(\theta)\mathrm{d}\theta\mathrm{d}\phi = \int\limits_{\infty} |R(r)Y(\theta,\phi)|^2 r^2 \mathrm{d}r \sin(\theta)\mathrm{d}\theta\mathrm{d}\phi\\ &= \int\limits_{\infty} |R(r)|^2 |Y(\theta,\phi)|^2 r^2 \mathrm{d}r \sin(\theta)\mathrm{d}\theta\mathrm{d}\phi\\ &= \int\limits_{\infty} |R(r)|^2 r^2 \mathrm{d}r \int\limits_{\infty} |Y(\theta,\phi)|^2 \sin(\theta)\mathrm{d}\theta\mathrm{d}\phi = 1\end{aligned} \tag{13.1.250}$$

Then it follows that:

$$\int\limits_{\infty} |R(r)|^2 r^2 \mathrm{d}r = 1 \quad \text{and} \quad \int\limits_{\infty} |Y(\theta,\phi)|^2 \sin(\theta)\mathrm{d}\theta\mathrm{d}\phi = 1 \tag{13.1.251}$$

With this result we can calculate the radial probability of finding the electron on each atomic orbital! So, it comes immediately with the previous result:

$$\frac{\mathrm{d}P_r}{\mathrm{d}r} = |R(r)|^2 r^2 \tag{13.1.252}$$

So in the case of our $1s$ atomic orbital:

$$\frac{\mathrm{d}P_r}{\mathrm{d}r} = \left(\frac{1}{r_0^{3/2}} e^{-(r/r_0)}\right)^2 r^2 = \frac{4}{r_0^3} e^{-(2r/r_0)} r^2 \tag{13.1.253}$$

It is now super interesting to calculate the point r point where the probability of finding the electron is maximum on the $1s$ orbital!

For this, we notice that $\mathrm{d}P_r/\mathrm{d}r$ reaches a maximum when we have trivially:

$$\frac{\mathrm{d}^2 P_r}{\mathrm{d}r^2} = 0 \tag{13.1.254}$$

Therefore:

$$\frac{\mathrm{d}^2 P_r}{\mathrm{d}r^2} = \frac{\mathrm{d}}{\mathrm{d}r}\left(\frac{4}{r_0^3}e^{-(2r/r_0)}r^2\right) = \frac{4}{r_0^3}e^{-(2r/r_0)}\left(-\frac{2r^2}{r_0}+2r\right) = 0 \tag{13.1.255}$$

Hence:

$$r = r_0 \tag{13.1.256}$$

Which is remarkable, because we fall back on the result of the Bohr model (see section Corpuscular Physics page 4626)!!!

Remark

Notice that if we had kept $Z \neq 1$ then the result would have been of the shape: $r = r_0/Z$. That means more we have electrons, more these latter can be near the nucleus. We then say that the electrons screen each other somewhat from the nucleus.

To summarize a little all this, the stationary states of the hydrogen atom are specified by three quantum numbers $n \in \mathbb{N}^*, l \leq n-1, |m_l| \leq l$ and the Schrödinger wave function given finally by:

$$\boxed{\Psi_{nlm_l}(r,\theta,\phi) = R_{nl}(r)Y_{m_l l}(\theta,\phi) = \left[\left(\frac{2Z}{nr_0}\right)^3 \frac{(n-l-1)!}{2n(n+l)!}\right]^{1/2} e^{-Zr/nr_0}\left(\frac{2Z}{nr_0}r\right)^l L_{n-l-1}^{2l+1}\left(\frac{2Z}{nr_0}r\right)Y_{m_l,l}(\theta,\phi)} \tag{13.1.257}$$

We then have the following traditional nomenclature in the case of the hydrogen atom:

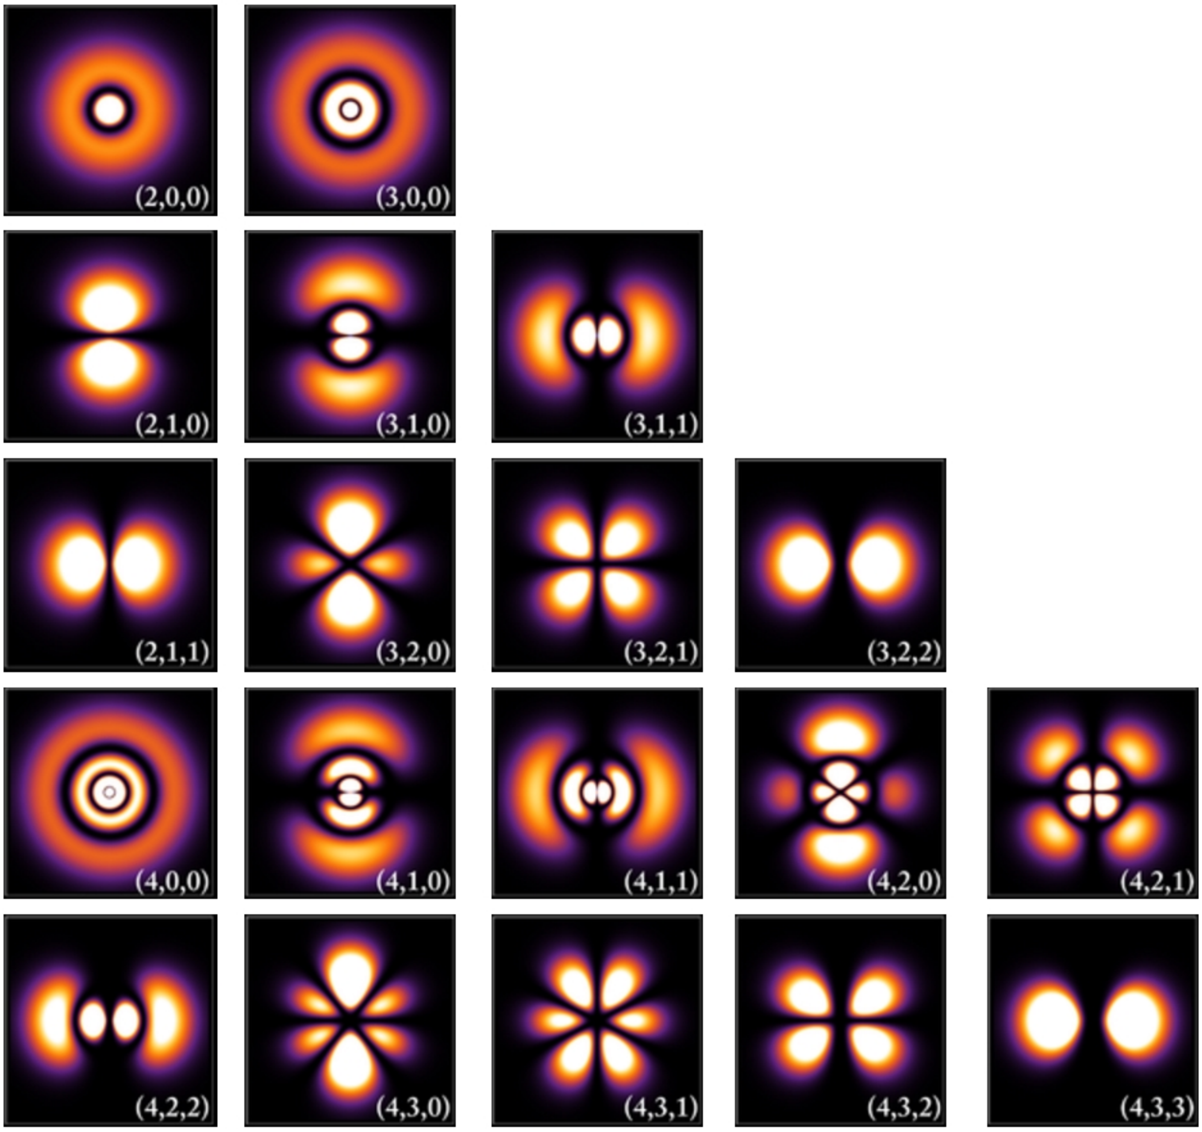
n	l	m_l	Function	Nomenclature
1	0	0	$\Psi_{1,0,0}$	$1s$
2	0	0	$\Psi_{2,0,0}$	$2s$
	1	1	$\Psi_{2,1,1}$	$2p_1$
		0	$\Psi_{2,1,0}$	$2p_0$
		-1	$\Psi_{2,1,-1}$	$2p_{-1}$
3	0	0	$\Psi_{3,0,0}$	$3s$
	1	1	$\Psi_{3,1,1}$	$3p_1$
		-1	$\Psi_{3,1,-1}$	$3p_{-1}$
	2	2	$\Psi_{3,2,2}$	$3d_2$
		1	$\Psi_{3,2,1}$	$3d_1$
		0	$\Psi_{3,2,0}$	$3d_0$
		-1	$\Psi_{3,2,-1}$	$3d_{-1}$
		-2	$\Psi_{3,2,-2}$	$3d_{-2}$

Table 13.1: **Nomenclature of layers and sub-layers of the hydrogen atom**

We can include the spin of the electron in the description of the electronic structure of the atom. If we treat the spin as an additional degree of freedom then the lack of interaction term between conventional degrees of freedom (positions in real space) and the spin interaction named "spin-orbit coupling" in the previous Hamiltonian implies that we can write the total wave function, spin included, in the form of a product:

$$\Psi_{n,l,m_l,m_s}(r,\theta,\phi)=\Psi_{n,l,m_l}(r,\theta,\phi)\omega_{m_s}=R_{n,l}(r)Y_{m_l,l}(\theta,\phi)\omega_{m_s} \qquad (13.1.258)$$

So taking into account everything seen so far we have the following density plots:



where we added the spin quantum number $m_s=\pm 1/2$ (see section Corpuscular Quantum Physics page 4669).

The same remark we made in the section of Corpuscular Quantum Physics then applies: the levels remain $2n^2$ times degenerated.

Let us do an example! So we have:

$$\Psi_{1,0,0}=R_{1,0}Y_{0,0}=\left(\frac{Z}{r_0}\right)^{3/2}e^{-Zr/r_0}\frac{1}{4\sqrt{2}}=\frac{1}{\sqrt{\pi}}\left(\frac{Z}{r_0}\right)^{3/2}e^{-Zr/r_0} \tag{13.1.259}$$

Thus for 1 proton:

$$\Psi_{1,0,0}=\frac{1}{\sqrt{\pi}}\left(\frac{1}{r_0}\right)^{3/2}e^{-r/r_0}=\frac{1}{\sqrt{\pi r_0^3}}e^{-r/r_0} \tag{13.1.260}$$

This wave function is often named the "wave function of hydrogen" or the "ground state of the hydrogen atom" and denoted Ψ_{1s}. This function says that the hydrogen atom's electron is in a weighted superposition of all possible distances r from the nucleus.

Now let us apply the 5th postulate of wave quantum physics (see section of the same name page 4699) for unlike earlier, not calculate the modal radius (most likely one), but the average radius! Then, as the operator position is the position itself (see section Wave Quantum Physics page 4695), the average value of the radius will be given by (do not forget that we are in spherical coordinates!):

$$\begin{aligned}\langle r\rangle&=\int\bar{\Psi}_{1,0,0}\Psi_{1,0,0}\mathrm{d}V=\int\frac{1}{\sqrt{\pi}}\left(\frac{1}{r_0}\right)^{3/2}e^{-r/r_0}r\frac{1}{\sqrt{\pi}}\left(\frac{1}{r_0}\right)^{3/2}e^{-r/r_0}\mathrm{d}V\\&=\int\frac{1}{\pi r_0^3}e^{-2r/r_0}r\mathrm{d}V=\frac{1}{\pi r_0^3}\int\limits_0^{+\infty}\int\limits_0^{+\pi}\int\limits_0^{2\pi}e^{-2r/r_0}rr^2\sin(\theta)\mathrm{d}r\mathrm{d}\theta\mathrm{d}\phi\\&=\frac{1}{\pi r_0^3}\int\limits_0^{+\infty}\int\limits_0^{+\pi}\int\limits_0^{2\pi}r^3e^{-2r/r_0}\sin(\theta)\mathrm{d}r\mathrm{d}\theta\mathrm{d}\phi\end{aligned} \tag{13.1.261}$$

Using the Fubini theorem proved in the section of Differential and Integral Calculus at page 1521, we can write (well in this case it's even trivial that we have the right to write this... we should not even have to mention Fubini theorem normally...):

$$\begin{aligned}\langle r\rangle&=\frac{1}{\pi r_0^3}\int\limits_0^{+\infty}\int\limits_0^{+\pi}\int\limits_0^{2\pi}r^3e^{-2r/r_0}\sin(\theta)\mathrm{d}r\mathrm{d}\theta\mathrm{d}\phi=\frac{1}{\pi r_0^3}\int\limits_0^{+\infty}r^3e^{-2r/a0}\mathrm{d}r\int\limits_0^{\pi}\mathrm{d}\phi\int\limits_0^{2\pi}\sin(\theta)\mathrm{d}\theta\\&=\frac{1}{\pi r_0^3}\int\limits_0^{+\infty}r^3e^{-2r/a0}\mathrm{d}r\pi2\int\limits_0^{\pi}\sin(\theta)\mathrm{d}\theta=\frac{1}{\pi r_0^3}\int\limits_0^{+\infty}r^3e^{-2r/a0}\mathrm{d}r\pi2\cdot2\\&=\frac{4}{r_0^3}\int\limits_0^{+\infty}r^3e^{-2r/a0}\mathrm{d}r\end{aligned} \tag{13.1.262}$$

For the last integral, we will use integration by parts:

$$\begin{aligned}\int\limits_0^{+\infty} r^3e^{-br}\mathrm{d}r &= \underbrace{-\frac{1}{b}r^3e^{-br}\Big|_0^{+\infty}}_{=0}+\frac{3}{b}\int\limits_0^{+\infty} r^3e^{-br}\mathrm{d}r\\ &=\frac{3}{b}\left(\underbrace{-\frac{1}{b}r^2e^{-br}\Big|_0^{+\infty}}_{=0}+\frac{2}{b}\int\limits_0^{+\infty} re^{-br}\mathrm{d}r\right)=\frac{6}{b^2}\int\limits_0^{+\infty} re^{-br}\mathrm{d}r\\ &=\frac{6}{b^2}\left(\underbrace{-\frac{1}{b}re^{-br}\Big|_0^{+\infty}}_{=0}+\frac{1}{b}\int\limits_0^{+\infty} e^{-br}\mathrm{d}r\right)=\frac{6}{b^3}\int\limits_0^{+\infty} e^{-br}\mathrm{d}r=-\frac{6}{b^4}e^{-br}\Big|_0^{+\infty}\\ &=-\frac{6}{b^4}\left(\underbrace{e^{-b\infty}}_{\to 0}-e^{-b0}\right)=-\frac{6}{b^4}(-1)=\frac{6}{b^4}\end{aligned}\tag{13.1.263}$$

Thus finally:

$$\langle r\rangle=\frac{4}{r_0^3}\int\limits_0^{+\infty} r^3e^{-2r/a0}\mathrm{d}r=\frac{4}{r_0^3}\frac{6}{\left(\dfrac{2}{r_0}\right)^4}=\frac{6}{2^2}r_0=\frac{3}{2}r_0\tag{13.1.264}$$

Or more explicitly:

$$\langle r\rangle_{1,0,0}=\langle r\rangle_{1s}=\frac{3}{2}r_0\tag{13.1.265}$$

Therefore the average distance of the electron to the core is equal to $3/2$ times that of the Bohr radius so further that the most likely radius we have calculated earlier above (and which corresponds to Bohr radius)!

Let us calculate now the modal value of the radius for the hydrogen wave function:

$$\Psi_{1s}=\frac{1}{\sqrt{\pi r_0^3}}e^{-r/r_0}\tag{13.1.266}$$

The probability density is therefore:

$$\|\Psi_{1s}\|^2=\frac{1}{\pi r_0^3}e^{-2r/r_0}\tag{13.1.267}$$

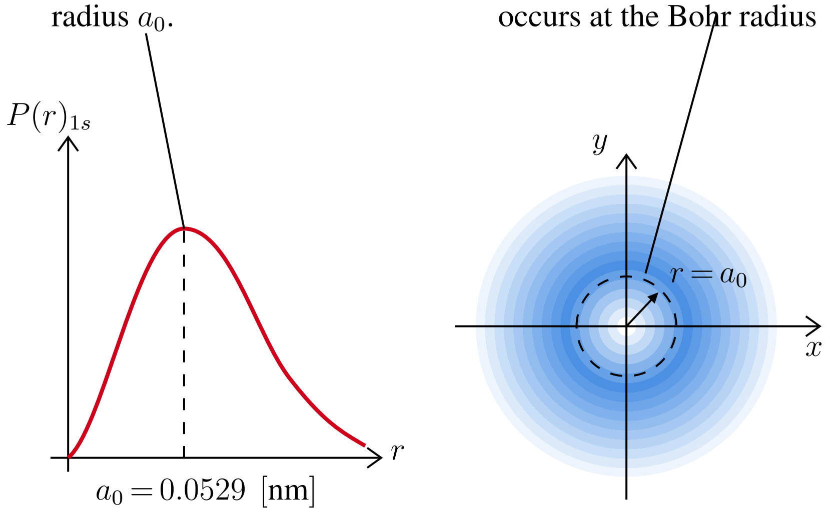
Because of the spherical symmetric of Ψ_{1s} we can write it's elementary probability as:

$$P(r)_{1s}\mathrm{d}r=\|\Psi_{1s}\|^2\mathrm{d}V=\|\Psi_{1s}\|^2 4\pi r^2\mathrm{d}r\tag{13.1.268}$$

Therefore, the radial probability density function for an s state is:

$$P(r)_{1s}=\|\Psi_{1s}\|^2\mathrm{d}V=\|\Psi_{1s}\|^2 4\pi r^2\tag{13.1.269}$$

A plot of the function $P(r)_{1s}$ is presented below:



the probability has its maximum value when r equals the Bohr radius a_0.

in this representation, the darkest color, representing the maximum probability, occurs at the Bohr radius

Figure 13.16: Probability of finding the electron as a function of distance from the nucleus for the hydrogen atom in the $1s$ state (source: [491])

The peak of the curve corresponds to the most likely value of r for this particular state. We prove easily that this peak occurs at the Bohr radius (just set the derivative of $P(r)_{1s}$ with respect to r to zero), the radial position of the electron when the hydrogen atom is in its ground state in the Bohr theory, another agreement between the Bohr theory and the quantum theory!

Physicist Aneta Stodólna captured the electron positions of hydrogen atoms on camera for the very first time based on velocity map imaging (technique involving LASERs). The images made in into Physics Review Letters [516] in May 12013 (holocene calendar) and gained worldwide attention from physicists and the general public afterwards.

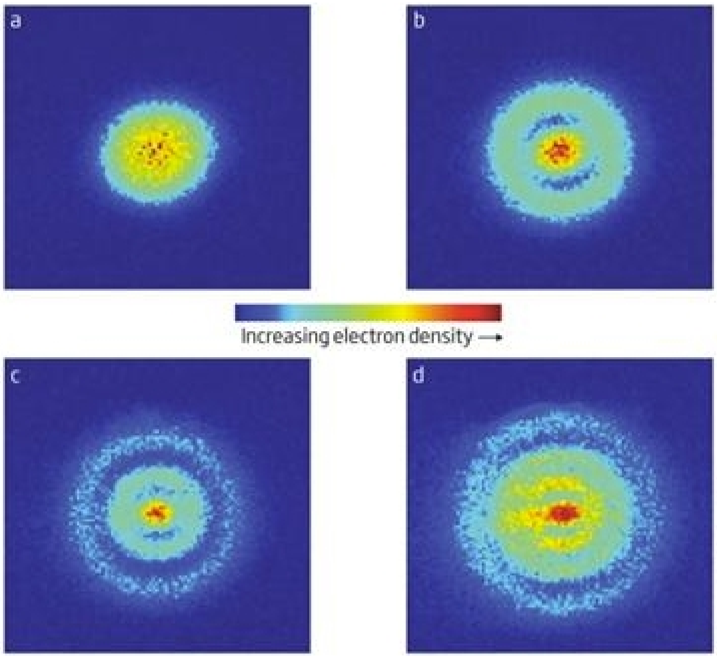


Figure 13.17: Hydrogen atoms imaged by A. Stodólna at four energy levels (increasing from a tod)

13.1.3.2.1 Potential Profile

Let us come back on an important point that is often used in physics book but never proved (as far as we know): the quantum potential profile of the hydrogen-like atom. Many books sometimes speak of "harmonic model of the atomic bonding" but it seems that this is a priori rather a misnomer.

So we saw much earlier in this section that:

$$\left[T_r+\frac{l(l+1)\hbar^2}{2\mu r^2}+E_p\right]\Psi=E\Psi \tag{13.1.270}$$

In view of the interpretation of the three terms of the Hamiltonian, it is customary to say that the two terms:

$$\frac{l(l+1)\hbar^2}{2\mu r^2}+E_p \tag{13.1.271}$$

constitute the "effective potential energy", thus explicitly:

$$E_{p,\text{eff}}=\frac{l(l+1)\hbar^2}{2\mu r^2}+E_p=\underbrace{\frac{l(l+1)\hbar^2}{2\mu r^2}}_{\geq 0}+\underbrace{-\frac{Zq_e^2}{4\pi\varepsilon_0\|\vec{r}_e-\vec{R}_N\|}}_{<0} \tag{13.1.272}$$

So the first term is (logically) repulsive while the second is attractive. A plot in Maple™ 4.00b of the effective potential energy gives with real experimental values for the radius with the real values of the constants:

```
>plot([-2.31E-28/r+6.11E-39*0*(0+1)/r^2,-2.31E-28/r+6.11E-39*1*(1+1)/r^2,
-2.31E-28/r+6.11E-39*2*(2+1)/r^2,-2.31E-28/r+6.11E-39*3*(3+1)/r^2,
-2.31E-28/r+6.11E-39*10*(10+1)/r^2],r=5E-11..10E-10,
y=-0.5E-17..0.5E-17,thickness=2);
```

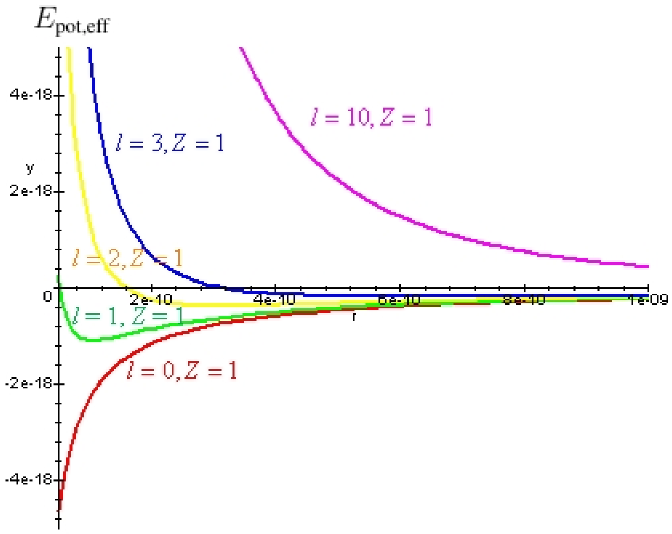

Figure 13.18: **Plot of the effective potential energy in Maple™ 4.00b for various l and Z**

where the legends were added afterwards with a text processor software. The reader will notice especially the case where $l = 1$ that matches to the case of the figure indicated by the majority of graduate books of physics. Either with a zoom:

```
>plot(-2.31E-28/r+6.11E-39*1*(1+1)/r^2,r=5E-11..10E-10,thickness=2,
color=green);
```

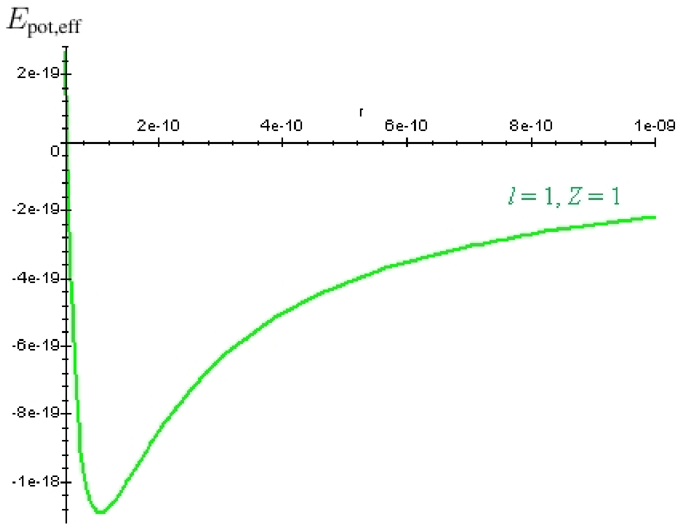

Figure 13.19: **Plot of the famous effective potential energy in Maple™ 4.00b for $l = 1$ and $Z = 1$**

The first graph also tells us quite clearly that for $l = 0$ the electron has a negative potential energy that firmly holds it in the orbit of the proton. By cons already at $l = 1$ we guess that the point of stability of the electron is where the derivative is zero. Beyond the $l = 1$, in the case of a nucleus with a single proton, the electron is not naturally linked anymore since its potential energy tends to be positive. The reader can also have fun with Maple™ by making vary Z and l. He will see that the effective potential energy is very sensitive to these parameters. For example, the plot below shows the effective potential energy with $l = 4$ and $Z = 1$ (thus unstable atom) and then with $l = 4$ and $Z = 6$ (which corresponds rather to an excited state):

```
>plot([-2.31E-28*1/r+6.11E-39*4*(4+1)/r^2,-2.31E-28*6/r+6.11E-39*4*(4+1)/r^2],
r=5E-11..10E-10,thickness=2);
```

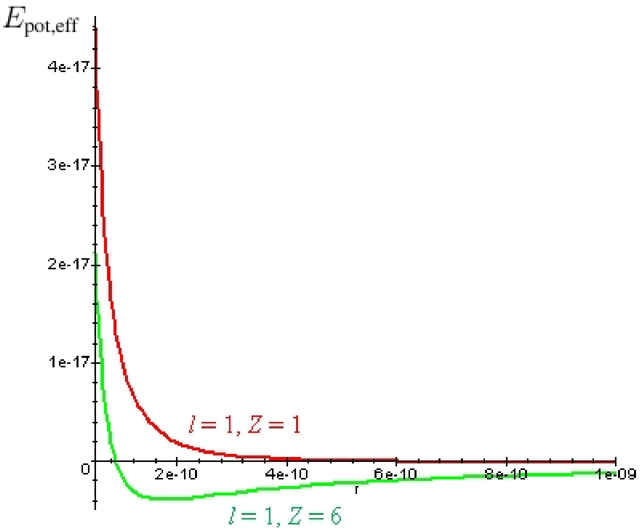

Figure 13.20: Plot of the effective potential energy for $l=1$ and various Z

It is customary in practice to consider that:

$$E_{p,\text{eff}}=\frac{l(l+1)\hbar^2}{2\mu r^2}-\frac{Zq_e^2}{4\pi\varepsilon_0\|\vec{r}_e-\vec{R}_N\|} \tag{13.1.273}$$

is to a given factor (electric charge factor) an "effective electrical potential" or "electric screened potential". Indeed by defining the electric potential (see section Electrostatics page 3976), there are only an electric charge factor ratio between the electric potential energy and the electric potential. So we have:

$$U_{\text{eff}}=\frac{1}{Zq}E_{p,\text{eff}}\Rightarrow U_{\text{eff}}\propto E_{p,\text{eff}} \tag{13.1.274}$$

13.2. Molecular Chemistry

MOLECULAR CHEMISTRY is the central area that interconnects thanks to the study of molecules many promising advanced technologies of the early 121st century (holocene calendar) which are to name only the best known: molecular biology, molecular materials, molecular electronics, polymers, etc.

Knowing it was found experimentally that a single molecule can have several very different functions, its theoretical study allows to use them better (sometimes better performance in terms of R&D) in its areas of application. The reader will therefore understand that, as usually in this textbook, we will focus here only on the theoretical aspect (mathematical) of molecular chemistry even if we limit ourselves only to theoretical developments made between the years 11910 (holocene calendar) and about 11935 according to holocene calendar (beyond the complexity of the modern theories require too many pages to a general book like this one).

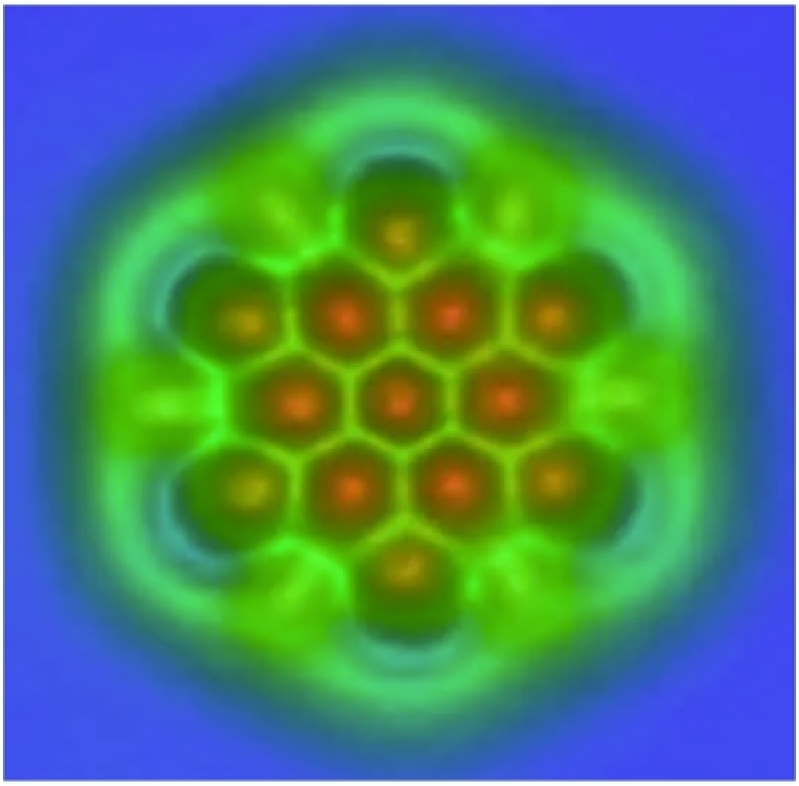

Figure 13.21: Force Atomic Microscope image of chemical bonds of a nanographene molecule C60 **(source: IBM Research Center Zurich)**

We are in the beginning of the 121st century (holocene calendar) at the infancy of the discovery of what nature has done with plenty of time and chance (probabilities): that is to say complex molecules working as nano-machines capable locally (active site) to filter, oxidize, to make catalysis ... and many other manipulations (there is just to observe your own body!).

A molecule is often treated in school classes with the Schrödinger equation (so no relativistic case and no consideration of the spins) in the usual form (see section Wave Quantum Physics page 4760):

$$H\Psi = E\Psi \tag{13.2.1}$$

or also in a stationary from (time-independent) where as a reminder Ψ is a eigenfunctions and E an eigenvalue of the application H.

In reality, the wave functions are impossible to calculate normally with contemporary mathematical tools and the only thing we can do are numerical calculations (perturbation method). This is why some chemistry centers are transformed over time into data centers where the predictive character (and inexpensive) of quantum chemistry is becoming more and more important.

It remains of course essential, as always, to understand how the theoretical models are built and their underlying assumptions.

But we can still thanks to calculations predict the form of reasonable size of molecules, the energy of their internal connections, their energy capacity under stress deformation, the shape of the molecular orbitals (M.O.), energy state transitions (when parts of the molecule move therein), their reactivity vis-a-vis of a reaction medium...

We commonly distinguish two cases of study of the molecular chemistry:

1. Quantum mechanics: all interactions between particles are taken into account under the assumption of some acceptable simplifications.
2. Molecular mechanics: For large molecules, we are not concerned anymore over the electronic problem, but the interaction of certain parameters on which we want to focus.

For example, haemoglobin (protein carrying oxygen carrying in the muscles) is a huge molecular structure which we will study only active site with the tools of quantum mechanics. The overall behaviour of the molecule itself is treated with the molecular mechanics tools.

It follows that excepts for hydrogen-like atoms, we can not analytically describe a molecule from a purely quantum point of view! All current quantum methods rely on one or more approximations. The wave functions are therefore approximated and the level of calculation is adjusted according to what we want to show and the precision that we seek (seeking to minimize the computation time for cost problems...). The good understanding of approximations permits to express simple models requiring only a minimum of calculations (often trivial).

We propose here to show two common models (and the most simplest):

13.2.1 Orbital Approximations

A molecule is obviously an extremely complex problem: N nuclei, n electrons and everything is moving!

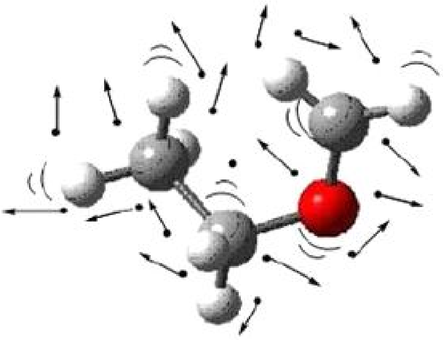

Figure 13.22: **Example ofa molecule where almost everything is moving**

The Hamiltonian (see section Wave Quantum Physics page 4694):

$$H=E_c+E_p=-\frac{\hbar^2}{2m}\vec{\nabla}^2+V(q_1,q_2,\ldots,t)=\sum_{k=1}^{n}\left(\frac{-\hbar^2}{2m_k}\frac{\partial}{\partial q_k^2}\right)+V(q_1,q_2,\ldots,t) \quad (13.2.2)$$

is then a nightmare but in the intuitive form (the subscript G of the Hamiltonian means "General") below:

$$H_{\mathrm{G}}=\underbrace{\left(-\sum_{k=1}^{N}\frac{\hbar^2}{2M_k}\vec{\nabla}_k^2-\sum_{i=1}^{n}\frac{\hbar^2}{2m_e}\vec{\nabla}_i^2\right)}_{E_{\mathrm{c}}}+\underbrace{\left(-\sum_{k=1}^{N}\sum_{i=1}^{n}\frac{Ze^2}{4\pi\varepsilon_0 r_{ik}}+\sum_{\substack{i=1\\j>1}}^{n-1}\frac{e^2}{4\pi\varepsilon_0 r_{ik}}+\sum_{\substack{k=1\\i>k}}^{N-1}\frac{Z_kZ_ie^2}{4\pi\varepsilon_0 r_{ik}}\right)}_{E_p} \quad (13.2.3)$$

where:

1. $-\sum_{k=1}^{N}\frac{\hbar^2}{2M_k}\vec{\nabla}_k^2$ is the kinetic energy of the k nuclei of mass M_k in the molecule.
2. $-\sum_{i=1}^{n}\frac{\hbar^2}{2m_e}\vec{\nabla}_i^2$ is the kinetic energy of the n electrons of mass m_e.
3. $-\sum_{k=1}^{N}\sum_{i=1}^{n}\frac{Ze^2}{4\pi\varepsilon_0 r_{ik}}$ is the potential energy due to the attraction electron($-$)/nucleus($+$).
4. $\sum_{\substack{i=1\\j>1}}^{n-1}\frac{e^2}{4\pi\varepsilon_0 r_{ik}}$ is the potential energy of the repulsion electron($-$)/electron($-$).

5. $\displaystyle\sum_{\substack{k=1\\i>k}}^{N-1}\frac{Z_kZ_ie^2}{4\pi\varepsilon_0 r_{ik}}$ is the potential energy of repulsion nucleus(+)/nucleus(+).

Often we find these terms in the following form of the Schrödinger equation in the literature:

$$[(T_e+T_n)+(V_{ee}+V_{en}+V_{nn})]\Psi_n\Psi_{el}=E\Psi_n\Psi_{\text{el}} \tag{13.2.4}$$

A first approximation we might try is to decouple the movement of the nuclei of the electrons. Indeed, as the nucleus is much more massive (about $2,000$ times) than the cloud of electrons, the center of mass is assimilated to the nucleus of the atom and all the motion to the entire electron cloud. This approximate approach is well known under the name "Born-Oppenheimer approximation":

$$\begin{aligned}H_{\text{el}}&=-\sum_{i=1}^{n}\frac{\hbar^2}{2m_e}\vec{\nabla}_i^2-\sum_{k=1}^{N}\sum_{i=1}^{n}\frac{Ze^2}{4\pi\varepsilon_0 r_{ik}}+\sum_{\substack{i=1\\j>1}}^{n-1}\frac{e^2}{4\pi\varepsilon_0 r_{ik}}\\&=-\sum_{i=1}^{n}\frac{\hbar^2}{2m_e}\vec{\nabla}_i^2+\frac{e^2}{4\pi\varepsilon_0}\left(-\sum_{k=1}^{N}\sum_{i=1}^{n}\frac{Z}{r_{ik}}+\sum_{\substack{i=1\\j>1}}^{n-1}\frac{1}{r_{ik}}\right)\end{aligned} \tag{13.2.5}$$

which then allows us to study the molecular orbitals. But unfortunately this approximation is not sufficient because of the repulsion inter-electronic term (the double sum) that prevents using the separation of variables technique as we did in the section of Quantum Chemistry with the hydrogenoid-atom.

Moreover, this latter equation is also written as the first line of the couple of equations below (Schrödinger equation of electrons and nuclei):

$$\underbrace{(T_e+V_{ee}+V_{en})}_{H_{\text{el}}}\Psi_{\text{el}}=E\Psi_{\text{el}} \tag{13.2.6a}$$

$$\underbrace{(T_n+V_{nn})}_{H_{\text{nuclei}}}\Psi_n\Psi_{\text{el}}=E\Psi_n\Psi_{\text{el}} \tag{13.2.6b}$$

This system of equations is what some name the "adiabatic approximation" (???).

The idea that then comes to mind will be using the following property:

Given two operators A and B, $f(u)$ and $g(v)$ their respective eigenfunctions associated with eigenvalues a and b. Then $f(u)g(v)$ is an eigenfunction of the operator $A+B$ with associated eigenvalue $a+b$.

Which is written:

$$\left.\begin{aligned}Af(u)&=af(u)\\Bg(v)&=bg(v)\end{aligned}\right\}\Rightarrow(A+B)f(u)g(v)=(a+b)f(u)g(v) \tag{13.2.7}$$

Proof 13.0.4. We have:

$$\begin{aligned}(A+B)f(u)g(v)&=[Af(u)]g(v)+[Bf(u)]g(v)\\&=[af(u)]g(v)+[bf(u)]g(v)=(a+b)f(u)g(v)\end{aligned} \tag{13.2.8}$$

■ Q.E.D.

And that's what we will use to break the n-electronic Hamiltonian H_{el} into a sum of independent-electron Hamiltonian knowing of the above that if we find the eigenfunction for each (which is relatively easier) it will be sufficient to simply multiply them to get the overall eigenfunction!

Thus, we write:

$$H_{\text{el}}=H_1+H_2+\ldots+H_i+\ldots+H_n \tag{13.2.9}$$

and therefore we have to find for each i:

$$H_i\Psi_i=E_i\Psi_i \tag{13.2.10}$$

Then we have:

$$H_{\text{el}}\Psi_{\text{el}}=\sum_{i=1}^{n}H_i\prod_{i=1}^{n}\Psi_i=\sum_{i=1}^{n}E_i\prod_{i=1}^{n}\Psi_i=E_{\text{el}}\Psi_{\text{el}} \tag{13.2.11}$$

with therefore:

$$\Psi_{\text{el}}=\Psi_1\cdot\Psi_2\cdot\ldots\cdot\Psi_i\cdot\ldots\cdot\Psi_n \tag{13.2.12}$$

This approach by one-electron Hamiltonian approach will lead us to replace:

$$H_{\text{el}}=-\sum_{i=1}^{n}\frac{\hbar^2}{2m_e}\vec{\nabla}_i^2-\sum_{k=1}^{N}\sum_{i=1}^{n}\frac{Ze^2}{4\pi\varepsilon_0 r_{ik}}+\sum_{\substack{i=1\\j>1}}^{n-1}\frac{e^2}{4\pi\varepsilon_0 r_{ij}} \tag{13.2.13}$$

by the sum of Hamiltonian for an electron named "effective Hamiltonian":

$$H_i=-\frac{\hbar^2}{2m_e}\vec{\nabla}_i^2-\frac{Ze^2}{4\pi\varepsilon_0 r_i}+\frac{e^2}{4\pi\varepsilon_0 r_i}=-\frac{\hbar^2}{2m_e}\vec{\nabla}_i^2-\frac{e^2(Z-1)}{4\pi\varepsilon_0 r_i}=-\frac{\hbar^2}{2m_e}\vec{\nabla}_i^2-\frac{Z^*e^2}{4\pi\varepsilon_0 r_i} \tag{13.2.14}$$

This approximation method is sometimes named in theoretical chemistry "independent electron approximation" or "orbital approximation". It consists therefore to include the electron-electron interactions and to write that each electron moves in an average potential resulting from the presence of all other electrons.

The "Slater method" consists by definition to write the latter relation in the form:

$$H_i\cong-\frac{\hbar^2}{2m_e}\vec{\nabla}_i^2-\frac{e^2(Z-\sigma)}{4\pi\varepsilon_0 r_i} \tag{13.2.15}$$

where σ is named the "screen constant".

The Slater method basically means replacing the purely electronic terms by a constant. It can be regarded as a parametric method since the constants were determined purely experimentally.

The principle of empirical calculation of the screening constant is relatively simple: In a poly-electronic atom, the core electrons are on much contracted orbits while the valence electrons that will be responsible for the chemical properties of the atom in question are on orbits much more "relaxed".

The attraction of the nucleus on the latter electrons is much lower than that exerted on the core electrons and these electrons only receive a portion of the atomic charge.

Slater then proposed that the effective charge, which is usually denoted by Z^* could be calculated by taking into account the screening constant. This constant represents then the average effect of the other electrons on the considered electron of the effective Hamiltonian i:

$$Z^* = Z - \sigma \tag{13.2.16}$$

For a peripheral electron, we will need to consider its screen constant is due to all electrons placed on orbits equal or below its own. The tradition (or rather the "trick") is that the calculation is done by combining atomic orbitals in several groups $1s/2s, 2p/3s, 3p/3d/4s, 4p/4d/4f/5s, 5p/$ etc.

Then the calculation is simple because it is based on an array of predefined values and we simply have to add the screening contributions of all the electrons following the table below:

	$n' < n-1$	$n' = n-1$	$n' = n$	$n' > n$
$1s$			0.30	0
ns, np	1	0.85	0.35	0
nd, nf	1	1	0.35	0

Table 13.2: **Screening contributions of electrons**

This table deserves some explanation of course !:

The index indicates the number of the group that contributes to the screening constant while n is the number of the group of electron that we consider.

✍**Example:**

In the case of the Carbon of configuration $1s^2 2s^2 2p^2$, the nuclear charge is $Z = 6$. One electron $1s$ is shielded by only the another $1s$ electron, the effective charge it sees is therefore:

$$Z^* = Z - \sigma = 6 - 0.3 = 5.7 \tag{13.2.17}$$

A $2s$ or $2p$ electron is shielded by the two $1s$ electrons and by the other 3 electrons $2s$ and $2p$. The effective charge by which it is attracted is then:

$$Z^* = Z - \sigma = 6 - (2 \cdot 0.85 + 3 \cdot 0.35) = 3.25 \tag{13.2.18}$$

So we see that the effective charge experienced decreases rather quickly!

13.2.2 LCAO Method

A linear combination of atomic orbitals or LCAO is a quantum superposition of atomic orbitals and a technique for calculating molecular orbitals in quantum chemistry. In quantum mechanics, electron configurations of atoms are described as wave functions. In mathematical sense, these wave functions are the basis set of functions, the basis functions, which describe the electrons of a given atom. In chemical reactions, orbital wave functions are modified, i.e. the electron cloud shape is changed, according to the type of atoms participating in the chemical bond.

So as already mentioned, this method, rather qualitative, considers that the molecular wave function is a "Linear Combination of Atomic Orbitals" (LCAO) unlike the previous method where we multiply the effective Hamiltonian.

This method is important because it is the basis of much of the current vocabulary of chemists when the chemistry done is cutting edge one!

Let us take the example of the dihydrogen molecule H_2. The idea is then following:

If we have the function of the atomic orbital $1s_A$ of H_1 and respectively the function $1s_B$ of H_B, then we assume that the dicentric molecular orbital (linked to two atoms) thereof is given by:

$$\Psi_{AB}=a\Psi_A+b\Psi_B \qquad (13.2.19)$$

which defines a quantum system with two eigenstates.

But as we well know, in reality, only the square of the wave function has a physical sense (probability of presence). Thus, if we assume that the wave function has no value in $\mathbb{C}$, we have for the single electron of interest ($1s$):

$$\Psi_{AB}^2=(a\Psi_A+b\Psi_B)^2=a^2\Psi_A^2+2ab\Psi_A\Psi_B+b^2\Psi_B^2 \qquad (13.2.20)$$

where we assume that:

- $a^2\Psi_A^2$ represents the probability of presence to be near A.
- $b^2\Psi_B^2$ represents the probability of presence to be near B.
- $2ab\Psi_A\Psi_B$ represents the probability of presence of the electron that do the link $A-B$.

In the particular case of the symmetric diatomic molecule we have chosen as an example, the atoms A and B perform the same function and there is no reason that the electron is closer to A than to B or vice versa.

Thus, the probability of finding the electron near A is equal to the probability of finding it near B.

$$a^2\Psi_A^2=b^2\Psi_B^2 \qquad (13.2.21)$$

Moreover, in this case the orbitals Ψ_A and Ψ_B are completely identical ($1s$ orbitals, both of the same atom) and there is therefore no need to distinguish them. So we have:

$$a^2=b^2\Rightarrow a=\pm b \qquad (13.2.22)$$

We have two solutions for Ψ_{AB} that are (these two solutions can be found in very different notations in the literature):

$$\Psi_{AB}^{(1)} = a\Psi_A + a\Psi_B = a(\Psi_A + \Psi_B) \quad \text{if } b = +a \tag{13.2.23}$$

and:

$$\Psi_{AB}^{(2)} = a\Psi_A - a\Psi_B = a(\Psi_A - \Psi_B) \quad \text{if } b = -a \tag{13.2.24}$$

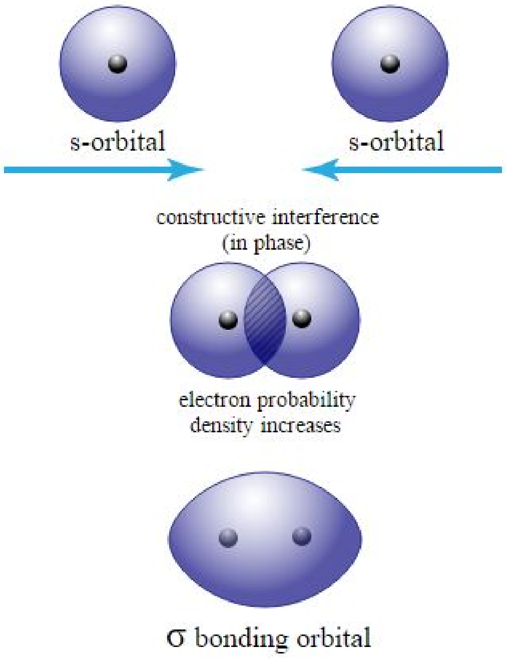
Caution! We can not put for the last two relations that $\Psi_A = \Psi_B$. The latter equality occurs at any point only if the distance between the two nucleus is zero (which is unlikely) or, if they are spaced a distant of a certain value D in the middle thereof.

These two expressions are simultaneously solutions of the Schrödinger equation. So we get two molecular orbitals from the two atomic orbitals in the case of symmetrical diatomic molecule.

The function:

$$\Psi_A + \Psi_B \tag{13.2.25}$$

is named "bonding function" because it corresponds to a reinforcement of the probability of presence of the electron between atoms A and B which corresponds to the creation of the bond!

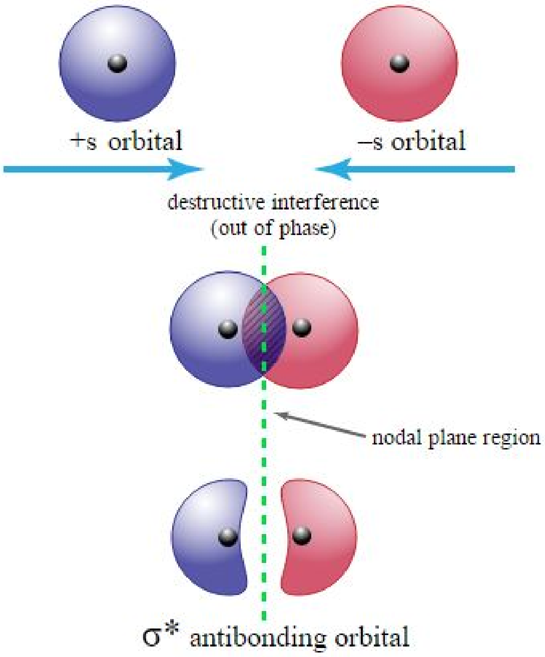


s-orbital
s-orbital
constructive interference
(in phase)
electron probability
density increases
σ bonding orbital

Conversely, the function:

$$\Psi_A - \Psi_B \tag{13.2.26}$$

is named "anti-bonding function" because it corresponds to a reduction of the probability of presence of the electron between atoms A and B which corresponds to the destruction of the bond!



Ultimately, by overlapping, the two atomic orbitals with the same energy give birth to two molecular orbitals of different energy, a stabilized binding and the other anti-bonding destabilized.

We have obviously from what we see just above that, in more complex cases, the energy level of the bonding molecular orbital is smaller than the anti-bonding (we will prove this rigorously in details below).

Thus, it takes more energy to ionize respectively the electron of the binding orbital σ than to ionize the electron of the anti-bonding orbital σ^*. It is commonly accepted that the energy of the bond function is stronger than the anti-bonding one (but we will make the proof further below).

Let us also indicate that in chemistry, a chemical bond wherein each of the bonded atoms is sharing an electron from one of its outer layers to form a pair of electrons linking two atoms is commonly known as "covalent bond".

The chemists then say the covalent bond involves the equitable sharing of only one pair of electrons, named "bonding pair" (but in fact where only one electron is really shared). Each atom provides an electron, the electron pair is then delocalized between two atoms as we have shown.

These are the reasons why we commonly say that the bond σ is a covalent chemical bond between two atoms generated by orbital axial overlap.

Now let us in-deep this approach! The molecular orbitals are to be normalized as we know.

Which means that:

$$\int\limits_{-\infty}^{+\infty}|\Psi|^2\mathrm{d}x\mathrm{d}y\mathrm{d}z=1 \tag{13.2.27}$$

What gives, since the atomic orbitals are normalized for Ψ_1 and are real functions:

$$\begin{aligned}\int\limits_{-\infty}^{+\infty}|\Psi_{AB}^{(1)}|^2\mathrm{d}x\mathrm{d}y\mathrm{d}z&=\int\limits_{-\infty}^{+\infty}|a(\Psi_A+\Psi_B)|^2\mathrm{d}x\mathrm{d}y\mathrm{d}z\\&=\int\limits_{-\infty}^{+\infty}(a^2\Psi_A^2+2a^2\Psi_A\Psi_B+a^2\Psi_B^2)\mathrm{d}x\mathrm{d}y\mathrm{d}z=1\end{aligned} \tag{13.2.28}$$

Since a (real number in our case) is imposed as a constant, it comes immediately:

$$\begin{aligned}&a^2\left(\int\limits_{-\infty}^{+\infty}\Psi_A^2\mathrm{d}x\mathrm{d}y\mathrm{d}+\int\limits_{-\infty}^{+\infty}\Psi_B^2\mathrm{d}x\mathrm{d}y\mathrm{d}z+2\int\limits_{-\infty}^{+\infty}\Psi_A\Psi_B\mathrm{d}x\mathrm{d}y\mathrm{d}z\right)\\=&a^2\left(2+2\int\limits_{-\infty}^{+\infty}\Psi_A\Psi_B\mathrm{d}x\mathrm{d}y\mathrm{d}z\right)=a^2(2+2S_{12})=1\end{aligned} \tag{13.2.29}$$

Therefore for Ψ_{AB}^1:

$$a=\frac{1}{\sqrt{2(1+S_{12})}} \tag{13.2.30}$$

Identically, we have for Ψ_{AB}^2:

$$a=\frac{1}{\sqrt{2(1-s_{12})}} \tag{13.2.31}$$

If we have $S_{12}\ll 1$, it comes the following format that we find in many books:

$$\begin{aligned}\Psi_{AB}^{(1)}&\cong\frac{1}{\sqrt{2}}(\Psi_A+\Psi_B)\\\Psi_{AB}^{(2)}&\cong\frac{1}{\sqrt{2}}(\Psi_A-\Psi_B)\end{aligned} \tag{13.2.32}$$

Let us make a small example using as orbital, the lowest atomic orbital ($1s$) of the hydrogen atom in the case of a dihydrogeneous bond H_2 for which we have proved at the end of the section of Quantum Chemistry (see page 6178) that:

$$\Psi_{1s}=\Psi_{1,0,0,0}=R_{1,0}Y_{0,0}=\frac{2}{r_0^{3/2}}e^{-r/r_0}\frac{1}{\sqrt{4\pi}}=\frac{1}{\sqrt{\pi}}\frac{1}{r_0^{3/2}}e^{-r/r_0} \tag{13.2.33}$$

Therefore it comes:

$$\Psi_A=\frac{1}{\sqrt{\pi}}\frac{1}{r_0^{3/2}}e^{-r_1/r_0}=\lambda e^{-r_1/r_0}\qquad\text{and}\qquad\Psi_B=\frac{1}{\sqrt{\pi}}\frac{1}{r_0^{3/2}}e^{-r_2/r_0}=\lambda e^{-r_2/r_0} \tag{13.2.34}$$

with for recall:

$$r_0 = 4\pi\varepsilon_0 \frac{\hbar}{\mu e^2} \tag{13.2.35}$$

It comes then for the molecular binding orbital of level s:

$$\sigma_s = \frac{\lambda}{\sqrt{2}} \left(e^{-r_1/r_0} + e^{-r_2/r_0} \right) \tag{13.2.36}$$

and for the anti-bonding of also the s level:

$$\sigma_s^* = \frac{\lambda}{\sqrt{2}} \left(e^{-r_1/r_0} - e^{-r_2/r_0} \right) \tag{13.2.37}$$

We then see immediately that σ_s^* vanishes in the middle of the two protons because in this place $r_1 = r_2$. The molecular anti-bonding orbital therefore has a nodal plane and the electrons are mainly located on the protons.

By cons, for the molecular orbital σ_s the density does not vanish. Then we understand easily that an electron of σ_s ensures the stability of the molecule and is therefore responsible for the chemical bond.

We therefore conclude that the electronic stabilization due to the two identical orbital interaction is proportional to their recovery. More the recovery is big, the more the stabilization is important.

There is a more technical approach using Dirac notation (see section Wave Quantum Physics page 4729) and that has the advantage of allowing the determination of the eigenvalues of energy.

First we write the general expression of the time independent Schrödinger equation with the Bra-Ket notation for one molecular orbital, superposition of two atomic orbitals:

$$H|\Psi_{AB}\rangle = E|\Psi_{AB}\rangle \tag{13.2.38}$$

Either in explicit form:

$$H|a\Psi_A + b\Psi_B\rangle = E|a\Psi_A + b\Psi_B\rangle \tag{13.2.39}$$

If we multiply by the bra $\langle\Psi_A|$ on the left and taking into account that a, b and the specific eigenvalues of the energy are constants, we get the following equation:

$$a\langle\Psi_A|H|\Psi_A\rangle + b\langle\Psi_A|H|\Psi_B\rangle = aE\langle\Psi_A|\Psi_A\rangle + bE\langle\Psi_A|\Psi_B\rangle \tag{13.2.40}$$

Similarly, we get the bra $\langle\Psi_B|$:

$$a\langle\Psi_B|H|\Psi_A\rangle + b\langle\Psi_B|H|\Psi_B\rangle = aE\langle\Psi_B|\Psi_A\rangle + bE\langle\Psi_B|\Psi_B\rangle \tag{13.2.41}$$

Let us simplify the notations even more:

$$\begin{gathered} aH_{AA} + bH_{AB} = aES_{AA} + bES_{AB} \\ aH_{BA} + bH_{BB} = aES_{BA} + bES_{BB} \end{gathered} \tag{13.2.42}$$

By symmetry of the problem in the case of dihydrogen, we put:

$$\langle\Psi_A|H|\Psi_B\rangle=H_{AB}=\langle\Psi_B|H|\Psi_A\rangle=H_{BA} \tag{13.2.43}$$

which are named "resonance integrals" because it is a term relating to the combination (resonance) of the both atomic orbital relative to the two atoms that made the molecular structure.

We also have:

$$\langle\Psi_A|H|\Psi_A\rangle=H_{AA} \qquad \text{and} \qquad \langle\Psi_B|H|\Psi_B\rangle=H_{BB} \tag{13.2.44}$$

which are named "Coulomb integrals" because they correspond according to the fifth postulate of Wave Quantum Physics (see section of the same name page 4699) to the average value of the total energy of the electron.

We have obviously:

$$\langle\Psi_A|\Psi_A\rangle=S_{AA}=\langle\Psi_B|\Psi_B\rangle=S_{BB}=1 \tag{13.2.45}$$

which are named "recovery integrals" because the two atomic orbitals of the same type of each atom overlap.

And finally, we have always by symmetry of our particular case:

$$\langle\Psi_A|\Psi_B\rangle=S_{AB}=\langle\Psi_B|\Psi_A\rangle=S_{BA} \tag{13.2.46}$$

We can then write, since the recovery integrals are unitary:

$$\begin{aligned}a(H_{AA}-E)+b(H_{AB}-ES_{AB})=0\\ a(H_{BA}-ES_{BA})+b(H_{BB}-E)=0\end{aligned} \tag{13.2.47}$$

These two equations are named "secular equations". The trivial solution is a priori not physical because it would mean that the electron has a zero probability density at any point in the space corresponding at $a=b=0$.

There is a non-trivial solution and unique solution if and only if the following determinant (see section Linear Algebra page 1961), known in molecular chemistry under the name "secular determinant", is equal to zero:

$$\begin{vmatrix} H_{AA}-E & H_{AB}-ES_{AB} \\ H_{BA}-ES_{BA} & H_{BB}-E \end{vmatrix}=(H_{AA}-E)(H_{BB}-E)-(H_{AB}-ES_{AB})(H_{BA}-ES_{BA})=0 \tag{13.2.48}$$

As we have by symmetry in our particular case:

$$H_{AA}=H_{BB} \qquad H_{AB}=H_{BA} \qquad S_{AB}=S_{BA} \tag{13.2.49}$$

Therefore it comes:

$$(H_{AA}-E)^2-(H_{AB}-ES_{AB})^2=0 \tag{13.2.50}$$

Hence:

$$H_{AA}-E=\pm(H_{AB}-ES_{AB}) \tag{13.2.51}$$

This gives us two solutions $(+)$:

$$-E_1+E_1S_{AB}=H_{AB}-H_{AA}\Rightarrow E_1(1-S_{AB})=H_{AA}-H_{AB}\Rightarrow E_1=\frac{H_{AA}-H_{AB}}{1-S_{AB}} \tag{13.2.52}$$

and minus $(-)$:

$$-E_2-E_2S_{AB}=-H_{AB}-H_{AA}\Rightarrow -E_2(1+S_{AB})=-(H_{AA}-H_{AB})\Rightarrow E_2=\frac{H_{AA}+H_{AB}}{1+S_{AB}} \tag{13.2.53}$$

Therefore we have:

$$E_1=\frac{H_{AA}-H_{AB}}{1-S_{AB}} \qquad \text{and} \qquad E_2=\frac{H_{AA}+H_{AB}}{1+S_{AB}} \tag{13.2.54}$$

But to be able to calculate the energy levels in detail, we must still have the shape of the Hamiltonian... and that using the both electrons of the dihydrogen molecule is quite difficult... To simplify the study, we reduce ourselves to the case of the cation (positive ion) H_2^+ consisting of two protons and one electron:

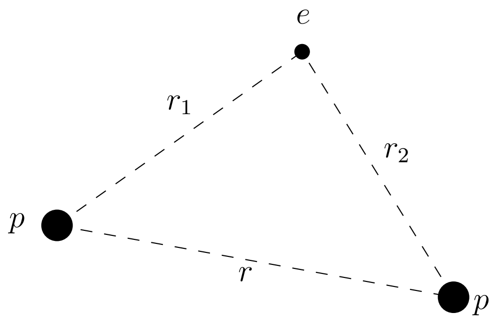


Figure 13.23: **Simplified study of the dihydrogen cation** H_2^+

We then have base on the relation we have obtained at the beginning of this section:

$$H_{\text{el}}=-\sum_{i=1}^{n}\frac{\hbar^2}{2m_e}\vec{\nabla}_i^2-\sum_{k=1}^{N}\sum_{i=1}^{n}\frac{Ze^2}{4\pi\varepsilon_0 r_{ik}}+\sum_{\substack{i=1\\j>1}}^{n-1}\frac{e^2}{4\pi\varepsilon_0 r_{ik}} \tag{13.2.55}$$

The following relation:

$$H=-\frac{\hbar^2}{2m_e}\vec{\nabla}^2+\frac{e^2}{4\pi\varepsilon_0}\left(-\frac{1}{r_1}-\frac{1}{r_1}+\frac{1}{r}\right) \tag{13.2.56}$$

where the first two terms in the brackets are for recall associated with the potential energy of the electron and the last to the potential repulsion energy of proton (the first term on the right of the equality is the kinetic energy of the electron).

Now let us try to sort the energy of these two molecular orbitals. For this, we write:

$$E_1=\frac{H_{AA}-H_{AB}}{1-S_{AB}}=\frac{\alpha-\beta}{1-S} \qquad \text{and} \qquad E_2=\frac{H_{AA}+H_{AB}}{1+S_{AB}}=\frac{\alpha+\beta}{1+S} \tag{13.2.57}$$

Let us recall that for a system to be stable, the energies E_n must be negatives, this corresponding to the stable states (we need a supply of energy to take them out) and request from us because of the shape of E_2:

$$\alpha < 0 \qquad \beta < 0 \tag{13.2.58}$$

Knowing this it comes:

$$E_2 < E_1 < 0 \tag{13.2.59}$$

Therefore, we see that the notations are not consistent with the use in quantum physics because normally the index 1 is reserved to the lowest energy. So we will write in the future:

$$E_1 = \frac{\alpha+\beta}{1+S} \qquad \text{and} \qquad E_2 = \frac{\alpha-\beta}{1-S} \tag{13.2.60}$$

with the associated eigenfunctions Ψ_1 and Ψ_2 and therefore:

$$E_1 < E_2 < 0 \tag{13.2.61}$$

We can also noticed an important thing! This is that if we consider the atoms in isolated, the interaction terms cancel and we have:

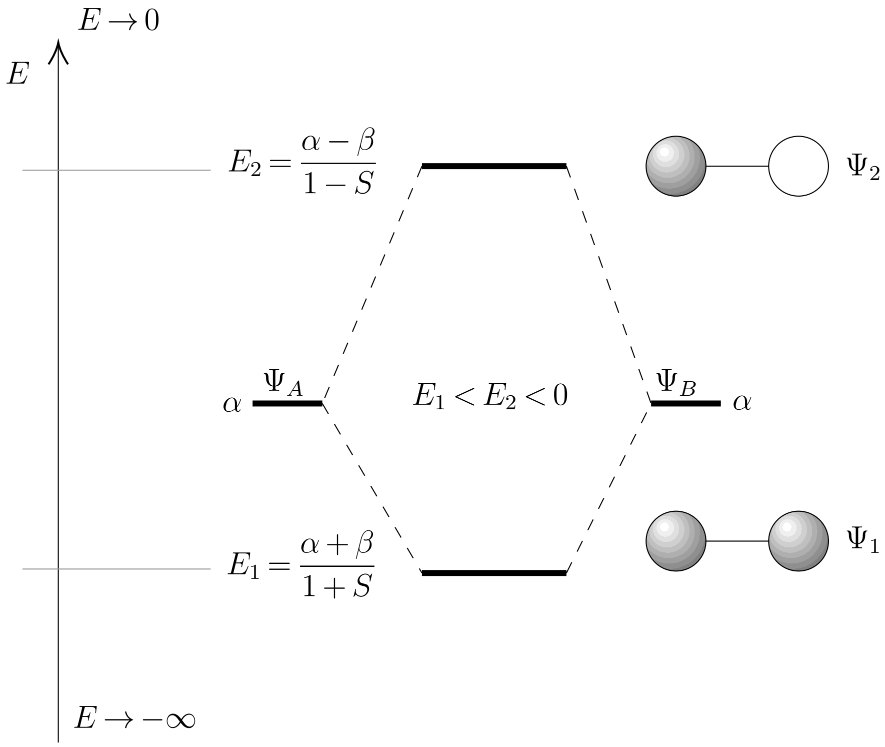
$$E_{1,2} \cong \alpha \tag{13.2.62}$$

Therefore we have the qualitative difference between a single atom and a simple diatomic (ionized) system:

$$\frac{\alpha+\beta}{1+S} < \alpha < 0 \tag{13.2.63}$$

This means that the energy of the lowest level of a diatomic ionized molecule is less than the energy of a single atom which is near α. This observation confirms that the system is stabilized in energy compared to two isolated atoms, which seems consistent with the experimental determination of the existence of such molecules.

Traditionally chemists represent the energy differences in the following form for our particular case:



$E \to 0$
E
$E_2 = \frac{\alpha-\beta}{1-S}$
Ψ_2
α
Ψ_A
$E_1 < E_2 < 0$
Ψ_B
α
Ψ_1
$E_1 = \frac{\alpha+\beta}{1+S}$
$E \to -\infty$

Figure 13.24: Energy levels of dihydrogen cation H_2

We therefore conclude - by generalizing a little bit... - that when two atoms (each contributing with an electron) combine, their atomic orbitals will combine to generate two molecular orbitals, one of energy level Ψ_1 and the second of higher energy level Ψ_2 than that of the isolated atoms. Thus, the split up that will make leave one of the electron with one of atoms will be exothermic in comparison to the single atoms.

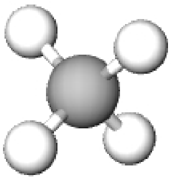
Up to now we have discussed the electronic states of rigid molecules, where the nuclei are clamped to a fixed position. In this section we will improve our model of molecules and include the rotation and vibration of diatomic molecules.

13.2.3 Molecular Rotational Energy Levels

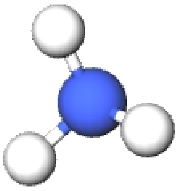
As we have seen in the section of Quantum chemistry, for analytical reasons we consider molecules as rigid rotators.

The rigid rotators are commonly classified into four types:

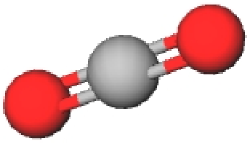
- Spherical rotors: have equal moments of inertia (e.g., CH_4).

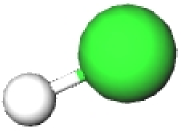


- Symmetric rotors: have two equal moments of inertia (e.g., NH_3).

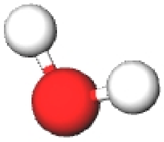


- Linear rotors: have one moment of inertia equal to zero (e.g., CO_2, HCl).





- Asymmetric rotors: have three different moments of inertia (e.g., H_2O).



Let us now recall that we have proved in the section of Quantum Chemistry that for the rigid rotator (see page 6134) the part of the Hamiltonian dedicated to the rotation of energy is:

$$E_{\text{rot}}=\frac{L^2}{2\mu r^2} \tag{13.2.64}$$

Where L^2 was is an operator but from which we know from our study of Wave Quantum Physics (see page 4887) that the eigenvalues are:

$$L\leq\sqrt{l(l+1)}\hbar \tag{13.2.65}$$

and where r is the distance between the two corpuscles (nucleus and electron in the context of our study of the hydrogenous atom in the section of Quantum Chemistry) and:

$$\mu=\frac{m_eM}{M_{\text{tot}}}=\frac{m_eM}{m_e+M} \tag{13.2.66}$$

In the context of diatomic molecules A and B it is more common to write r_{AB} and:

$$\mu=\frac{M_AM_B}{M_A+M_B} \tag{13.2.67}$$

In the section of Wave Quantum Physics we have seen (page 4877) that if we must consider the spin we have to write the more general form:

$$J\leq\sqrt{J_z(J_z+1)}\hbar \tag{13.2.68}$$

with $J=0,1/2/,1,3/2,2,5/2,\ldots$. Therefore:

$$\boxed{E_{\text{rot}}=\frac{J^2}{2\mu r^2}=\frac{J_z(J_z+1)\hbar^2}{2\mu r^2}} \tag{13.2.69}$$

In the old style spectroscopic literature, the rotational term values $F(J)=E(J)/hc$ are used instead of the energies....The previous relation is then written:

$$F_{\text{rot}}=\frac{J_z(J_z+1)\hbar^2}{2hc\mu r^2}=\bar{B}J(J+1) \tag{13.2.70}$$

with the "rotational constant":

$$\bar{B}=\frac{\hbar}{4\pi c\mu r^2} \tag{13.2.71}$$

We also know from the section of Classical Mechanics (page 3297) that:

$$E_{\text{rot}}=\frac{1}{2}\omega^2 J \tag{13.2.72}$$

Therefore:

$$\frac{1}{2}\omega^2 J=\frac{J^2}{2\mu r^2} \tag{13.2.73}$$

That simplifies to:

$$\omega=\frac{2\pi}{T}=\sqrt{\frac{J}{\mu r^2}} \tag{13.2.74}$$

Hence:

$$T=2\pi\sqrt{\frac{\mu r^2}{J}}=2\pi\sqrt{\frac{\mu r^2}{\sqrt{J_z(J_z+1)}\hbar}} \tag{13.2.75}$$

The energy separation between the rotational levels J and $J+1$ is given obviously by:

$$\begin{aligned}\Delta E_{\text{rot}}=E_{\text{rot}}(J+1)-E_{\text{rot}}(J)&=\frac{(J_z+1)((J_z+1)+1)\hbar^2}{2\mu r^2}-\frac{J_z(J_z+1)\hbar^2}{2\mu r^2}\\&=\frac{\hbar^2}{2\mu r^2}\left(J_z^2+2J_z+J_z+2-J_z^2-J_z\right)=\frac{(J_z+1)\hbar^2}{\mu r^2}\end{aligned} \tag{13.2.76}$$

and increase linearly with J.

Let us now calculate the moment of inertia, that we will denoted I to avoid the confusion with the orbital kinetic momentum J used above, of a diatomic molecule. Let us imagine the diatomic molecule as a system of two tiny spheres at either end of a thin weightless rod.

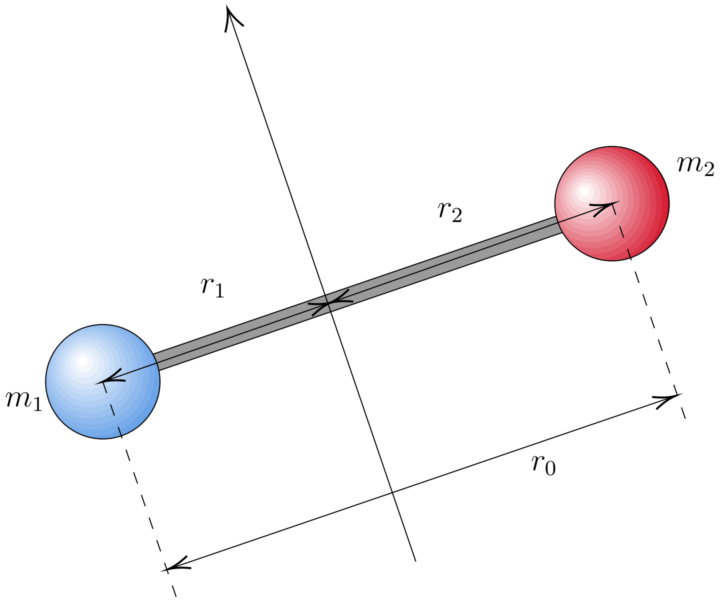


Figure 13.25: Construction for the study of inertia momentum of a diatomic molecule

Let C be the center of mass of the molecule. Let r_1 and r_2 be the distances of the two atoms of respective masses m_1, m_2 from the center of mass C of the molecule: We see that:

$$r_1+r_2=r_0 \tag{13.2.77}$$

and we have (see section Classical Mechanics page 3213):

$$m_1 r_1 = m_2 r_2 \tag{13.2.78}$$

Therefore:

$$r_2 = r_0 - r_1 \tag{13.2.79}$$

Hence:

$$m_1 r_1 = m_2 r_2 = m_2(r_0 - r_1) = m_2 r_0 - m_2 r_1 \tag{13.2.80}$$

After rearranging we get:

$$r_1(m_1 + m_2) = m_2 r_0 \tag{13.2.81}$$

or:

$$r_1 = \frac{m_2}{m_1 + m_2} r_0 \tag{13.2.82}$$

Similarly:

$$r_2 = \frac{m_1}{m_1 + m_2} r_0 \tag{13.2.83}$$

Let I (instead of the traditional notation J) be the total moment of inertia of the diatomic molecule about an axis passing through the center of mass of the molecule and perpendicular to the bond length.

Then we have seen in the section of Classical Mechanics (see page 3297) that:

$$I = m_1 r_1^2 + m_2 r_2^2 \tag{13.2.84}$$

or:

$$I = m_1 \left(\frac{m_2}{m_1 + m_2} r_0\right)^2 + m_2 \left(\frac{m_1}{m_1 + m_2} r_0\right)^2 \tag{13.2.85}$$

thus:

$$I = \frac{m_1 m_2^2}{(m_1 + m_2)^2} r_0^2 + \frac{m_2 m_1^2}{(m_1 + m_2)^2} r_0^2 \tag{13.2.86}$$

after simplification:

$$I = \frac{m_1 m_2 (m_2 + m_1)}{(m_1 + m_2)^2} r_0^2 \tag{13.2.87}$$

Hence:

$$I = \frac{m_1 m_2}{m_1 + m_2} r_0^2 \tag{13.2.88}$$

So finally for a diatomic molecule (or any pair of object turning around a common center) we get the following moment of inertia:

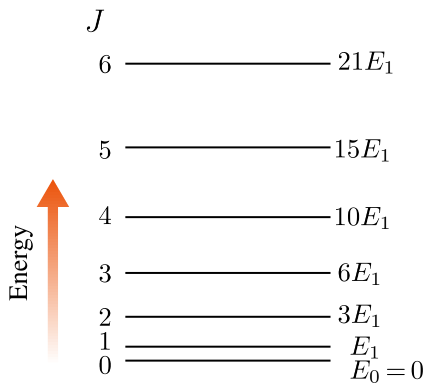
$$\boxed{I = \frac{m_1 m_2}{m_1 + m_2} r_0^2 = \mu r_0^2} \tag{13.2.89}$$

Hence the fact that we often found in the literature the previous main relations under the form:

$$\boxed{E_{\text{rot}}=\frac{J_z(J_z+1)\hbar^2}{2I}} \tag{13.2.90}$$

and:

$$\boxed{\Delta E_{\text{rot}}=\frac{(J_z+1)\hbar^2}{I}} \tag{13.2.91}$$



Therefore, as:

$$h\nu=\Delta E_{\text{rot}}=\frac{(J_z+1)\hbar^2}{I} \tag{13.2.92}$$

the frequencies at which transitions can occur are given by :

$$\nu=\frac{(J_z+1)\hbar}{2\pi I} \tag{13.2.93}$$

Notice that for $J_z=0$ we have a non-null zero point energy and frequency:

$$\nu=\frac{\hbar}{2\pi I} \tag{13.2.94}$$

✍**Example:**

The molecule NaH is found to undergo a rotational transition from $J=0$ to $J=1$ when it absorbs a photon of frequency $2.94\cdot 10^{11}$ [Hz]. We want to know the equilibrium bond length of the molecule.

For this purpose we use $J_z=0$ in the formula for the transition frequency:

$$\nu=\frac{\hbar}{2\pi I}=\frac{\hbar}{2\pi\mu r_0^2} \tag{13.2.95}$$

Solving for r_0 gives:

$$r_0 = \sqrt{\frac{\hbar}{2\pi\mu\nu}} \tag{13.2.96}$$

The reduced mass is given by:

$$\mu = \frac{m_{\mathrm{Na}} m_{\mathrm{H}}}{m_{\mathrm{Na}} + m_{\mathrm{H}}} \cong \frac{22.989 \cdot 1.0078}{22.989 + 1.0078} \cong 0.9655 \tag{13.2.97}$$

which is in atomic mass units or relative units. In order to convert to kilograms, we need the conversion factor $1\,[\mathrm{au}] = 1.66 \cdot 10^{-27}$ [kg]. Multiplying this by 0.9655 gives a reduced mass of $1.603 \cdot 10^{-27}$ [kg]. Substituting in for r_0 gives:

$$r_0 \cong \sqrt{\frac{1.055 \cdot 10^{-34}}{2\pi(1.603 \cdot 10^{-27})(2.94 \cdot 10^{11})}} \cong 1.89 \cdot 10^{-10}\,[\mathrm{m}] \tag{13.2.98}$$

13.2.4 Molecular Vibrational Energy Levels

Let us consider the simple case of a vibrating diatomic molecule, where restoring force is proportional to displacement such that (see section Mechanics page 3416):

$$F = -kx \tag{13.2.99}$$

The potential energy is as we have proved it in the previously mentioned section, but with the notation of Quantum Physics, given by:

$$V = \frac{1}{2}kx^2 \tag{13.2.100}$$

Now remember that we have proved in the section of Wave Quantum Physics (see page 4758), that the Schrödinger equation was given by:

$$\left(E_p - \frac{\hbar^2}{2m}\frac{\partial^2}{\partial^2 x}\right)\Psi = E_{\text{tot}}\Psi \tag{13.2.101}$$

After rearrangement:

$$\frac{\hbar^2}{2m}\frac{\partial^2}{\partial^2 x}\Psi + (E_{\text{tot}} - E_p) = 0 \tag{13.2.102}$$

And using the conventional notations in chemistry and quantum physics:

$$\frac{\hbar^2}{2m}\frac{\partial^2}{\partial^2 x}\Psi + (E - V) = 0 \tag{13.2.103}$$

Before continuing we need to study a bit this important configuration of masses:

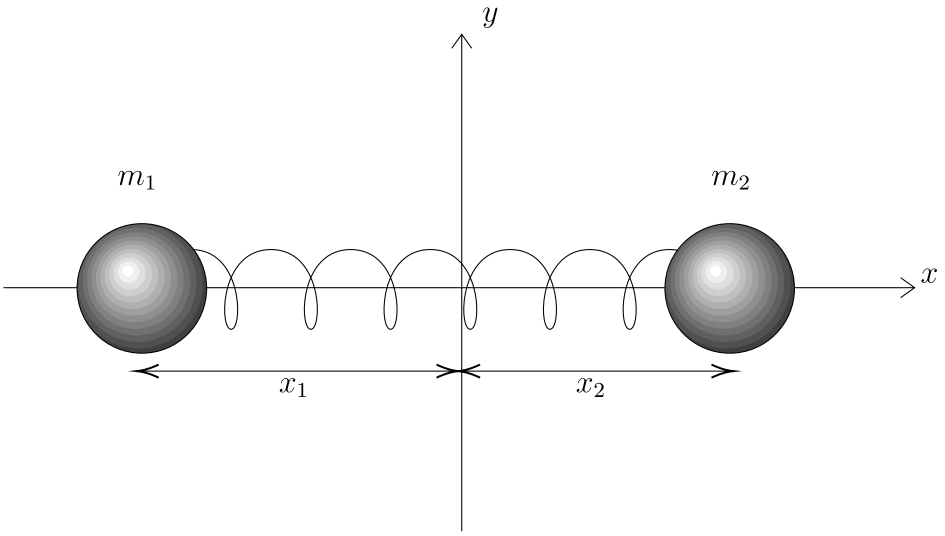


Figure 13.26: **Harmonic oscillator with two masses**

We will assume that the two masses m_1 and m_2 in figure above have positions labelled as x_1 and x_2 relatively to the center of mass but are moving back and forth as a harmonic oscillator. We will ignore any other motion of these two masses (like translation or rotation) and focus solely on the oscillation. In a purely harmonic oscillation (also named a "vibration") the center of mass r_g (see section Classical Mechanics page 3213) does not change, so that:

$$m_1\frac{\mathrm{d}x_1}{\mathrm{d}t}=-m_2\frac{\mathrm{d}x_2}{\mathrm{d}t} \tag{13.2.104}$$

The negative sign indicates that the masses are moving in the opposite directions. By adding the mixed term $m_2(\mathrm{d}x_1/\mathrm{d}t)$ to both sides, we get:

$$m_1\frac{\mathrm{d}x_1}{\mathrm{d}t}+m_2\frac{\mathrm{d}x_1}{\mathrm{d}t}=-m_2\frac{\mathrm{d}x_2}{\mathrm{d}t}+m_2\frac{\mathrm{d}x_1}{\mathrm{d}t} \tag{13.2.105}$$

Therefore:

$$(m_1+m_2)\frac{\mathrm{d}x_1}{\mathrm{d}t}=m_2\left(\frac{\mathrm{d}x_1}{\mathrm{d}t}-\frac{\mathrm{d}x_2}{\mathrm{d}t}\right) \tag{13.2.106}$$

This is rearranged to:

$$\frac{\mathrm{d}x_1}{\mathrm{d}t}=\frac{m_2}{m_1+m_2}\left(\frac{\mathrm{d}x_1}{\mathrm{d}t}-\frac{\mathrm{d}x_2}{\mathrm{d}t}\right) \tag{13.2.107}$$

Let us define now the relative coordinate r as:

$$r=x_1-x_2 \tag{13.2.108}$$

and thus:

$$\frac{\mathrm{d}r}{\mathrm{d}t}=\frac{\mathrm{d}x_1}{\mathrm{d}t}-\frac{\mathrm{d}x_2}{\mathrm{d}t} \tag{13.2.109}$$

Now we can substitute that into:

$$\frac{\mathrm{d}x_1}{\mathrm{d}t}=\frac{m_2}{m_1+m_2}\left(\frac{\mathrm{d}x_1}{\mathrm{d}t}-\frac{\mathrm{d}x_2}{\mathrm{d}t}\right) \tag{13.2.110}$$

to get:

$$\frac{\mathrm{d}x_1}{\mathrm{d}t}=\frac{m_2}{m_1+m_2}\frac{\mathrm{d}r}{\mathrm{d}t} \tag{13.2.111}$$

Identically we can get:

$$\frac{\mathrm{d}x_2}{\mathrm{d}t}=\frac{m_1}{m_1+m_2}\frac{\mathrm{d}r}{\mathrm{d}t} \tag{13.2.112}$$

as a second expression.

In considering the total energy of this harmonic oscillation, the potential energy is the same as for any other harmonic oscillator but the kinetic energy is the sum of the kinetic energies of the two particles. That is:

$$E_c=\frac{1}{2}m_1\left(\frac{\mathrm{d}x_1}{\mathrm{d}t}\right)^2+\frac{1}{2}m_1\left(\frac{\mathrm{d}x_2}{\mathrm{d}t}\right)^2 \tag{13.2.113}$$

Using the two previous relations, it is easy to substitute and show that the kinetic energy has a simple form in terms of the time derivative of the relative coordinate $\mathrm{d}r/\mathrm{d}t$:

$$E_c=\frac{1}{2}\frac{m_1 m_2}{m_1+m_2}\left(\frac{\mathrm{d}r}{\mathrm{d}t}\right)^2 \qquad (13.2.114)$$

The reduced mass μ (see section Classical Mechanics page 3213) is as we know:

$$\mu=\frac{m_1 m_2}{m_1+m_2} \qquad (13.2.115)$$

What this means is that the kinetic energy of the oscillator can be represented by the kinetic energy of a single mass moving back and forth, if that single mass has the reduced mass of the two masses in the original system. This allows us to treat the two-particle harmonic oscillator as a one-particle harmonic oscillator and use the same equations and expressions that we derived for a simple harmonic oscillator.

So the result we get for the simple harmonic oscillator (see section Music Mathematics page 8224):

$$\omega=\sqrt{\frac{k}{m}} \qquad (13.2.116)$$

will be written:

$$\omega=\sqrt{\frac{k}{\mu}} \qquad (13.2.117)$$

So coming back to our initial problem, we have that:

$$\frac{\hbar^2}{2\mu}\frac{\partial^2}{\partial^2 x}\Psi+\left(E-\frac{1}{2}kx^2\right)=0 \qquad (13.2.118)$$

has for solution using what we have proved in the section of Wave Quantum Physics (see page 4807)and just above:

$$E_n=\hbar\omega_0\left(n+\frac{1}{2}\right)=\hbar\sqrt{\frac{k}{\mu}}\left(n+\frac{1}{2}\right) \qquad (13.2.119)$$

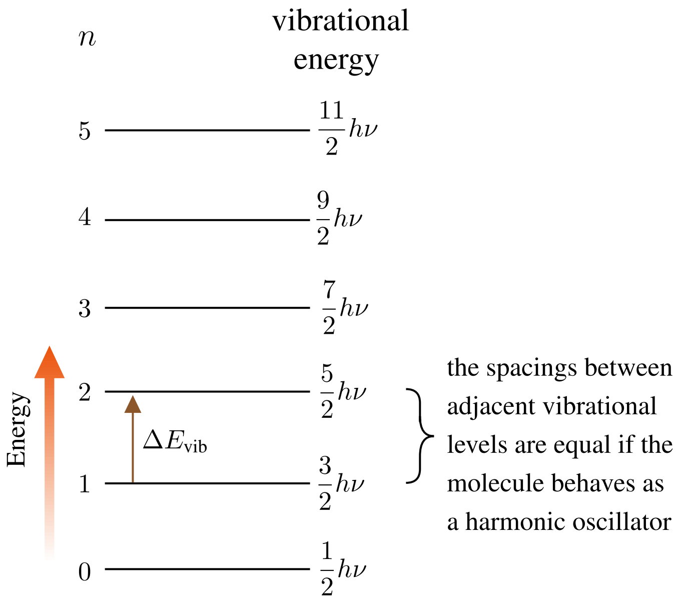
with for recall $n\in\mathbb{N}$. More often denoted:

$$\boxed{E_{\text{vib}}=\hbar\sqrt{\frac{k}{\mu}}\left(n+\frac{1}{2}\right)} \qquad (13.2.120)$$

Notice that for the same reason the harmonic oscillator has a zero point energy. We see that if $n=0$ in the above relation lead us to an equivalent zero point vibrational energy (it remains the $1/2$ factor interpreted by some chemists as a half-quantum number).

With the new studies of band spectra in the early 11920s (holocene calendar) the concept of zero-point energy became respectable among molecular physicists. Yet it was only in the fall of 11924 (holocene calendar) that half-quanta were firmly established in molecular spectroscopy.

In a study of the spectrum of boron monoxide (BO), Robert Mulliken, a young physical chemist at Harvard University, concluded that observations could only be understood on the assumption of quantum numbers with a minimum value of one-half.



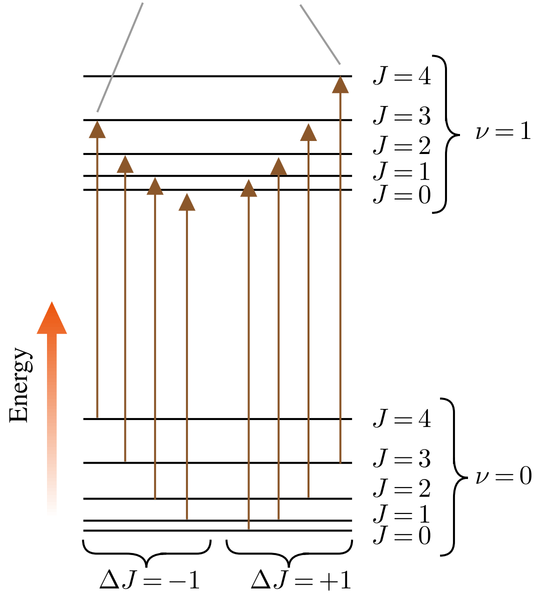
n
vibrational energy
5
$\frac{11}{2}h\nu$
4
$\frac{9}{2}h\nu$
3
$\frac{7}{2}h\nu$
2
$\frac{5}{2}h\nu$
1
$\frac{3}{2}h\nu$
0
$\frac{1}{2}h\nu$
Energy
ΔE_{vib}
the spacings between adjacent vibrational levels are equal if the molecule behaves as a harmonic oscillator

So we can combine the previous results to get the "vibrational-rotational energies level":

$$\boxed{E(n,J_z)=\hbar\sqrt{\frac{k}{\mu}}\left(n+\frac{1}{2}\right)+\frac{J_z(J_z+1)\hbar^2}{2\mu r^2}} \qquad (13.2.121)$$

Sometimes the n in the relation above is named the "vibrational quantum number" and often denoted by the letter v.

The energy levels of any molecule can be calculated from this expression, and each level is indexed by the two quantum numbers v and J. From these calculations, an energy-level diagram like the one shown below can be constructed:



the transitions obey the selection rule $\Delta J = \pm 1$ and fall into two sequences, those for $\Delta J = +1$ and those for $\Delta J = -1$

$J=4$
$J=3$
$J=2$
$J=1$
$J=0$
$\nu=1$
Energy
$J=4$
$J=3$
$J=2$
$J=1$
$J=0$
$\nu=0$
$\Delta J=-1$
$\Delta J=+1$

For each allowed value of the vibrational quantum number v, there is a complete set of rotational levels corresponding to $J = 0, 1, 2, \ldots$. The energy separation between successive rotational levels is much smaller than the separation between successive vibrational levels.

The following figure summarize the different types of energies and corresponding radiations involved in different typical phenomenon in molecular chemistry in normal conditions of temperature and pressure:

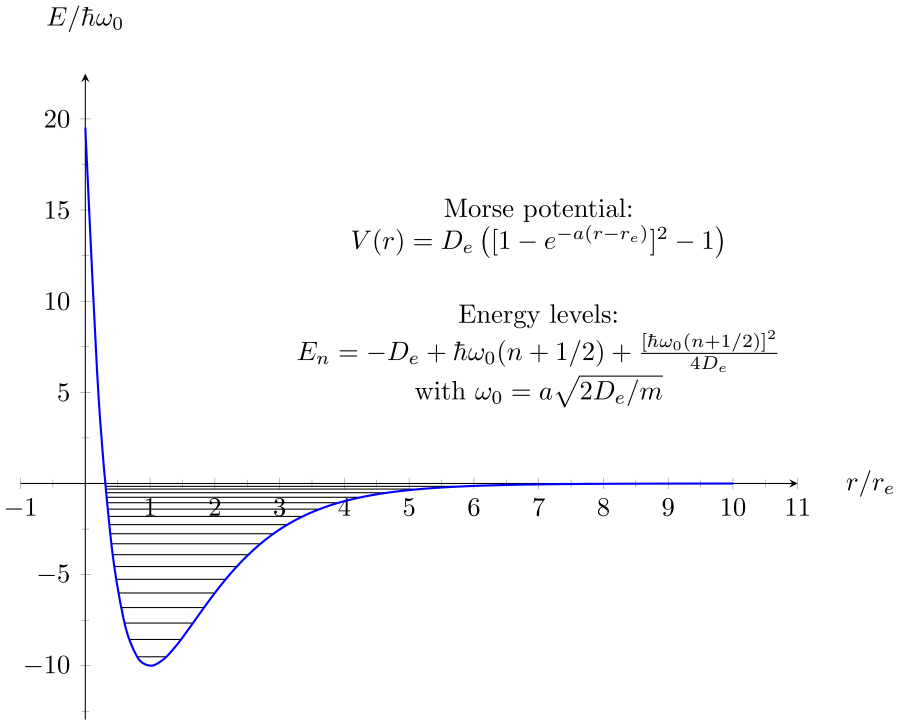
Figure 13.27: **Various energies and corresponding radiation involved in some chemical/molecular phenomenon**

Since the early 121st century (holocene calendar) aberration-corrected transmission electron microscopy is shown to be a powerful analytical tool for the investigation and imaging of dynamics of metallic bonding at the atomic level almost in real-time (for an example see [88]).

13.2.5 Morse potential

The "Morse potential", named after physicist Philip M. Morse (paper published in 11929 - according to holocene calendar - see [401]), is a convenient interatomic interaction model for the potential energy of a diatomic molecule. It is a better approximation for the vibrational structure of the molecule than the quantum harmonic oscillator because it explicitly includes the effects of bond breaking, such as the existence of unbound states. It also accounts for the anharmonicity of real bonds and the non-zero transition probability for overtone and combination bands. The Morse potential can also be used to model other interactions such as the interaction between an atom and a surface. Due to its simplicity (only three fitting parameters), it is not used in modern spectroscopy. However, its mathematical form inspired the MLR (Morse/Long-range) potential, which is the most popular potential energy function used for fitting spectroscopic data.



The form of the Morse potential, in terms of the internuclear distance, is:

$$\boxed{V(r) = D\left(1 - e^{-\alpha\frac{r-r_0}{r_0}}\right)^2} \tag{13.2.122}$$

where r_0 is the "equilibrium internuclear distance" and D (often denoted D_e) is the "bond dissociation energy" (we can found the values of r_0 and D for 56 diatomic molecules in the original paper of Morse entitled *Diatomic molecules according to the wave mechanics*), and α the "Morse parameter".

Remark

How D_e and α in:

$$V(r)=D_e\left(\left[1-e^{-\alpha(r-r_0)}\right]^2-1\right) \tag{13.2.123}$$

are measured in out of the scope of this textbook (ask a professional spectroscopic chemistry).

In optical and infrared spectroscopy, experimentalists directly measure frequencies (ν) or wavelengths of light (λ). Therefore, D_e is frequently expressed in $[\text{cm}^{-1}]$ his is technically a unit of reciprocal length, but it is used as a proxy for energy via the relationship $E=h\nu=hc\lambda$. For example, strong covalent bonds have a D_e depth on the order of $20,000\,[\text{cm}^{-1}]$ to $40,000\,[\text{cm}^{-1}]$.

Morse couldn't determine the shape of his potential curve. He took the simplest method, which is heurestic: First, we draw the curve $y_1=-e^{-kx}$. This curve starts at $-\infty$ when $x=0$ and tends towards zero as $x\rightarrow+\infty$. If we add 1, we find $y_2=1-e^{-kx}$. This curve starts at $-\infty$ when $x=0$ and tends towards $+1$ as $x\rightarrow+\infty$. But it passes through $y=0$ at $x=1/k$. Squaring this curve gives $y_3=\left(1-e^{-kx}\right)^2$, which is always a positive curve. It starts at $+\infty$ at $x=0$, becomes zero at $x=1/k$, and tends towards $+1$ as $x\rightarrow+\infty$ (this is a matter of normalization only obviously as in reality $V(r)\rightarrow 0$ when $r\rightarrow+\infty$).

The Morse curve is this y_3 curve multiplied by D, where D is the dissociation energy of the diatomic molecule. The coefficient k is adjusted so that $1/k$ is equal to the interatomic distance r_0 between the two atoms of the diatomic molecule: $k=1/r_0$. The Morse curve thus defined has the further advantage of being approximated by a parabola around $x=1/k$, and therefore resembles a harmonic oscillator.

Remark

If we develop the square of the Morse potential we get obviously:

$$V(r)=D\left(1-2e^{-\alpha\frac{r-r_0}{r_0}}+e^{-2\alpha\frac{r-r_0}{r_0}}\right) \tag{13.2.124}$$

Often rearranged as:

$$V(r)=D\left(\underbrace{e^{-2\alpha\frac{r-r_0}{r_0}}}_{\substack{\text{short distance}\\\text{repulsion}}}-\underbrace{2e^{-\alpha\frac{r-r_0}{r_0}}}_{\substack{\text{attraction at}\\\text{far distance}}}+\underbrace{1}_{\substack{\text{asymptote}\\ r\rightarrow+\infty}}\right) \tag{13.2.125}$$

And often redefined as (because we don't care too much about a constant shift):

$$V(r):=V(r)-D=D\left(e^{-2\alpha\frac{r-r_0}{r_0}}-2e^{-\alpha\frac{r-r_0}{r_0}}\right)=D\left[\left(1-e^{-\alpha\frac{r-r_0}{r_0}}\right)^2-1\right] \tag{13.2.126}$$

It is common to define a variable x, such that:

$$x=\frac{r-r_0}{r_0} \tag{13.2.127}$$

which allows us to rewrite the potential as:

$$V(x) = D\left(1 - e^{-\alpha x}\right)^2 \tag{13.2.128}$$

It leads to a Schrödinger equation of the form:

$$-\frac{\hbar^2}{2\mu}\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2} + D\left(1 - e^{-\alpha x}\right)^2\Psi = E\Psi \tag{13.2.129}$$

Before attempting a solution, we follow standard practice and attempt to clean up this equation by changing variables. Thus, we define $y = \alpha x$, so that:

$$\frac{\mathrm{d}}{\mathrm{d}x} = \frac{\mathrm{d}y}{\mathrm{d}x}\frac{\mathrm{d}}{\mathrm{d}y} = \alpha\frac{\mathrm{d}}{\mathrm{d}y} \tag{13.2.130}$$

which transforms the Schrödinger equation into:

$$-\frac{\hbar^2\alpha^2}{2\mu}\frac{\mathrm{d}^2\Psi}{\mathrm{d}y^2} + D\left(1 - e^{-y}\right)^2\Psi = E\Psi \tag{13.2.131}$$

yields:

$$-\frac{\hbar^2\alpha^2}{2\mu}\frac{\mathrm{d}^2\Psi}{\mathrm{d}y^2} + D\left(1 - 2e^{-y} + e^{-2y}\right)\Psi = E\Psi \tag{13.2.132}$$

Rearranging terms to isolate the second derivative:

$$\frac{\mathrm{d}^2\Psi}{\mathrm{d}y^2} + \left[\frac{2\mu E}{\hbar^2\alpha^2} - \frac{2\mu D}{\hbar^2\alpha^2} + \frac{4\mu D}{\hbar^2\alpha^2}e^{-y} - \frac{2\mu D}{\hbar^2\alpha^2}e^{-2y}\right]\Psi = 0 \tag{13.2.133}$$

Now, we introduce two dimensionless parameters to represent energy and potential depth:

$$\gamma = \frac{\sqrt{2\mu D}}{\hbar\alpha} \quad \text{and} \quad K = \frac{\sqrt{2\mu(D-E)}}{\hbar\alpha} \tag{13.2.134}$$

(for bound states, $0 < E < D$, meaning K remains real and positive).

Substituting y and K simplifies our differential equation to:

$$\frac{\mathrm{d}^2\Psi}{\mathrm{d}y^2} + \left[-K^2 + 2\gamma^2 e^{-y} - \gamma^2 e^{-2y}\right]\Psi = 0 \tag{13.2.135}$$

To eliminate the exponential terms in the potential, we perform a change of variable by defining:

$$z = 2\gamma^2 e^{-y} \tag{13.2.136}$$

We map the derivatives from y to z using the chain rule:

$$\frac{\mathrm{d}z}{\mathrm{d}y} = -2\gamma^2 e^{-y} = -z \tag{13.2.137}$$

Hence:

$$\frac{\mathrm{d}\Psi}{\mathrm{d}y} = \frac{\mathrm{d}\Psi}{\mathrm{d}z}\frac{\mathrm{d}z}{\mathrm{d}y} = -z\frac{\mathrm{d}\Psi}{\mathrm{d}z} \tag{13.2.138}$$

For the second derivative:

$$\frac{\mathrm{d}^2\Psi}{\mathrm{d}y^2} = -z\frac{\mathrm{d}}{\mathrm{d}z}\left(-z\frac{\mathrm{d}\Psi}{\mathrm{d}z}\right) = z^2\frac{\mathrm{d}^2\Psi}{\mathrm{d}z^2} + z\frac{\mathrm{d}\Psi}{\mathrm{d}z} \tag{13.2.139}$$

We can also express the exponential coefficients in the brackets in terms of z :

$$2\gamma^2 e^{-y} = z \quad \text{and} \quad \gamma^2 e^{-2y} = \frac{1}{4}z^2 \tag{13.2.140}$$

Substituting these back into the differential equation gives:

$$z^2\frac{\mathrm{d}^2\Psi}{\mathrm{d}z^2} + z\frac{\mathrm{d}\Psi}{\mathrm{d}z} + \left[-K^2 + z - \frac{1}{4}z^2\right]\Psi = 0 \tag{13.2.141}$$

Dividing the entire equation by z^2 :

$$\frac{\mathrm{d}^2\Psi}{\mathrm{d}z^2} + \frac{1}{z}\frac{\mathrm{d}\Psi}{\mathrm{d}z} + \left[-\frac{1}{4} + \frac{\gamma}{z} - \frac{K^2}{z^2}\right]\Psi = 0 \tag{13.2.142}$$

Now we strip out the asymptotic behavior of $\Psi(z)$ at its boundaries ($z \rightarrow +\infty$ and $z \rightarrow 0$):

- As $z \rightarrow +\infty$:

  The dominant term in the brackets is $-1/4$. The equation behaves like:

  $$\Psi'' - \frac{1}{4}\Psi \cong 0 \tag{13.2.143}$$

  which yields a physically acceptable solution of $\Psi(z) \sim e^{-z/2}$.

- As $z \rightarrow 0$:

  The dominant term is $-K^2/z^2$. The equation approaches Euler-Cauchy form:

  $$\Psi'' + \frac{1}{z}\Psi' - \frac{K^2}{z^2}\Psi \cong 0 \tag{13.2.144}$$

  Trying a solution of $\Psi(z) \sim z^S$ yields $s^2 = K^2$, meaning $\Psi(z) \sim z^K$ for a regular solution at the origin.

Combining these behaviors, we define a transformation ansatz (very clever move...!) using an unknown function $w(z)$:

$$\Psi(z) = z^K e^{-z/2} w(z) \tag{13.2.145}$$

Now we evaluate the derivatives of our ansatz $\Psi(z) = z^K e^{-z/2} w(z)$ to substitute them back into the differential equation:

We must compute the new derivatives, we start with the first one:

$$\Psi' = z^{K-1}e^{-z/2}\left(zw'(z) + \left(K - \frac{z}{2}\right)w(z)\right) = z^K e^{-z/2}\left[w' + \left(\frac{K}{z} - \frac{1}{2}\right)w\right] \tag{13.2.146}$$

And the second derivative:

$$\begin{aligned}
\Psi'' &= \frac{\mathrm{d}}{\mathrm{d}z}\left[z^{K-1}e^{-z/2}\left(zw'(z)+\left(K-\tfrac{z}{2}\right)w(z)\right)\right]\\
&= \frac{\mathrm{d}}{\mathrm{d}z}\left[z^{K-1}e^{-z/2}\right]\cdot\left(zw'(z)+\left(K-\tfrac{z}{2}\right)w(z)\right)+z^{K-1}e^{-z/2}\cdot\frac{\mathrm{d}}{\mathrm{d}z}\left(zw'(z)+\left(K-\tfrac{z}{2}\right)w(z)\right)\\
&= \left((K-1)z^{K-2}e^{-z/2}-\frac{1}{2}z^{K-1}e^{-z/2}\right)\left(zw'(z)+\left(K-\tfrac{z}{2}\right)w(z)\right)+z^{K-1}e^{-z/2}\left(w'(z)+zw''(z)-\frac{1}{2}w(z)+\left(K-\tfrac{z}{2}\right)w'(z)\right)\\
&= z^{K-2}e^{-z/2}\left(K-1-\tfrac{z}{2}\right)\left(zw'(z)+\left(K-\tfrac{z}{2}\right)w(z)\right)+z^{K-2}e^{-z/2}\left(z^2w''(z)+z\left(1+K-\tfrac{z}{2}\right)w'(z)-\tfrac{z}{2}w(z)\right)\\
&= z^{K-2}e^{-z/2}\left[\left(K-1-\tfrac{z}{2}\right)zw'(z)+\left(K-1-\tfrac{z}{2}\right)\left(K-\tfrac{z}{2}\right)w(z)+z^2w''(z)+\left(z+Kz-\frac{z^2}{2}\right)w'(z)-\tfrac{z}{2}w(z)\right]\\
&= z^{K-2}e^{-z/2}\left[z^2w''(z)+\left(Kz-z-\frac{z^2}{2}+z+Kz-\frac{z^2}{2}\right)w'(z)+\left(K^2-\frac{Kz}{2}-K+\frac{z}{2}-\frac{Kz}{2}+\frac{z^2}{4}-\frac{z}{2}\right)w(z)\right]\\
&= z^{K-2}e^{-z/2}\left[z^2w''(z)+(2Kz-z^2)w'(z)+\left(K^2-K-Kz+\frac{z^2}{4}\right)w(z)\right]\\
&= z^{K}e^{-z/2}\left[w''(z)+\left(\frac{2K}{z}-1\right)w'(z)+\left(\frac{K(K-1)}{z^2}-\frac{K}{z}+\frac{1}{4}\right)w(z)\right]\\
&= z^{K}e^{-z/2}\left[\frac{\mathrm{d}^2w}{\mathrm{d}z^2}+2\left(\frac{K}{z}-\frac{1}{2}\right)\frac{\mathrm{d}w}{\mathrm{d}z}+\left(\frac{K^2-K}{z^2}-\frac{K}{z}+\frac{1}{4}\right)w\right]
\end{aligned} \tag{13.2.147}$$

Plugging $\Psi, \mathrm{d}\Psi/\mathrm{d}z$, and $\mathrm{d}^2\Psi/\mathrm{d}z^2$ into :

$$\frac{\mathrm{d}^2\Psi}{\mathrm{d}z^2}+\frac{1}{z}\frac{\mathrm{d}\Psi}{\mathrm{d}z}+\left[-\frac{1}{4}+\frac{\gamma}{z}-\frac{K^2}{z^2}\right]\Psi=0 \tag{13.2.148}$$

and dividing out the common factor $z^K e^{-z/2}$:

$$\begin{aligned}
\left[\frac{\mathrm{d}^2w}{\mathrm{d}z^2}+\left(\frac{2K}{z}-1\right)\frac{\mathrm{d}w}{\mathrm{d}z}+\left(\frac{K^2-K}{z^2}-\frac{K}{z}+\frac{1}{4}\right)w\right]+\frac{1}{z}\left[\frac{\mathrm{d}w}{\mathrm{d}z}+\left(\frac{K}{z}-\frac{1}{2}\right)w\right]\\
+\left[-\frac{1}{4}+\frac{\gamma}{z}-\frac{K}{z^2}\right]
\end{aligned} \tag{13.2.149}$$

Grouping like terms:

- $\frac{\mathrm{d}^2w}{\mathrm{d}z^2}$ term :

$$1 \tag{13.2.150}$$

- $\frac{\mathrm{d}w}{\mathrm{d}z}$ term:

$$\left(\frac{2K}{z}-1\right)+\frac{1}{z}=\frac{2K+1}{z}-1 \tag{13.2.151}$$

- w term:

$$\left(\frac{K^2-K}{z^2}-\frac{K}{z}+\frac{1}{4}\right)+\left(\frac{K}{z^2}-\frac{1}{2z}\right)+\left(-\frac{1}{4}+\frac{\gamma}{z}-\frac{K^2}{z^2}\right)=\frac{\gamma-K-\frac{1}{2}}{z} \tag{13.2.152}$$

This simplifies the system down to:

$$\frac{\mathrm{d}^2w}{\mathrm{d}z^2}+\left(\frac{2K+1}{z}-1\right)\frac{\mathrm{d}w}{\mathrm{d}z}+\left(\frac{\gamma-K-\frac{1}{2}}{z}\right)w=0 \tag{13.2.153}$$

Multiplying the entire expression by z :

$$z\frac{\mathrm{d}^2w}{\mathrm{d}z^2}+(2K+1-z)\frac{\mathrm{d}w}{\mathrm{d}z}-\left(K+\frac{1}{2}-\gamma\right)w=0 \tag{13.2.154}$$

The final expression matches exactly with Kummer's Confluent Hypergeometric Equation:

$$\boxed{z\frac{\mathrm{d}^2w}{\mathrm{d}z^2}+(b-z)\frac{\mathrm{d}w}{\mathrm{d}z}-aw=0} \tag{13.2.155}$$

where the characteristic parameters are:

$$\begin{aligned} a&=K+\frac{1}{2}-\gamma \\ b&=2K+1 \end{aligned} \tag{13.2.156}$$

So this is the one-dimensional Schrödinger equation with a Morse potential written into something named the "Kummer's differential equation" (also known as the "confluent hypergeometric equation").

The Kummer's function of the first kind M is a generalized hypergeometric series introduced by Kummer in 11837 (holocene calendar) and a solution of this differential equation given by:

$$M(a,b,z)=\sum_{n=0}^{+\infty}\frac{a^{(n)}z^n}{b^{(n)}n!}={}_1F_1(a;b;z) \tag{13.2.157}$$

where $x^{(n)}$) is the "rising factorial" (sometimes named the "Pochhammer function", "Pochhammer polynomial", "ascending factorial", "rising sequential product", or "upper factorial") is defined as:

$$\begin{aligned} x^{(n)}=x^{\bar{n}}&=\overbrace{x(x+1)(x+2)\cdots(x+n-1)}^{n\text{ factors}} \\ &=\prod_{k=1}^{n}(x+k-1)=\prod_{k=0}^{n-1}(x+k). \end{aligned} \tag{13.2.158}$$

The first few rising factorials are as follows:

$$\begin{aligned} &x^{(0)} && =1 \\ &x^{(1)} && =x \\ &x^{(2)}=x(x+1) && =x^2+x \\ &x^{(3)}=x(x+1)(x+2) && =x^3+3x^2+2x \\ &x^{(4)}=x(x+1)(x+2)(x+3) && =x^4+6x^3+11x^2+6x \end{aligned} \tag{13.2.159}$$

Remark

Laguerre polynomials can be defined by confluent hypergeometric functions and Kummer's transformation as:

$$L_n^{(\alpha)}(x):=\binom{n+\alpha}{n}M(-n,\alpha+1,x) \tag{13.2.160}$$

That said let us show the the Kummer's fuction is indeed a solution of the Kummer's differential equation! First we have:

$$y(x)=\sum_{n=0}^{+\infty}\frac{a^{(n)}x^n}{b^{(n)}n!}=1+\sum_{n=1}^{+\infty}\frac{a^{(n)}x^n}{b^{(n)}n!} \tag{13.2.161}$$

Hence for the third term of the Kummer's differential equation:

$$ay(x)=a+\sum_{n=1}^{+\infty}\frac{a\cdot a^{(n)}x^n}{b^{(n)}n!} \tag{13.2.162}$$

And we also have for the second term of the Kummer's differential equation:

$$\begin{aligned}(b-x)y'(x)=(b-x)\sum_{n=1}^{+\infty}\frac{a^{(n)}nx^{n-1}}{b^{(n)}n!}&=\sum_{n=1}^{+\infty}b\cdot\frac{a^{(n)}nx^{n-1}}{b^{(n)}n!}-\sum_{n=1}^{+\infty}x\cdot\frac{a^{(n)}nx^{n-1}}{b^{(n)}n!}\\&=\sum_{n=1}^{+\infty}\frac{a^{(n)}x^{n-1}}{(b+1)^{(n-1)}(n-1)!}-\sum_{n=1}^{+\infty}\frac{a^{(n)}x^n}{b^{(n)}(n-1)!}\\&=a+\sum_{n=1}^{+\infty}\frac{a^{(n+1)}x^n}{(b+1)^{(n)}n!}-\sum_{n=1}^{+\infty}\frac{a^{(n)}x^n}{b^{(n)}(n-1)!}\end{aligned} \tag{13.2.163}$$

And for the first term of the Kummer's differential equation:

$$xy''(x)=\sum_{n=2}^{+\infty}x\cdot\frac{a^{(n)}n(n-1)x^{n-2}}{b^{(n)}n!}=\sum_{n=2}^{+\infty}\frac{a^{(n)}x^{n-1}}{b^{(n)}(n-2)!}=\sum_{n=1}^{+\infty}\frac{a^{(n+1)}x^n}{b^{(n+1)}(n-1)!} \tag{13.2.164}$$

So we can finally check:

$$\begin{aligned}&xy''(x)+(b-x)y'(x)-ay(x)\\&=\sum_{n=1}^{+\infty}\frac{a^{(n+1)}x^n}{b^{(n+1)}(n-1)!}+\left(a+\sum_{n=1}^{+\infty}\frac{a^{(n+1)}x^n}{(b+1)^{(n)}n!}-\sum_{n=1}^{+\infty}\frac{a^{(n)}x^n}{b^{(n)}(n-1)!}\right)-\left(a+\sum_{n=1}^{+\infty}\frac{a\cdot a^{(n)}x^n}{b^{(n)}n!}\right)\\&=\sum_{n=1}^{+\infty}\left(\frac{a^{(n+1)}}{b^{(n+1)}(n-1)!}+\frac{a^{(n+1)}}{(b+1)^{(n)}n!}-\frac{a^{(n)}}{b^{(n)}(n-1)!}-\frac{a\cdot a^{(n)}}{b^{(n)}n!}\right)x^n\\&=\sum_{n=1}^{+\infty}((a+n)n+(a+n)b-(b+n)n-a(b+n))\frac{a^{(n)}}{b^{(n+1)}n!}x^n=0\end{aligned} \tag{13.2.165}$$

And that proves our ansatz!

For the wave function $\Psi(\zeta)$ to remain physically wellbehaved (square-normalizable) as $z\rightarrow+\infty$, the series expansion of $M(a,b,z)$ must terminate into a finite polynomial. This truncation occurs if and only if the parameter a is a non-positive integer, i.e.:

$$a=-n \quad \text{where } n=0,1,2,\ldots \tag{13.2.166}$$

To prove that the confluent hypergeometric function of the first kind, $M(a,b,z)$ (also denoted as ${}_1F_1(a;b;z)$), terminates into a finite polynomial if and only if the parameter a is a non-positive integer, we must analyze its series expansion.

The series definition of the Kummer function is given for reminder by:

$$M(a,b,z)=\sum_{n=0}^{+\infty}\frac{a^{(n)}}{b^{(n)}}\frac{z^n}{n!} \tag{13.2.167}$$

where $x^{(n)}$ denotes the Pochhammer symbol (or rising factorial), defined for $n \geq 1$ as:

$$x^{(n)}=x(x+1)(x+2)\cdots(x+n-1) \tag{13.2.168}$$

with the convention that $x^{(0)}=1$.

Let $a=-m$, where m is a non-negative integer $(m \in \{0,1,2,\ldots\})$.

Remark

We assume throughout this proof that b is not a non-positive integer ($b \notin \mathbb{Z}_{\leq 0}$), otherwise the terms $b^{(n)}$ would vanish in the denominator, making the function undefined.

Let's examine the behavior of the numerator's Pochhammer symbol $a^n=(-m)^{(n)}$ as n increases:

- For $n \leq m$, the product contains only strictly negative terms, so $(-m)_n \neq 0$.
- For $n=m+1$, the product becomes:

$$(-m)_{m+1}=(-m)(-m+1)(-m+2)\cdots(-m+m+1-1)=0 \tag{13.2.169}$$

- For any index $n>m$, the term $(-m+m)=0$ will always be a factor inside the product expansion!

Because $a^{(n)}=0$ for all $n \geq m+1$, every coefficient in the series beyond $n=m$ identically vanishes. The infinite series truncates in this case to a finite sum:

$$M(-m,b,z)=\sum_{n=0}^{m}\frac{(-m)^{(n)}}{b^n}\frac{z^n}{n!} \tag{13.2.170}$$

Remember that in the confluent hypergeometric equation given by:

$$z\frac{\mathrm{d}^2w}{\mathrm{d}z^2}+(b-z)\frac{\mathrm{d}w}{\mathrm{d}z}-aw=0 \tag{13.2.171}$$

we have in our case (see earlier above):

$$a=K+\frac{1}{2}-\gamma=\frac{\sqrt{2\mu(D-E)}}{\hbar\alpha}+\frac{1}{2}-\frac{\sqrt{2\mu D}}{\hbar\alpha} \tag{13.2.172}$$

Setting $a:=-n$ we therefore have:

$$n=\frac{\sqrt{2\mu D}}{\hbar\alpha}-\frac{\sqrt{2\mu(D-E)}}{\hbar\alpha}-\frac{1}{2} \tag{13.2.173}$$

$$\begin{aligned}
n&=\frac{\sqrt{2\mu D}}{\hbar\alpha}-\frac{\sqrt{2\mu(D-E)}}{\hbar\alpha}-\frac{1}{2}\\
\Rightarrow \frac{\sqrt{2\mu(D-E)}}{\hbar\alpha}&=\frac{\sqrt{2\mu D}}{\hbar\alpha}-n-\frac{1}{2}\\
\Rightarrow \sqrt{2\mu(D-E)}&=\sqrt{2\mu D}-\hbar\alpha\left(n+\frac{1}{2}\right)\\
\Rightarrow 2\mu(D-E)&=\left[\sqrt{2\mu D}-\hbar\alpha\left(n+\frac{1}{2}\right)\right]^2\\
\Rightarrow D-E&=\frac{1}{2\mu}\left[\sqrt{2\mu D}-\hbar\alpha\left(n+\frac{1}{2}\right)\right]^2\\
\Rightarrow E&=D-\frac{1}{2\mu}\left[\sqrt{2\mu D}-\hbar\alpha\left(n+\frac{1}{2}\right)\right]^2
\end{aligned} \tag{13.2.174}$$

Finally:

$$E_n=D-\frac{1}{2\mu}\left[\sqrt{2\mu D}-\hbar\alpha\left(n+\frac{1}{2}\right)\right]^2 \tag{13.2.175}$$

The eigenenergies in the initial variables is often written as:

$$\boxed{E_n=h\nu_0\left(n+\frac{1}{2}\right)-\frac{\left[h\nu_0\left(n+\frac{1}{2}\right)\right]^2}{4D}} \tag{13.2.176}$$

where n is the vibrational quantum number and ν_0 has units of frequency. The latter is mathematically related to the particle mass, m, and the Morse constants via:

$$\nu_0=\frac{\alpha}{2\pi}\sqrt{\frac{2D}{\mu}} \tag{13.2.177}$$

Whereas the energy spacing between vibrational levels in the quantum harmonic oscillator is constant at $h\nu_0$, the energy between adjacent levels decreases with increasing v in the Morse oscillator. Mathematically, the spacing of Morse levels is:

$$E_{n+1}-E_n=h\nu_0-\frac{(n+1)\left(h\nu_0\right)^2}{2D_e} \tag{13.2.178}$$

This trend matches the inharmonicity found in real molecules. However, this equation fails above some value of n_m where $E\left(n_m+1\right)-E\left(n_m\right)$ is calculated to be zero or negative. Specifically:

$$n_m=\frac{2D_e-h\nu_0}{h\nu_0} \quad \text{(integer part only)} \tag{13.2.179}$$

This failure is due to the finite number of bound levels in the Morse potential, and some maximum n_m that remains bound. For energies above n_m, all the possible energy levels are allowed and the equation for E_n is no longer valid.

Remark

In molecular physics, the real potential energy $V(r)$ of a vibrating molecule is often approximated using analytical Morse functions. The "Herzberg anomaly" highlights specific regions, generally near the middle of the potential well, where these mathematical approximations systematically intersect and diverge from the actual experimental potential curve. The anomaly was originally observed through isotopic and vibrational analyses detailed by Nobel laureate Gerhard Herzberg in his seminal book *Spectra of Diatomic Molecules* (originally published in the 11930 (holocence calendar).

Here is a table of a few values (among a thousands of others) of D_e and α according to:

$$V(r)=D_e\left(\left[1-e^{-\alpha(r-r_0)}\right]^2-1\right) \tag{13.2.180}$$

and taken from [429]:

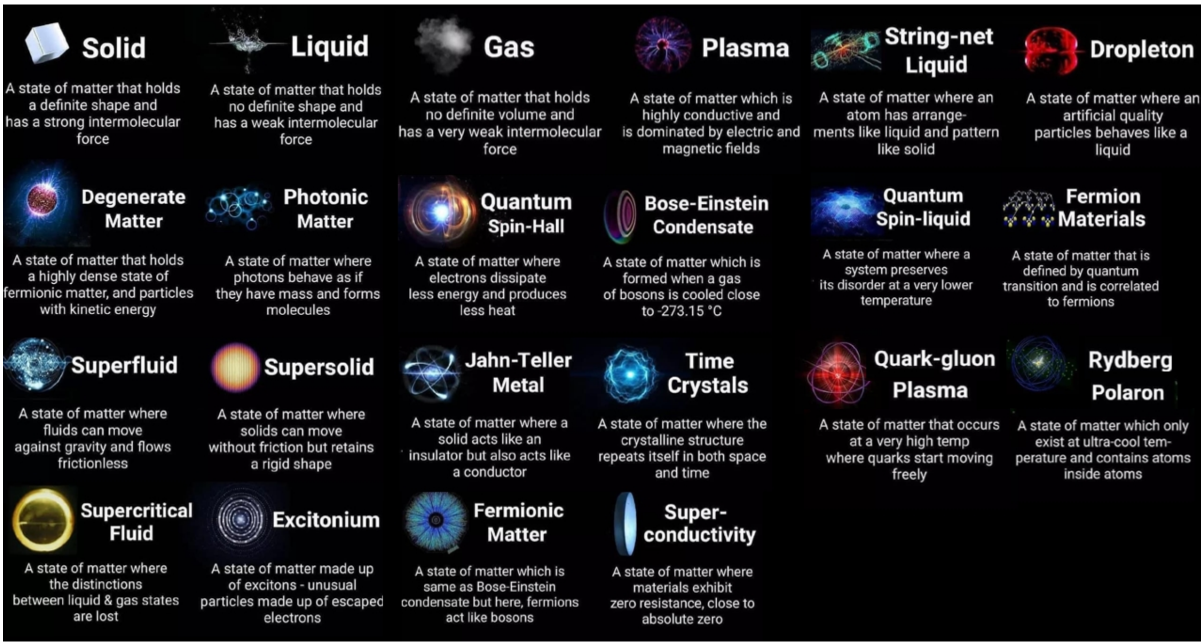
13.3. Analytical Chemistry

CHEMISTRY is a very complex n-body science that mathematics can not explained without the input of numerical computer simulations or approximations regarding the use of quantum theory (see Atomistic chapter page 4612). Until these tools are powerful enough and accessible to everyone, chemistry remains a primarily experimental science based on the observation of different properties of matter and we would like here give some very important definitions (which we find also elsewhere in other fields as chemistry).

Analytical chemistry is concerned with the chemical characterization of matter and the answer to two important questions: what is it (qualitative analysis) and how much is it (quantitative analysis). Chemicals make up everything we use or consume, and knowledge of the chemical composition of many substances is important in our daily lives. Analytical chemistry plays an important role in nearly all aspects of chemistry, for example, agricultural, clinical, environmental, forensic, manufacturing, metallurgical, and pharmaceutical chemistry. The nitrogen content of a fertilizer determines its value. Foods must be analysed for contaminants (e.g., pesticide residues) and for essential nutrients (e.g., vitamin content). The air we breathe must be analysed for toxic gases (e.g., carbon monoxide). Blood glucose must be monitored in diabetics (and, in fact, most diseases are diagnosed by chemical analysis). The presence of trace elements from gun powder on a perpetrator's hand will prove a gun was fired by that hand. The quality of manufactured products often depends on proper chemical proportions, and measurement of the constituents is a necessary part of quality assurance. The carbon content of steel will influence its quality. The purity of drugs will influence their efficacy.

In this section, we will focus only on the mathematical tools and techniques for performing these different types of analyses.



Solid
A state of matter that holds a definite shape and has a strong intermolecular force

Liquid
A state of matter that holds no definite shape and has a weak intermolecular force

Gas
A state of matter that holds no definite volume and has a very weak intermolecular force

Plasma
A state of matter which is highly conductive and is dominated by electric and magnetic fields

String-net Liquid
A state of matter where an atom has arrangements like liquid and pattern like solid

Dropleton
A state of matter where an artificial quality particles behaves like a liquid

Degenerate Matter
A state of matter that holds a highly dense state of fermionic matter, and particles with kinetic energy

Photonic Matter
A state of matter where photons behave as if they have mass and forms molecules

Quantum Spin-Hall
A state of matter where electrons dissipate less energy and produces less heat

Bose-Einstein Condensate
A state of matter which is formed when a gas of bosons is cooled close to -273.15 °C

Quantum Spin-liquid
A state of matter where a system preserves its disorder at a very lower temperature

Fermion Materials
A state of matter that is defined by quantum transition and is correlated to fermions

Superfluid
A state of matter where fluids can move against gravity and flows frictionless

Supersolid
A state of matter where solids can move without friction but retains a rigid shape

Jahn-Teller Metal
A state of matter where a solid acts like an insulator but also acts like a conductor

Time Crystals
A state of matter where the crystalline structure repeats itself in both space and time

Quark-gluon Plasma
A state of matter that occurs at a very high temp where quarks start moving freely

Rydberg Polaron
A state of matter which only exist at ultra-cool temperature and contains atoms inside atoms

Supercritical Fluid
A state of matter where the distinctions between liquid & gas states are lost

Excitonium
A state of matter made up of excitons - unusual particles made up of escaped electrons

Fermionic Matter
A state of matter which is same as Bose-Einstein condensate but here, fermions act like bosons

Super-conductivity
A state of matter where materials exhibit zero resistance, close to absolute zero

Figure 13.28: **Most common classical and exotic states of matter**

Remark

All matter is made of chemicals. Every single thing you see, touch, taste, smell and even hear is made of chemicals or observable as a result of chemicals. Your body, clothes, and food are made of chemicals. Everything that isn't energy (pure particles) is matter and therefore made of chemicals. All chemicals and chemical compounds are, or are made up of, the same known chemicals found on the period table. Whether or not people can pronounce a chemical is irrelevant for is dangerousness (the chemical name of water is "dihydrogen monoxide").

Caution! Whether is harnessed from Nature or developed in laboratory, a chemical's make up and the way it behaves is going TO BE EXACTLY THE SAME. The makeup of the chemical and the way it behaves will not change based on where it's made. «*Chemical Free*» argument is a LIE. Whether a chemical is man-made or natural tells us precisely nothing about how dangerous it is (the reader may take a look to the famous and friendly Manchineel tree...).

Definitions (#13.3.548):

D1. A "subjective property" is a property based on personal / individual printing, for example: beauty, sympathy, color, utility, etc.

D2. An "objective property" is an experienced property (which can not be contradicted), for example: mass, volume, shape, etc.

D3. A "qualitative property" is a descriptive property given using words. For example: oval, magnetic, conductive, etc.

D4. A "quantitative property" is a property that can be measured. For example: mass, volume, density, etc.

D5. A "characteristic property" is an exclusive property that identifies a pure substance. It does not change even if it is physically transformed material, for example: its density, its boiling point, its melting point, etc.

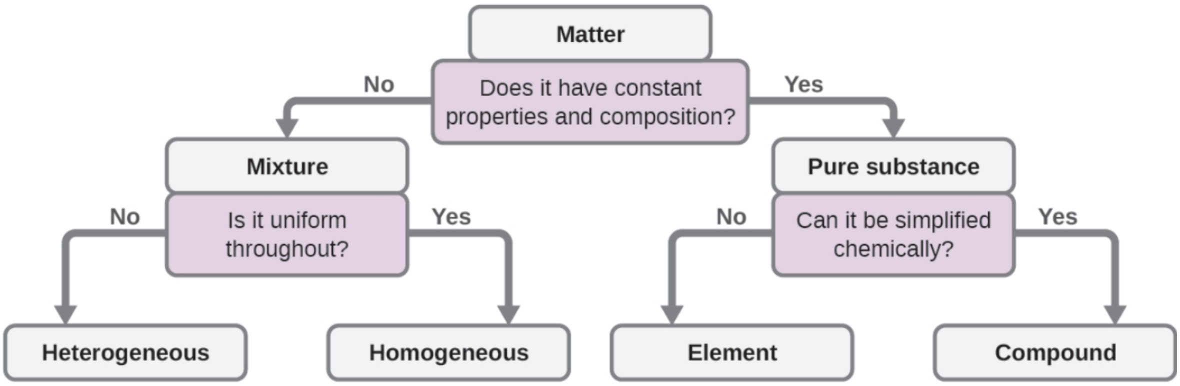
> **Remark**
>
> We know about $2,000,000$ different pure substances in the early 121st century (holocene calendar), that is to say ... there is quite lot of work behind it.

D6. We name "compound bodies", the bodies, that subjected to chemical processes, restore their components in the form of pure substances.

D7. If we make the separation of mixtures and the decomposition of compositions, we finally get the bodies that are non-decomposable by conventional chemical methods; we name them "elements" or "simple bodies".

D8. The smallest part of a chemical combination yet having all of the properties thereof is the "molecule" of this combination. The smallest part of an element or simple body is the "atom" of that element.

Although there are just over 100 elements, tens of millions of chemical compounds result from different combinations of these elements. Each compound has a specific composition and possesses definite chemical and physical properties by which we can distinguish it from all other compounds. And, of course, there are innumerable ways to combine elements and compounds to form different mixtures. A summary of how to distinguish between the various major classifications of matter is shown in the figure below:



Matter
Does it have constant properties and composition?
No
Yes
Mixture
Is it uniform throughout?
No
Yes
Pure substance
Can it be simplified chemically?
No
Yes
Heterogeneous
Homogeneous
Element
Compound

Figure 13.29: Depending on its properties, a given substance can be classified as a homogeneous mixture, a heterogeneous mixture, a compound, or an element (source: OpenStax)

Let us also give some reminders of what we saw at the very start of the Mechanics chapter:

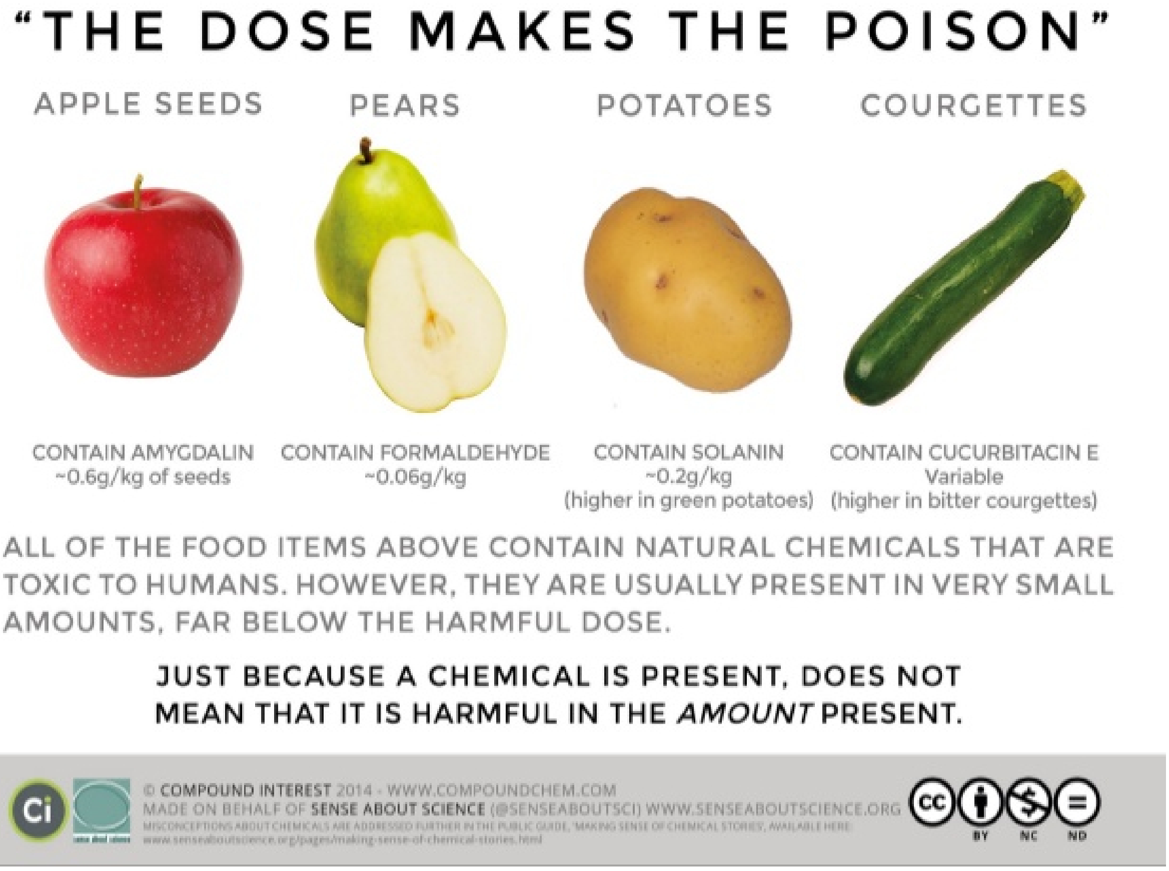
1. A mixture is named "heterogeneous" in chemistry if the components are immediately discernible to the naked eye or through the microscope.

2. A mixture is said to be "homogeneous" in chemistry if the components are not discernible to the naked eye or through the microscope.
3. A system or body is said to be "isotropic" if it has identical values of a property in all directions otherwise it is said "anisotropic".

Also because there is a lot of biased knowledge, the study of chemistry and quantum physics and atomistic should help the reader to understand why:

> *All things are poisons, for there is nothing without poisonous qualities. It is only the dose which makes a thing poison*[5]*!*
>
> Paracelsus

quote 13.3:6231.#75



"THE DOSE MAKES THE POISON"
APPLE SEEDS
PEARS
POTATOES
COURGETTES
CONTAIN AMYGDALIN
~0.6g/kg of seeds
CONTAIN FORMALDEHYDE
~0.06g/kg
CONTAIN SOLANIN
~0.2g/kg
(higher in green potatoes)
CONTAIN CUCURBITACIN E
Variable
(higher in bitter courgettes)

ALL OF THE FOOD ITEMS ABOVE CONTAIN NATURAL CHEMICALS THAT ARE TOXIC TO HUMANS. HOWEVER, THEY ARE USUALLY PRESENT IN VERY SMALL AMOUNTS, FAR BELOW THE HARMFUL DOSE.

JUST BECAUSE A CHEMICAL IS PRESENT, DOES NOT MEAN THAT IT IS HARMFUL IN THE *AMOUNT* PRESENT.

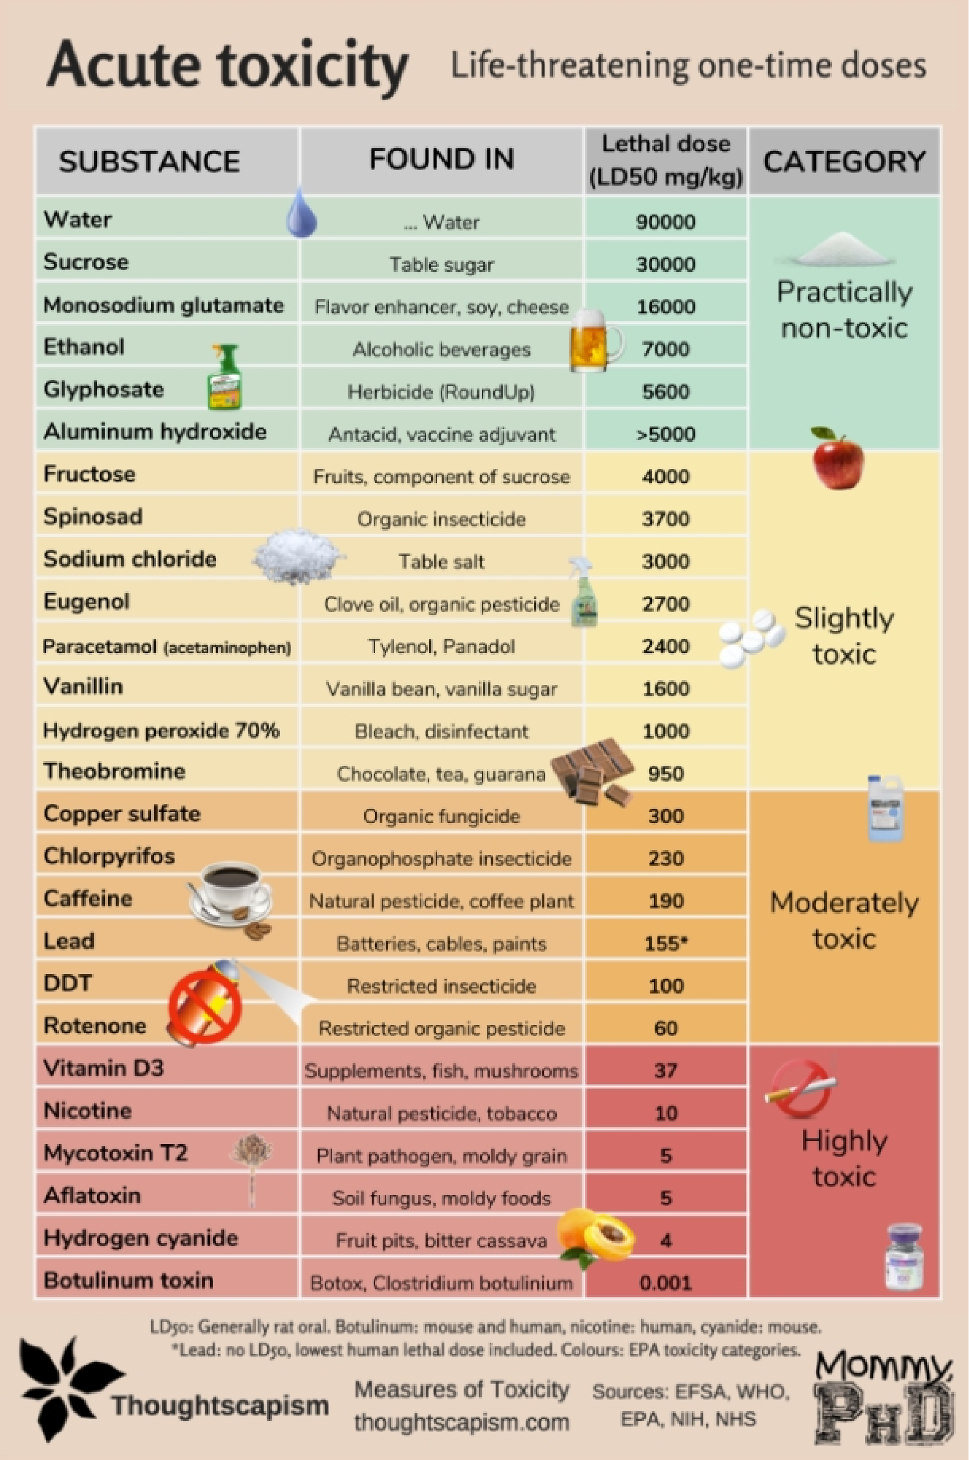
BY NC ND

---

[5] A famous scientific experiment has provided evidence that at the contrary to the intuition that increasing dose makes something more poisonous, there exist sometimes non-monotonic (see section Functional Analysis page 2203) dose response curves (NMDRCs) demonstrated for natural hormones and endocrine disrupting chemicals (EDCs) like Bisphenonal A!



Acute toxicity

Life-threatening one-time doses

SUBSTANCE	FOUND IN	Lethal dose (LD50 mg/kg)	CATEGORY
Water	... Water	90000	Practically non-toxic
Sucrose	Table sugar	30000	
Monosodium glutamate	Flavor enhancer, soy, cheese	16000	
Ethanol	Alcoholic beverages	7000	
Glyphosate	Herbicide (RoundUp)	5600	
Aluminum hydroxide	Antacid, vaccine adjuvant	>5000	
Fructose	Fruits, component of sucrose	4000	Slightly toxic
Spinosad	Organic insecticide	3700	
Sodium chloride	Table salt	3000	
Eugenol	Clove oil, organic pesticide	2700	
Paracetamol (acetaminophen)	Tylenol, Panadol	2400	
Vanillin	Vanilla bean, vanilla sugar	1600	
Hydrogen peroxide 70%	Bleach, disinfectant	1000	
Theobromine	Chocolate, tea, guarana	950	
Copper sulfate	Organic fungicide	300	Moderately toxic
Chlorpyrifos	Organophosphate insecticide	230	
Caffeine	Natural pesticide, coffee plant	190	
Lead	Batteries, cables, paints	155*	
DDT	Restricted insecticide	100	
Rotenone	Restricted organic pesticide	60	
Vitamin D3	Supplements, fish, mushrooms	37	Highly toxic
Nicotine	Natural pesticide, tobacco	10	
Mycotoxin T2	Plant pathogen, moldy grain	5	
Aflatoxin	Soil fungus, moldy foods	5	
Hydrogen cyanide	Fruit pits, bitter cassava	4	
Botulinum toxin	Botox, Clostridium botulinium	0.001	

LD50: Generally rat oral. Botulinum: mouse and human, nicotine: human, cyanide: mouse.
*Lead: no LD50, lowest human lethal dose included. Colours: EPA toxicity categories.

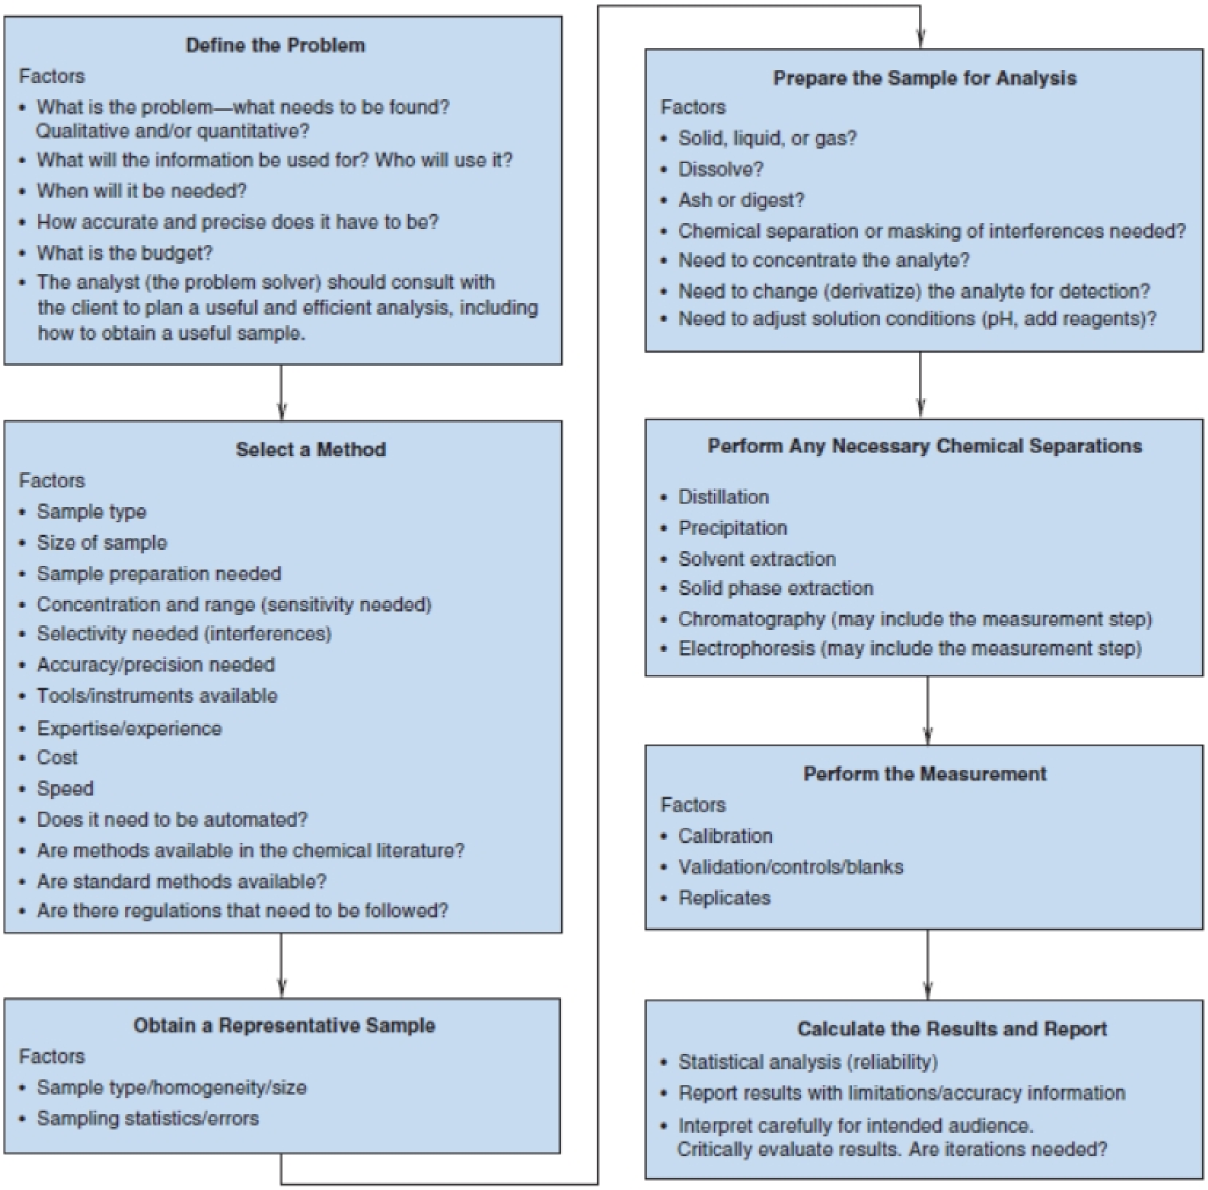
13.3.1 Analytical chemistry process

The general analytical process is shown in the figure below. The analytical chemist should be involved in every step. The chemical analyst is like the physicist, mathematician and engineer: a problem solver, a critical part of the team deciding what, why, and how. The unit operations of analytical chemistry that are common to most types of analyses are considered in more detail below that should in part belongs to process to other science jobs.



Define the Problem

Factors

- What is the problem—what needs to be found? Qualitative and/or quantitative?
- What will the information be used for? Who will use it?
- When will it be needed?
- How accurate and precise does it have to be?
- What is the budget?
- The analyst (the problem solver) should consult with the client to plan a useful and efficient analysis, including how to obtain a useful sample.

Select a Method

Factors

- Sample type
- Size of sample
- Sample preparation needed
- Concentration and range (sensitivity needed)
- Selectivity needed (interferences)
- Accuracy/precision needed
- Tools/instruments available
- Expertise/experience
- Cost
- Speed
- Does it need to be automated?
- Are methods available in the chemical literature?
- Are standard methods available?
- Are there regulations that need to be followed?

Obtain a Representative Sample

Factors

- Sample type/homogeneity/size
- Sampling statistics/errors

Prepare the Sample for Analysis

Factors

- Solid, liquid, or gas?
- Dissolve?
- Ash or digest?
- Chemical separation or masking of interferences needed?
- Need to concentrate the analyte?
- Need to change (derivatize) the analyte for detection?
- Need to adjust solution conditions (pH, add reagents)?

Perform Any Necessary Chemical Separations

- Distillation
- Precipitation
- Solvent extraction
- Solid phase extraction
- Chromatography (may include the measurement step)
- Electrophoresis (may include the measurement step)

Perform the Measurement

Factors

- Calibration
- Validation/controls/blanks
- Replicates

Calculate the Results and Report

- Statistical analysis (reliability)
- Report results with limitations/accuracy information
- Interpret carefully for intended audience. Critically evaluate results. Are iterations needed?

Figure 13.32: **Steps in Analytical Chemistry (source: [101])**

13.3.2 Simple Mixtures

There a basically four type of "mixtures"!

Definitions (#13.3.549):

D1. **Solution**: A "solution" is a homogenous (a substance that is uniform in composition) mixture of one or more substances named "solutes" dissolved in another substance named the "solvent".

The solute can be solid, liquid, or gas but the solvent is always a liquid. E.g. salt solution, sugar solution,...

D2. **Suspension**: A "suspension" is a heterogeneous mixture of large solid substance in another substance made by mechanical agitation. The substances distributed in the background material is not dissolved and will settle out unless the mixture is constantly shaken.

The solute is always a solid substance but the solvent can be solid, liquid, or gas. E.g. mud in water, flour in water, some medicines, dust or water in air,...

D3. **Colloids**: Is a homogeneous solution with intermediate particle size between a solution and a suspension.

The solute can be solid, liquid, or gas substance AND the solvent can also be solid, liquid, or gas. E.g. Foam (Whipped cream), Gel (jelly), smoke, blood,...

D4. **Emulsion**: An "emulsion" is a mixture that consists of two or more liquids that do not mix.

There are two kinds of emulsions. An emulsion that settles is named "temporary emulsion". An emulsion that doesn't is named "permanent emulsion". An example of permanent emulsion is the mixture of oil and vinegar or oil and water.

These solution, suspension and emulsion mixtures were already known by the Greeks. Especially by Aristotle who wrote that salt water was heavier and more dense than fresh water (book II, part II, sixth section), and salt water would seek therefore a lower level[6] in his treatise *Meteorologica* in 9630 (holocene calendar).

---

[6] In facts we know since centuries that they do mix! But not necessarily quickly, so separate bodies of water can exist for quite some time.

Figure 13.33: **A phenomenon that was already understood by Aristotle for the special case of salt and fresh water**

Notice we can observe in practice by zooming that there are no "barrier", nor "complete separation" between two liquids that doesn't mix. With a special apparatus we can zoom in and see that in fact there is a gradient of a given width that depends strongly on the type of mixed liquids (be careful with the false dichotomy bias!).

Before going into more or less complicated equations, the simplest case of application of mathematics to chemistry by which we can start is the management of mixtures for analysis and control operations of simple chemical reactions with two mixtures.

Let us consider two typical and particular examples as theoretical introduction:

1. Given a solution (yellow) of 10 millilitres of a solution containing an acid concentration at 30%. How many millilitres of pure acid (blue) should we add to increase the concentration (green) to 50%?

   
   Figure 13.34: **The joy of mixtures...**

   Since the unknown is the amount of pure acid to be added, we will denote it by x. Then we have:

   $$10\cdot 30\%+x=50\%(10+x) \tag{13.3.1}$$

That gives:

$$3+x=5+0.5x \tag{13.3.2}$$

It comes the obviously:

$$x=4 \tag{13.3.3}$$

Therefore 4 millilitres of acid should be added to the original solution.

2. A canister contains 8 litres of gasoline and oil to run an aggregate. If 40% of the initial mixture is of the essence, how much should we remove of the mixture (pink) to replace it with pure gasoline (green) so that the final mixture (light green) contains 60% gasoline?

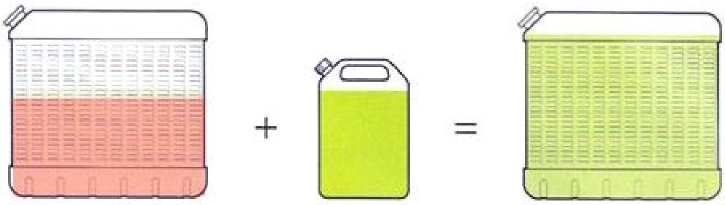


Figure 13.35: **The joy of mixtures for dyers and military ...**

We denote the unknown x that is the number of litres of the initial mixture to remove and replaced by the pure essence being of equal amount also x. Then we have:

$$(8\cdot 40\%-x40\%)+x=8\cdot 60\% \tag{13.3.4}$$

That gives:

$$0.4(8-x)=8\cdot 0.6 \tag{13.3.5}$$

We have then obviously:

$$x=2.\bar{6} \tag{13.3.6}$$

So approximately 2.6 litres should be removed from the original mixture and be replaced by approximately 2.6 litres of pure essence.

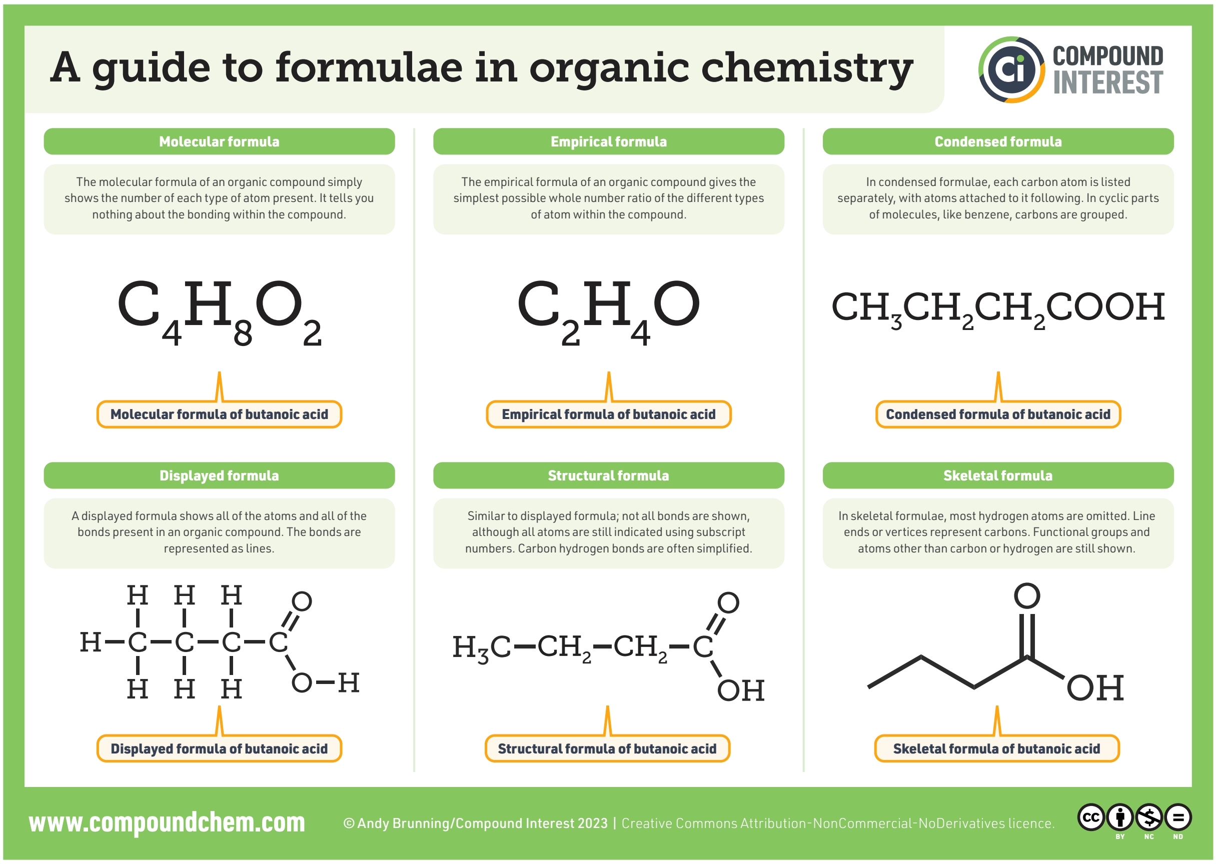
In short this is for all mixtures in this textbook until now. We can go much further and do much more complicated with more unknowns but we'll stop there for now.

13.3.3 Chemical formula

A "chemical formula" is a way of presenting information about the chemical proportions of atoms that constitute a particular chemical compound or molecule, using chemical element symbols, numbers, and sometimes also other symbols, such as parentheses, dashes, brackets, commas and plus (+) and minus (-) signs. These are limited to a single typographic line of symbols, which may include subscripts and superscripts. A chemical formula is not a chemical name since it does not contain any words. Although a chemical formula may imply certain simple chemical structures, it is not the same as a full chemical structural formula. Chemical formulae can fully specify the structure of only the simplest of molecules and chemical substances, and are generally more limited in power than chemical names and structural formulae.

> Caution! There are some traps, like the empirical formula for glucose that is CH_2O (twice as many hydrogen atoms as carbon and oxygen), while its molecular formula is $C_6H_{12}O_6$ (12 hydrogen atoms, six carbon and oxygen atoms).

Sometimes a chemical formula is complicated by being written as a condensed formula (or condensed molecular formula, occasionally called a "semi-structural formula"), which conveys additional information about the particular ways in which the atoms are chemically bonded together, either in covalent bonds, ionic bonds, or various combinations of these types. This is possible if the relevant bonding is easy to show in one dimension. An example is the condensed molecular/chemical formula for ethanol, which is CH_3-CH_2-OH or CH_3CH_2OH. However, even a condensed chemical formula is necessarily limited in its ability to show complex bonding relationships between atoms, especially atoms that have bonds to four or more different substituents.



A guide to formulae in organic chemistry

Molecular formula

The molecular formula of an organic compound simply shows the number of each type of atom present. It tells you nothing about the bonding within the compound.

Empirical formula

The empirical formula of an organic compound gives the simplest possible whole number ratio of the different types of atom within the compound.

Condensed formula

In condensed formulae, each carbon atom is listed separately, with atoms attached to it following. In cyclic parts of molecules, like benzene, carbons are grouped.

Displayed formula

A displayed formula shows all of the atoms and all of the bonds present in an organic compound. The bonds are represented as lines.

Structural formula

Similar to displayed formula; not all bonds are shown, although all atoms are still indicated using subscript numbers. Carbon hydrogen bonds are often simplified.

Skeletal formula

In skeletal formulae, most hydrogen atoms are omitted. Line ends or vertices represent carbons. Functional groups and atoms other than carbon or hydrogen are still shown.

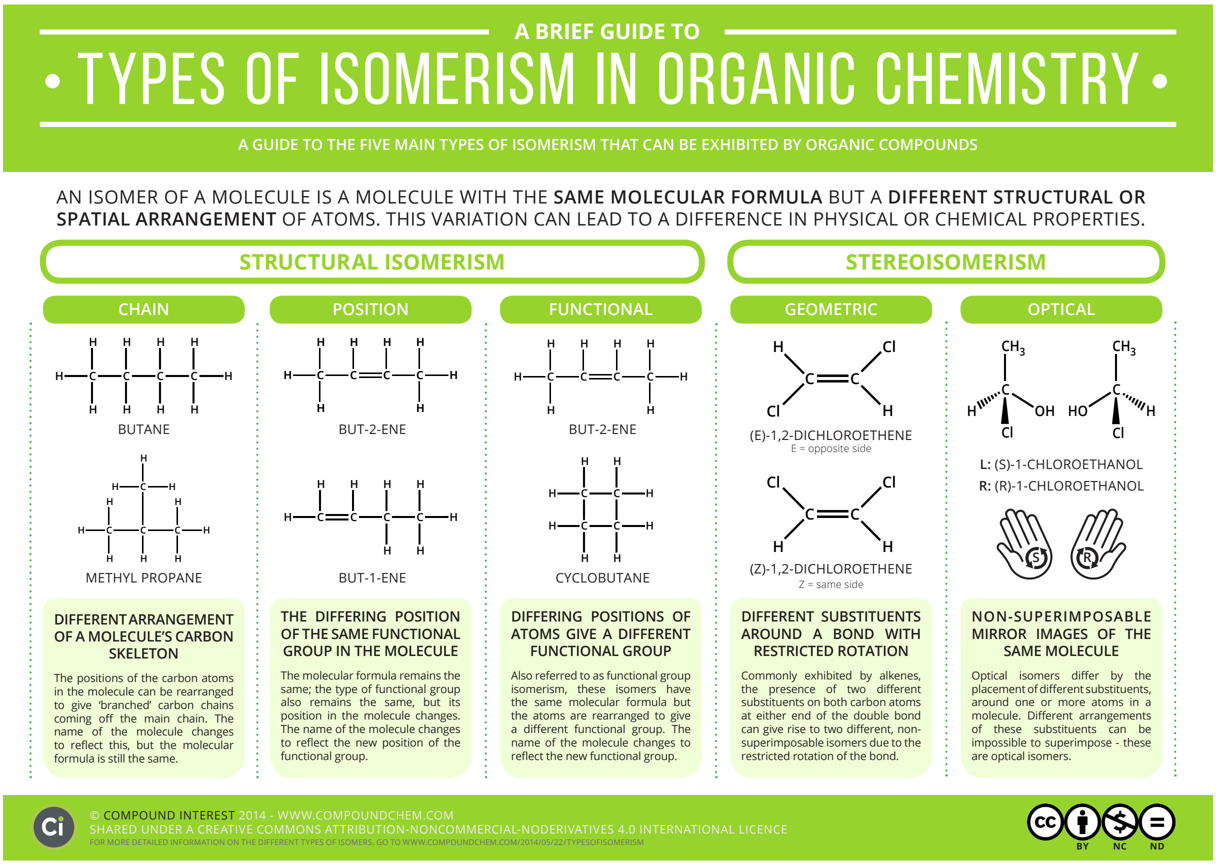
Since a chemical formula must be expressed as a single line of chemical element symbols, it often cannot be as informative as a true structural formula, which is a graphical representation of the spatial relationship between atoms in chemical compounds (see for example the figure for butane structural and chemical formulae, at right). For reasons of structural complexity, a single condensed chemical formula (or semi-structural formula) may correspond to different molecules, known as "isomers". For example, glucose shares its molecular formula $C_6H_{12}O_6$ with a number of other sugars, including fructose, galactose and mannose. Linear equivalent chemical names exist that can and do specify uniquely any complex structural formula (see chemical nomenclature), but such names must use many terms (words), rather than the simple element symbols, numbers, and simple typographical symbols that define a chemical formula.



A BRIEF GUIDE TO

• TYPES OF ISOMERISM IN ORGANIC CHEMISTRY •

A GUIDE TO THE FIVE MAIN TYPES OF ISOMERISM THAT CAN BE EXHIBITED BY ORGANIC COMPOUNDS

AN ISOMER OF A MOLECULE IS A MOLECULE WITH THE **SAME MOLECULAR FORMULA** BUT A **DIFFERENT STRUCTURAL OR SPATIAL ARRANGEMENT** OF ATOMS. THIS VARIATION CAN LEAD TO A DIFFERENCE IN PHYSICAL OR CHEMICAL PROPERTIES.

STRUCTURAL ISOMERISM

CHAIN

BUTANE

METHYL PROPANE

DIFFERENT ARRANGEMENT OF A MOLECULE'S CARBON SKELETON

The positions of the carbon atoms in the molecule can be rearranged to give 'branched' carbon chains coming off the main chain. The name of the molecule changes to reflect this, but the molecular formula is still the same.

POSITION

BUT-2-ENE

BUT-1-ENE

THE DIFFERING POSITION OF THE SAME FUNCTIONAL GROUP IN THE MOLECULE

The molecular formula remains the same; the type of functional group also remains the same, but its position in the molecule changes. The name of the molecule changes to reflect the new position of the functional group.

FUNCTIONAL

BUT-2-ENE

CYCLOBUTANE

DIFFERING POSITIONS OF ATOMS GIVE A DIFFERENT FUNCTIONAL GROUP

Also referred to as functional group isomerism, these isomers have the same molecular formula but the atoms are rearranged to give a different functional group. The name of the molecule changes to reflect the new functional group.

STEREOISOMERISM

GEOMETRIC

(E)-1,2-DICHLOROETHENE
E = opposite side

(Z)-1,2-DICHLOROETHENE
Z = same side

DIFFERENT SUBSTITUENTS AROUND A BOND WITH RESTRICTED ROTATION

Commonly exhibited by alkenes, the presence of two different substituents on both carbon atoms at either end of the double bond can give rise to two different, non-superimposable isomers due to the restricted rotation of the bond.

OPTICAL

L: (S)-1-CHLOROETHANOL
R: (R)-1-CHLOROETHANOL

NON-SUPERIMPOSABLE MIRROR IMAGES OF THE SAME MOLECULE

Optical isomers differ by the placement of different substituents, around one or more atoms in a molecule. Different arrangements of these substituents can be impossible to superimpose - these are optical isomers.

FOR MORE DETAILED INFORMATION ON THE DIFFERENT TYPES OF ISOMERS, GO TO WWW.COMPOUNDCHEM.COM/2014/05/22/TYPESOFISOMERISM

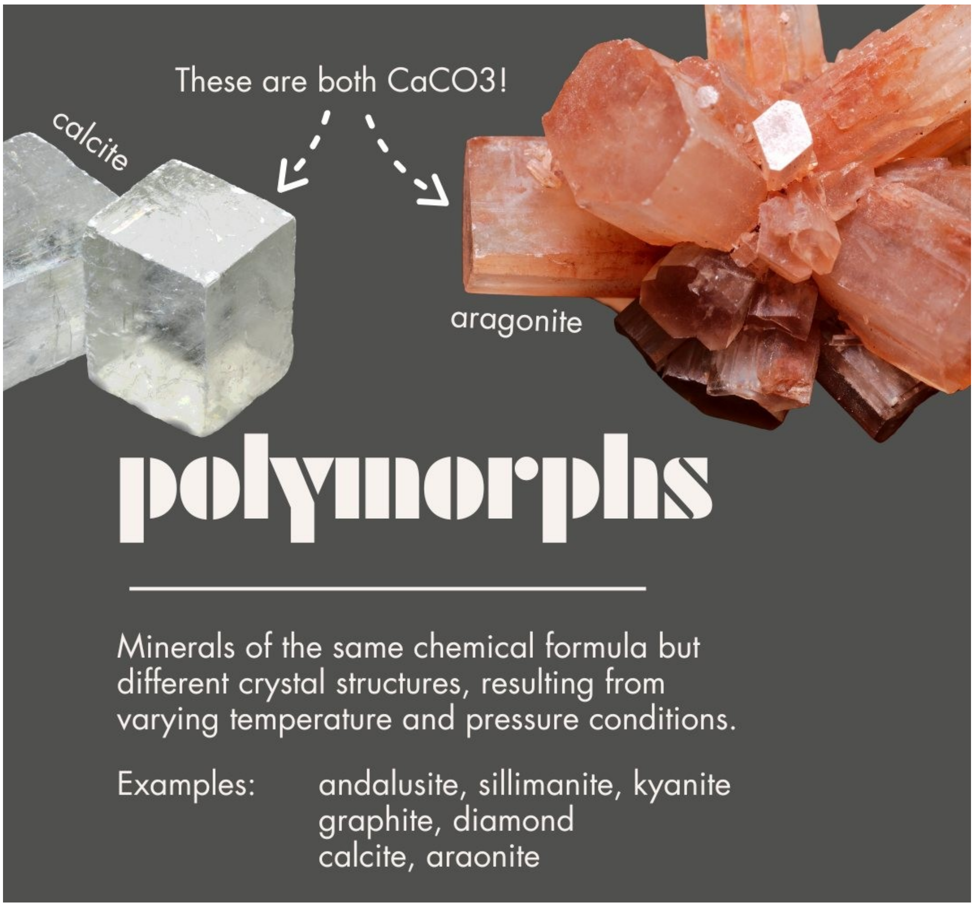
Remark

Isomers have caused multiple headaches since the beginning of modern industrial chemistry. The most famous medical example where an isomer caused catastrophic harm is the thalidomide tragedy, in which one enantiomer of the drug acted as a sedative while its mirror-image isomer caused severe birth defects, leading to thousands of cases of phocomelia and other malformations worldwide. In the past chemist where not able to identify isomer but nowadays various techniques exist to differentiate them.

Chemical formulae may be used in chemical equations to describe chemical reactions and other chemical transformations, such as the dissolving of ionic compounds into solution. While, as noted, chemical formulae do not have the full power of structural formulae to show chemical relationships between atoms, they are sufficient to keep track of numbers of atoms and numbers of electrical charges in chemical reactions, thus balancing chemical equations so that these equations can be used in chemical problems involving conservation of atoms, and conservation of electric charge.

Condensed chemical formulae may also be used to represent ionic compounds that do not exist as discrete molecules, but nonetheless do contain covalently bound clusters within them. These polyatomic ions are groups of atoms that are covalently bound together and have an overall ionic charge, such as the sulfate $[\mathrm{SO_4}]^{2-}$ ion. Each polyatomic ion in a compound is written individually in order to illustrate the separate groupings. For example, the compound dichlorine hexoxide has an empirical formula $\mathrm{ClO_3}$, and molecular formula $\mathrm{Cl_2O_6}$, but in liquid or solid forms, this compound is more correctly shown by an ionic condensed formula $[\mathrm{ClO_2}]^+[\mathrm{ClO_4}]^-$, which illustrates that this compound consists of $[\mathrm{ClO_2}]^+$ ions and $[\mathrm{ClO_4}]^-$ ions. In such cases, the condensed formula only need be complex enough to show at least one of each ionic species.

Isomers aren't the only structural trap in chemistry because "polymorphs" - different crystalline arrangements of the *same* molecule - can radically change a substance's behavior just as dramatically as switching between isomers. While isomers differ in connectivity or spatial arrangement, polymorphs differ only in how molecules pack in the solid state, yet this subtle shift can alter melting point, solubility, stability, bioavailability, and even toxicity. Famous cases like the HIV drug ritonavir, which suddenly became unusable when a more stable but poorly soluble polymorph appeared, show that even when the molecular structure is correct, the solid-state structure can still derail manufacturing, storage, or therapeutic performance.



These are both CaCO3!
calcite
aragonite
polymorphs
Minerals of the same chemical formula but different crystal structures, resulting from varying temperature and pressure conditions.
Examples: andalusite, sillimanite, kyanite
graphite, diamond
calcite, araonite

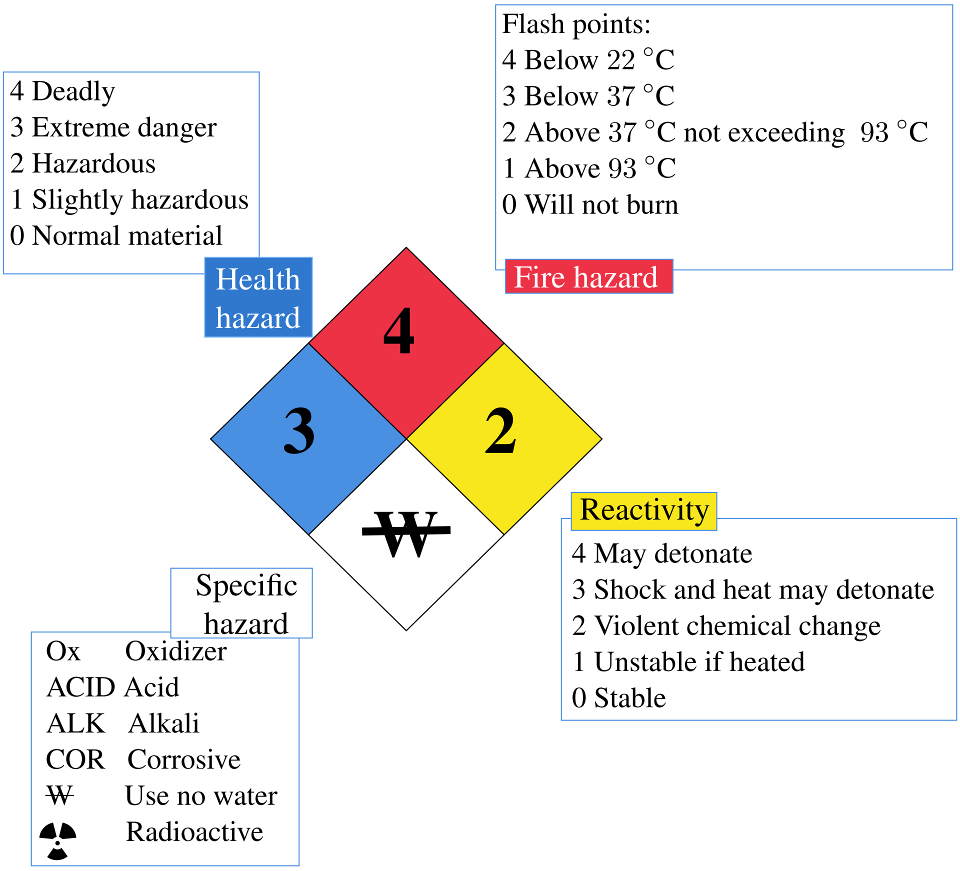
Figure 13.36: Example of polymorph

13.3.4 Reactions

Since the main study in chemistry is to observe the results of pure substances mixtures and/or of compounds mixtures, it is first necessary to deal with the basic rules governing these mixtures under normal conditions of pressure and temperature (N.C.P.T).

We should first clarify that we are not going to study in this section what generates the connections between the elements, as this is the role of quantum and molecular chemistry (see previous sections). Furthermore, we insist on the fact that every theoretical element will be illustrated with a practical example which can be useful sometimes to better understand.

But before, for prevention reason, let us introduce a symbol shown in the figure below and that we can see on containers of chemicals in a laboratory or workplace. Sometimes named a "fire diamond" or "hazard diamond", this chemical hazard diamond provides valuable information that briefly summarizes the various dangers of which to be aware when working with a particular substance:



4 Deadly
3 Extreme danger
2 Hazardous
1 Slightly hazardous
0 Normal material
Health hazard
Flash points:
4 Below 22 °C
3 Below 37 °C
2 Above 37 °C not exceeding 93 °C
1 Above 93 °C
0 Will not burn
Fire hazard
4
3
2
W
Reactivity
4 May detonate
3 Shock and heat may detonate
2 Violent chemical change
1 Unstable if heated
0 Stable
Specific hazard
Ox Oxidizer
ACID Acid
ALK Alkali
COR Corrosive
W Use no water
Radioactive

Figure 13.37: National Fire Protection Agency (NFPA) hazard diamond summarizes the major hazards of a chemical substance

Let us now consider a closed chemical system (without mass transfer therefore!). We translate the change in the composition (if applicable and if have there is one!) of the chemical system with a reaction equation of the form (the system does not always go both ways!):

$$\boxed{v_1A_1+v_2A_2+\ldots\rightleftharpoons v_1'A_1'+v_2'A_2'+\ldots} \quad (13.3.7)$$

but most of time written as:

$$v_1A_1+v_2A_2+\ldots+v_nA_n \rightleftharpoons v_{n+1}A_{n+1}+v_{n+2}A_{n+2}+\ldots+v_mA_m \tag{13.3.8}$$

named "reaction equation" where the coefficients $v_i \in \mathbb{N}^*$ are named "stoichiometric coefficients" in the sense that they indicate the "golden proportions", strictly named "stoichiometric ratio" necessary such that under normal conditions the reaction can take place and where the A_i are the reactants (pure or compounds) and the A'_i the formed products.

The sum of the coefficients of the reactants minus the sum of the coefficients of the products is the "stoichiometric sum". If this is zero, the equation is say to be a "balanced chemical reaction". In this case the reaction can be written:

$$\sum v_iA_i=0 \tag{13.3.9}$$

where the convention is that stoichiometric coefficients are positive for reactants and negative for products. The stoichiometric sum is $\sum v_i$.

✍**Example:**

Let us consider to illustrate these concepts the reaction (dinitrogen and hydrogen giving ammonia):

$$\mathrm{N_2}+3\mathrm{H_2} \rightleftharpoons 2\mathrm{NH_3} \tag{13.3.10}$$

where the Latin letters represent the pure substances (atoms) whose name does not matter to us in this textbook (notation proposed by Jöns Jacob Berzelius in 11813 according to holocene calendar). The indices simply represent the number of combination of atoms to obtain a molecule.

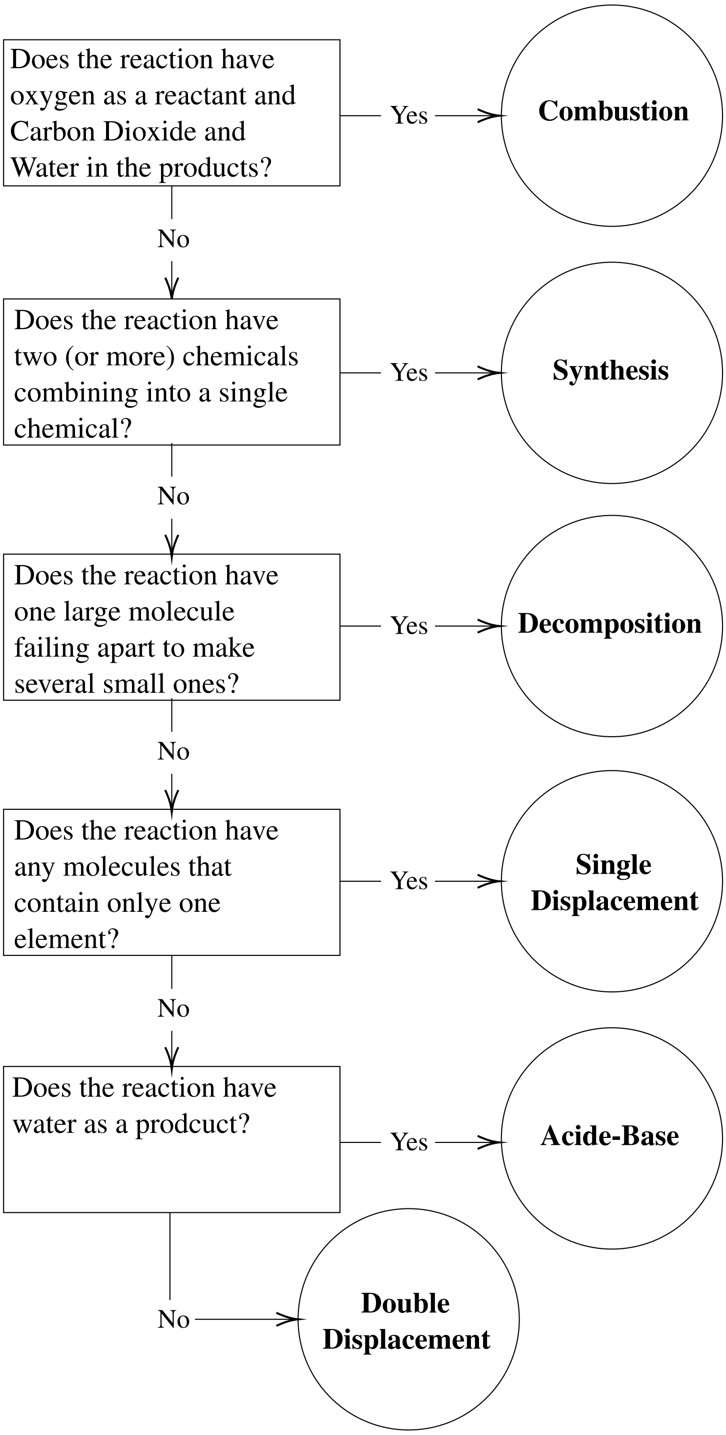
We then have in this reaction:

$$v_1=1,v_2=3,v'_1=2 \tag{13.3.11}$$

$$A_1:=\mathrm{N_2},A_2:=\mathrm{H_2},A'_1:=\mathrm{NH_3} \tag{13.3.12}$$

The reader will have noticed that we have well following our convention for the mass balance:

$$\sum_i v_iA_i=1\cdot(2\mathrm{N})+3\cdot(2\mathrm{H})-2\cdot(\mathrm{N})-2\cdot(3\mathrm{H})=0 \tag{13.3.13}$$



Does the reaction have oxygen as a reactant and Carbon Dioxide and Water in the products?
Yes
Combustion
No
Does the reaction have two (or more) chemicals combining into a single chemical?
Yes
Synthesis
No
Does the reaction have one large molecule failing apart to make several small ones?
Yes
Decomposition
No
Does the reaction have any molecules that contain onlye one element?
Yes
Single Displacement
No
Does the reaction have water as a prodcuct?
Yes
Acide-Base
No
Double Displacement

Figure 13.38: **Some typical chemical reactions**

Caution! In the writing of the above equation, we require that all the A_i without exception react to the chemical reaction and that therefore all the v_i are dependent.

If the "golden proportions" are respected (such that the coefficients are well stoichiometric) and exist when writing of the reaction equation, then for any $\alpha \in \mathbb{N}$ we have:

$$\alpha(v_1 A_1 + v_2 A_2 + \ldots) \rightleftharpoons \alpha(v_1' A_1' + v_2' A_2' + \ldots) \tag{13.3.14}$$

this proposal can be proven only if the stoichiometric coefficients on one side or the other of the reaction vary proportionally. Experience shows that in normal conditions of temperature and pressure (N.C.T.P.) this is the case!

Remark

A famous reaction that makes some scientific illiterate people scared around the World is the one that explains chemtrails (in fact it should be named "contrails", that is the abbreviation for "cond(densation)trails)" - or that also explains vapour you see going out of car's exhaust pipe:

$$\underbrace{\mathrm{C}_x\mathrm{H}_y}_{\text{Hydrocarbone}} + \mathrm{O}_2 \Rightarrow \mathrm{CO}_2 + \mathrm{H}_2\mathrm{O}$$

In other words, in thermic engines, the hydrocarbone is transformed at the exit on carbon dioxide and on condensed water... hence the name "contrails"... For Airplanes we have:

$$\underbrace{2\mathrm{C}_{12}\mathrm{H}_{26}}_{\text{Kerosen}} + \underbrace{37\mathrm{O}_2}_{\text{Oxygen}} \Rightarrow \underbrace{24\mathrm{CO}_2}_{\text{Carbon dioxide}} + \underbrace{26\mathrm{H}_2\mathrm{O}}_{\text{Water vapor}}$$

Both of the gaseous products expelled from the exhaust pipe of a jet- CO_2 and water vapor - are invisible. When the products hit the cold air, the water vapor condenses and freezes around small particles (see phase diagram at page 3910), known as nucleation sites, which are also present in the exhaust. This produces a visible cloud:

Figure 13.39: Some typical contrails

Contrails must not be confused with the evaporation of the water present in the air during a sonic boom as visible on the photo at page 8218.

Therefore, the stoichiometry of the reaction requires that if it disappears x_1 moles of A_1, x_2 moles of A_2 respectively with a variation of material of the products $\mathrm{d}n_1, \mathrm{d}n_2, \ldots$, it will appear accordingly x'_1 moles of A'_1, x'_2 moles of A'_2, ... with respectively a variation of material of the products $\mathrm{d}n'_1, \mathrm{d}n'_2, \ldots$... by respecting the proportionalities of the stoichiometric coefficients such that we can write the "material balance equation":

$$\frac{-\mathrm{d}n_1}{v_1} = \frac{-\mathrm{d}n_2}{v_2} = \ldots = \frac{-\mathrm{d}n'_1}{v'_1} = \frac{-\mathrm{d}n'_2}{v'_2} = \ldots = \mathrm{d}\xi \qquad (13.3.15)$$

where $\mathrm{d}\xi$ is named the "elementary reaction progress" (frequently we will take the absolute values of the ratios to not have to think about the sign of the variations).

The division of the variations $\mathrm{d}n_1, \mathrm{d}n_2$ and $\mathrm{d}n'_1, \mathrm{d}n'_2$ by their stoichiometric coefficients is justified only for normalization reasons having for purpose to bring $\mathrm{d}\xi$ to a value between 0 and 1 (between 0% and 100%...).

These last equalities simply indicate that if one of the reactive products disappear in a given quantity, the other reactants have their quantity that decreased in relation to their stoichiometric coefficient so as to maintain the golden proportions of the reaction.

The writing of the energy balance can be simplified by the introduction of algebraic stoichiometric coefficients v_i such that: $v_i > 0$ for a formed product, $v_i < 0$ for a reactive product.

Finally we can write:

$$\boxed{\mathrm{d}x_i = \frac{\mathrm{d}n_i}{v_i}} \tag{13.3.16}$$

we also often find in the literature with the absolute value at the numerator!

Therefore, with this algebraic convention, the reaction equation as it exists, can be written:

$$\boxed{\sum_i v_i A_i = 0} \tag{13.3.17}$$

which means that the algebraic sum of the total number of pure compounds of the reactants and products formed is always zero.

It is clear that at the initial time of the reaction we choose for the progress the value $\xi = 0$ (its maximum value being equal to unity), time at which the quantities of material are equal to $n_{i,0}$.

The integration of the differential expression of material balance obviously gives:

$$\begin{gathered}\int_{t_0}^{t} v_i \mathrm{d}\xi = \int_{t_0}^{t} \mathrm{d}n_i \Rightarrow v_i \left[\xi(t) - \underbrace{\xi(t_0)}_{=0}\right] = n_i(t) - \underbrace{n_i(t_0)}_{n_{i,0}} \\ \Rightarrow v_i\xi = n_i(t) - n_{i,0}\end{gathered} \tag{13.3.18}$$

Therefore:

$$\boxed{n_i = n_{i,0} + v_i\xi} \tag{13.3.19}$$

relation that we found in chemical progress tables (see further below), without forgetting that $v_i > 0$ for a formed product and, $v_i < 0$ for a reactive product.

This bring us to the question: What is the maximum value ξ_{max} of the progress of a reaction?

Well the answer to that question is in fact quite simple: The maximum progress value of a reaction having the stoichiometric proportions and such that it occurs when the reactants will have all disappeared is necessarily given by:

$$\xi_{\text{max}} = \left|\frac{n_i}{v_i}\right| \tag{13.3.20}$$

and named the "limiting reactant", that is to say, the reactant that disappears (has always the smallest value of molarity) first and stops the expected reaction (the other one being named the "excess reactant")! If there is no limiting reactant, that means that at the end of the reaction all reactants have been transformed: then we say that all reactants were in stoichiometric proportion.

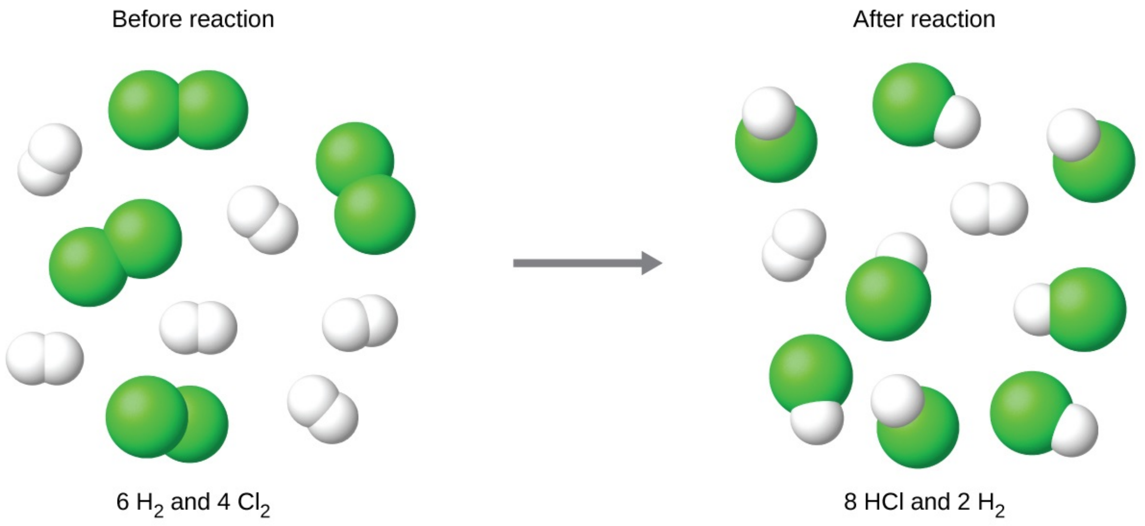


Figure 13.40: **When H_2 and Cl_2 are combined in non-stoichiometric amounts, one of these reactants will limit the amount of HCl that can be produced. This illustration shows a reaction in which hydrogen is present in excess and chlorine is the limiting reactant.**

It may be helpful to define the "percentage of completion" A_i given by the intensive quantity:

$$\tau_i=\frac{\text{quantity of } A_i \text{ having reacting}}{\text{initial quantity of } A_i} \tag{13.3.21}$$

which gives with a more formal notation:

$$\boxed{\tau_i=\frac{|v_i|\xi}{n_{i,0}}} \tag{13.3.22}$$

✍**Example:**

Let us consider to illustrate these concepts the reaction (dinitrogen and hydrogen giving ammonia):

$$N_2+3H_2 \rightleftharpoons 2NH_3 \tag{13.3.23}$$

where the Latin letters represent the pure substances (atoms) whose name does not matter to us in this textbook (notation proposed by Jöns Jacob Berzelius in 11813 according to holocene calendar). The indices simply represent the number of combination of atoms to obtain a molecule.

We then have in this reaction:

$$v_1=1,v_2=3,v'_1=2 \tag{13.3.24}$$

$$A_1:=N_2,A_2:=H_2,A'_1:=NH_3 \tag{13.3.25}$$

The reader will have noticed that we have well following our convention for the mass balance:

$$\sum_i v_i A_i = 1\cdot(2\mathrm{N}) + 3\cdot(2\mathrm{H}) - 2\cdot(\mathrm{N}) - 2\cdot(3\mathrm{H}) = 0 \qquad (13.3.26)$$

If we consider that there is one mole of each compound body, it gives us for the stoichiometric proportions (to a given factor $x \in \mathbb{R}^*$ for all values):

$$\begin{aligned} n_1 &= v_1\cdot 1 = 1\cdot 1 = 1\,[\mathrm{mol}] \\ n_2 &= v_2\cdot 1 = 3\cdot 1 = 3\,[\mathrm{mol}] \\ n_3 &= v_3\cdot 2 = 1\cdot 2 = 2\,[\mathrm{mol}] \end{aligned} \qquad (13.3.27)$$

If at any a given time $t \neq t_0$, we get by measurement:

$$n_3 = 0.2\,[\mathrm{mol}] \qquad (13.3.28)$$

What is the progress of that reaction?

The answer is:

$$\mathrm{d}\xi = \frac{\mathrm{d}n_i}{v_i} \Rightarrow \xi = \frac{\Delta n(\mathrm{NH_3})}{2} = \frac{0.2}{2} = 0.1 \qquad (13.3.29)$$

or in other words, we are at 10% of progress (logical!).

The conversion rate of $\mathrm{NH_3}$ is thereto:

$$\tau_i = \frac{|v_i|\xi}{n_{i,0}} = \frac{|-3|0.1}{3} = 0.1 \qquad (13.3.30)$$

And what is the maximum progress value $\xi_{\max}$ of the limiting reactant?

So in the context of the above example where we have $n_{1,0} = 1\,[\mathrm{mol}]$ for the $\mathrm{N_2}$ then:

$$\xi_{\max} = \left|\frac{n_i}{v_i}\right| = \left|\frac{1}{-1}\right| = 1\,[\mathrm{mol}] \qquad (13.3.31)$$

Chemists also often use what they name a "reaction progress table".

Let us take our previous example to introduce this table. We have:

	Equation	$\mathrm{N_2}$	$+3\mathrm{H_2}$	$+2\mathrm{NH_3}$
Initial State	$n_{i,0}$	1	3	0
Intermediate State	$n_i = n_{i,0} + v_i\xi$	$1-1\cdot\xi$	$3-3\cdot\xi$	$0+2\cdot\xi$
Final State	$\xi_{\max}$	$1-1\cdot\xi_{\max}$	$3-3\cdot\xi_{\max}$	$0+2\cdot\xi_{\max}$

Table 13.4: **Table progress of a chemical reaction**

Let us seek $\xi_{\max}$ from this table. The limiting reactant is either $\mathrm{N_2}$ or $3\mathrm{H_2}$.

So for N_2:

$$1-1\cdot\xi_{\max}=0\Rightarrow\xi_{\max}=\frac{n_i}{v_i}=1 \tag{13.3.32}$$

and for $3H_2$:

$$3-3\cdot\xi_{\max}=0\Rightarrow\xi_{\max}=\frac{n_i}{v_i}=1 \tag{13.3.33}$$

Each reactant having the same $\xi_{\max}$ progress, it is thus also the minimum $\xi_{\max}$. Consequently, according to the definition of limiting reactant, as the proportions are stoichiometric in the given example no reactant is limiting.

13.4. Thermochemistry

THERMOCHEMISTRY is the branch that historically focuses on thermic phenomena and to equilibrium accompanying chemical reactions. It mainly has its foundations in Thermodynamics. More technically, thermochemistry is the study of the energy and heat associated with chemical reactions and/or physical transformations. A reaction may release or absorb energy, and a phase change may do the same, such as in melting and boiling. Thermochemistry focuses on these energy changes, particularly on the system's energy exchange with its surroundings. Thermochemistry is useful in predicting reactant and product quantities throughout the course of a given reaction. In combination with entropy determinations, it is also used to predict whether a reaction is spontaneous or non-spontaneous, favourable or unfavourable.

We can only strongly recommend the readers to read before the section on Thermodynamics (see page 3597) because many concepts that have been seen there will be assumed to be known in this section.

Moreover, it is strongly recommended to read this chapter in parallel to that of Analytical Chemistry (this can be a boring but you must do with...).

13.4.1 Chemical transformations

Chemical reactions, such as those that occur when you light a match, involve changes in energy as well as matter. Societies at all levels of development could not function without the energy released by chemical reactions. In 12012 (holocene calendar), about 85% of US energy consumption came from the combustion of petroleum products, coal, wood, and garbage. We use this energy to produce electricity (38%); to transport food, raw materials, manufactured goods, and people (27%); for industrial production (21%); and to heat and power our homes and businesses (10%). While these combustion reactions help us meet our essential energy needs, they are also recognized by the majority of the scientific community as a major contributor to global climate change.

Useful forms of energy are also available from a variety of chemical reactions other than combustion. For example, the energy produced by the batteries in a cell phone, car, or flashlight results from chemical reactions. This chapter introduces many of the basic ideas necessary to explore the relationships between chemical changes and energy, with a focus on thermal energy.

Given the closed system of the following chemical reaction (see section Analytical Chemistry page 6241):

$$v_1 A_1 + v_2 A_2 + \ldots \rightleftharpoons v_1' A_1' + v_2' A_2' + \ldots \tag{13.4.1}$$

We will consider for simplicity that the chemical reaction is complete and that the reactants are used in stoichiometric amounts (state 1: Σ_1) to give the products formed, also in stoichiometric quantities (state 2: Σ_2).

If the transformation is done in (quasi-)steady volume, work on the surrounding atmosphere is zero because (see section Thermodynamics page 3641):

$$\Delta W=-\int_1^2 P\mathrm{d}V=0 \tag{13.4.2}$$

The application of the first law of thermodynamics is reduced and allows then us to write:

$$U_2-U_1=Q_V \tag{13.4.3}$$

where Q_v is within the thermal chemistry framework named "heat of reaction at constant volume", of course exchanged between the system and the external environment (we do not write the delta Δ in front of Q_V to indicate that it is a variation... by tradition...).

Let us recall that:

1. If $Q_V>0$ the reaction is said to be "endothermic" (the system receives heat from the external environment).
2. If $Q_V<0$ the reaction is said to be "exothermic" (the system gives heat to the external environment).
3. If $Q_V=0$ the reaction is said to be "athermic" (the system do not exchange any heat with the environment).

Remark

Let us also recall that a closed system is not an isolated system! For a review of different definitions, the reader is referred once again to the section of Thermodynamics (see page 3597).

If the reaction is carried out at constant pressure (the most usual case in practice), that is to say isobaric, then we have:

$$\Delta W=-\int_1^3 P\mathrm{d}V=-P(V_3-V_1) \tag{13.4.4}$$

Remark

The choice of integration indices are different to previously to differentiate the fact that a reaction a pressure or constant volume are not necessarily identical.

The application of the first law of thermodynamics, between the two states, gives:

$$U_3-U_1=Q_P-P(V_3-V_1) \tag{13.4.5}$$

where Q_p is the amount of heat, named "constant-pressure reaction heat", exchanged between the system and the external environment (Q_P is a variation... even if the traditional unfortunate notation of thermodynamician does not put that in evidence...).

Using the definition of enthalpy, we can write the last relation in the form:

$$Q_P = U_3 - U_1 + P(V_3 - V_1) = (U_3 + PV_3) - (U_1 + PV_1) = H_3 - H_1 \tag{13.4.6}$$

If we work with the molar volumes, those of condensed phases (therefore solid and liquid) is negligible compared to the gas molar volume, only the gas components have a very different enthalpy of their internal energy (see the example in the section of Thermodynamics). We would therefore have under the ideal gas approximation (see section Thermodynamics page 3643):

$$H_i = U_i + n_i RT \tag{13.4.7}$$

In the context of the ideal gas, the prior-previous relation can be written:

$$\begin{aligned} Q_P &= H_3 - H_1 = U_3 - U_1 + (n_3 - n_1)RT = U_3 - U_1 + U_2 + (n_3 - n_1)RT - U_2 \\ &= Q_V + (n_3 - n_1)RT + U_3 - U_2 \end{aligned} \tag{13.4.8}$$

But, as (see section Continuum Mechanics page 3897) U_2 and U_3 are both the same final states of a single complete reaction and that we know for a monoatomic gas we have:

$$U_i = \frac{3}{2} N_i kT \tag{13.4.9}$$

therefore the internal energy U_2 and U_3 only depends on the number of components but ... they are equal since they are the same final state of the same reaction!

Therefore we have:

$$U_2 = U_3 \Rightarrow U_3 - U_2 = 0 \tag{13.4.10}$$

By putting $\Delta n = n_2 - n_1$ (the difference between the number of moles of gas of formed products and those of reacting products), we can write for a chemical reaction:

$$\boxed{Q_P = Q_V + \Delta n RT} \tag{13.4.11}$$

that gives the possibility to differentiates the energy involved between isobaric and isochoric reaction and look for the best choice in terms of industrial objectives. It is interesting to notice that if the Δ of moles is zero. Isobaric or isochoric heat variations are equal and there is no a priori reason to prefer one or the other transformations.

Obviously in practice the problem is to know the values of the different variables of the latter relation. These values can be found on huge databases that chemists have access to... This relationship is only very rarely used in practice and in any case it is based on too simplifying and restrictive assumptions to be of real practical interest.

13.4.2 Molar Quantities

Definitions (#13.4.550):

D1. By convention, the "mole" is the quantity of substance of a system which contains as many chemical species as there are Carbon atoms in 12 [g] of Carbon 12 (see section Nuclear Physics page 5027).

The number of carbon atoms contained in 12 [g] is equal to the Avogadro's number given approximately by (notice that this number is by far bigger than the number of humans that are on Earth!):

$$N_\text{A} \cong 6.0221367 \cdot 10^{23} \tag{13.4.12}$$

This means verbatim and by construction that a mole of water, of iron, of electron, respectively always contains a number of atoms equal to the Avogadro's number.

Most of time the mole is simply denoted n and has its value in $\mathbb{R}^+$.

Notice that with a mixed system it is a mathematical nonsense to do the sum of the molar masses of the constituents for the total molar mass. The molar mass is an intensive quantity!

Remarks

R1. Hydrogen-1 was once used as a standard but given the inaccuracy that can occur because of its low mass, it was later disregarded. Once mass spectrometry was made available, physicists were using Carbon-12 for it's stability and abundance, and basically to stop everybody from fighting. Carbon-12 also more accurately defines a mass for hydrogen, and it is unbound in it's ground state and also is the most common and readily available isotope to have exactly the same number of protons and neutrons, 6 of each, and thus provides a perfect average when divided by the total number of protons and neutrons (electron is so small as to be considered negligible).

R2. The "Avogadro project" aims to redefine Avogadro's constant (currently defined by the kilogram: the number of atoms in 12 [g] of Carbon-12) and reverse the relationship so that the kilogram is precisely specified by Avogadro's constant. This method required creating the most perfect sphere on Earth. It is made out of a single crystal of silicon-28 atoms. By carefully measuring the diameter, the volume can be precisely specified. Since the atom spacing of silicon is well known, the number of atoms in a sphere can be accurately calculated. This allows for a very precise determination of Avogadro's constant.

D2. The "molar mass (MM)" is the mass of one mole of atoms of the chemical elements involved. Therefore by definition the molar mass of C_{12} is equal to 12 grams (yes historically we use the gram to express molar mass because for application purposes is obviously more convenient...

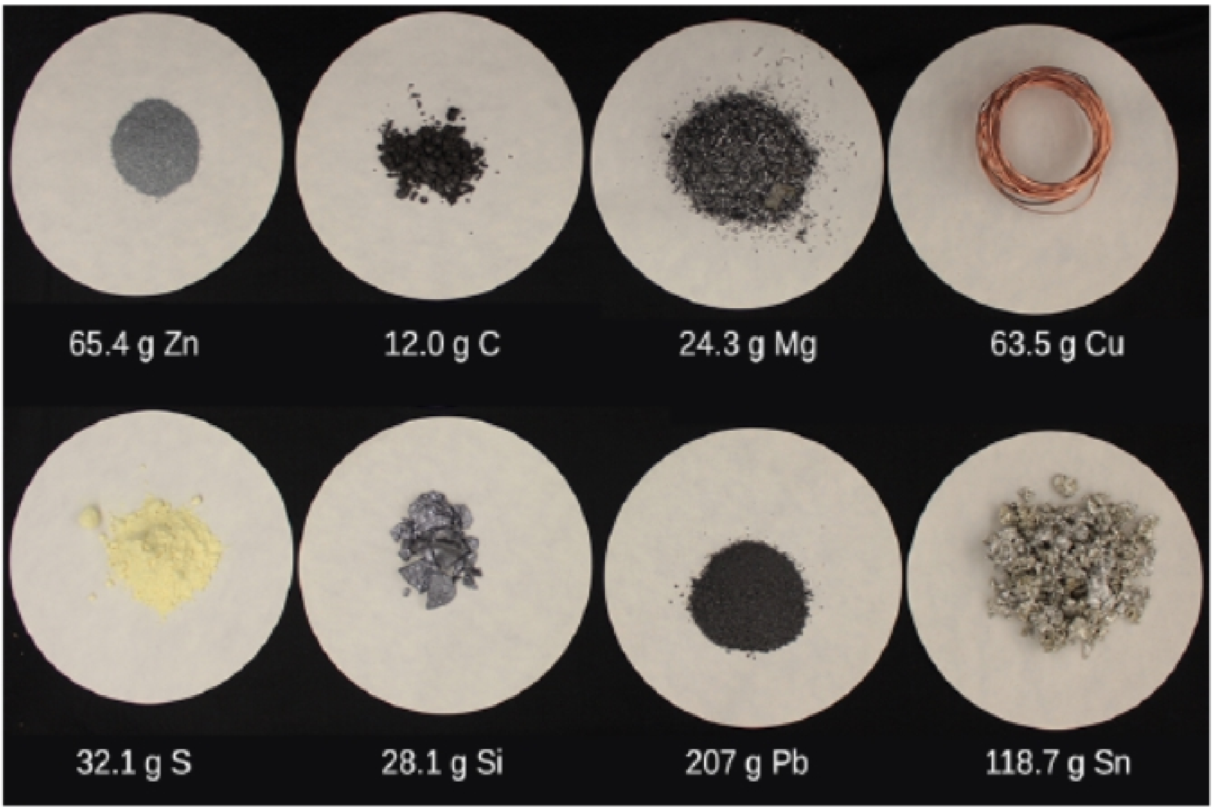

Figure 13.41: Each sample contains one mole of atoms. From left to right (top row): 65.4 [g] zinc, 12.0 [g] carbon, 24.3 [g] magnesium, and 63.5 [g] copper. From left to right (bottom row): 32.1 [g] sulphur, 28.1 [g] silicon, 207 [g] lead, and 118.7 [g] tin (source: Mark Ott)

> Remark
>
> We find these atomic molar masses in the periodic classification. But above all it must be known that those that are indicated take into account the natural isotopes (which is normal since they are chemically indistinguishable excepted for the nuclear chemist or nuclear physicist). So the value indicated in the tables is calculated as the sum of the respective proportions of the molar masses of the different corresponding isotopes (the validity of this method of calculation is obviously relative...).

D3. The "atomic molar mass" is the molar mass of a given element divided by the Avogadro number. Thus:

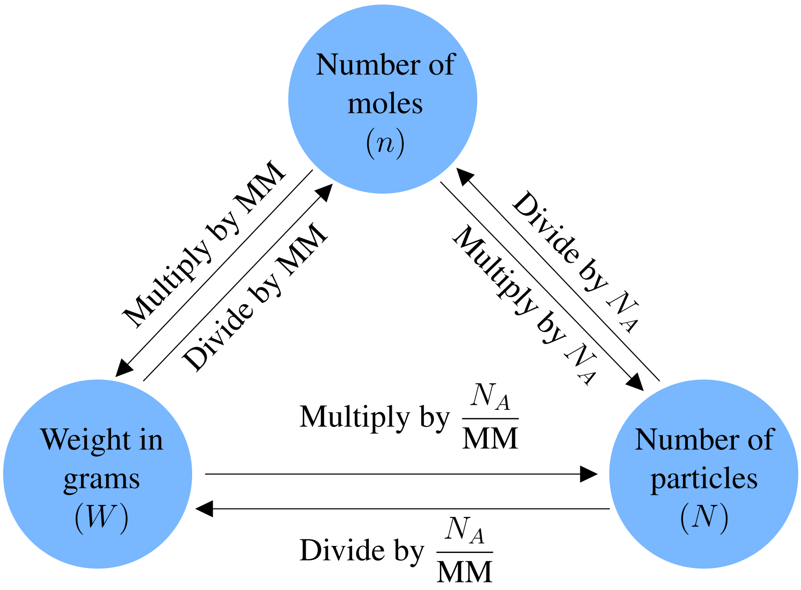
$$1\,[\text{amu}] = \frac{1}{N_\text{A}} \cong 1.6605392 \cdot 10^{-24}\,[\text{kg}] \tag{13.4.13}$$

Therefore the atomic (molar) mass is the mass of 1 atom of a particular element and the molar mass is the mass of 1 mole of an atom or molecule[7].

We therefore have the following graph:

---

[7] The number of molecules in a single droplet of water is roughly 100 billion times greater than the number of people on Earth.



Number of moles (n)
Multiply by MM
Divide by MM
Divide by N_A
Multiply by N_A
Weight in grams (W)
Number of particles (N)
Multiply by $\frac{N_A}{\text{MM}}$
Divide by $\frac{N_A}{\text{MM}}$

D4. The "molecular molar mass (MMM)" is equal to the sum of the atomic molars masses of the chemical elements that constitutes it.

It comes therefore immediately the following observation: the mass m of a sample consisting of an amount of n moles of identical chemical species of molar mass M_m is given by the relation:

$$\boxed{m = nM_m} \tag{13.4.14}$$

Somewhat in a little bit more formal way and in a thermodynamic aspect, here is also is how we can define the molar mass:

Let X be an extensive quantity on a single-phase system (see the section of Thermodynamics for precisions about the vocabulary used) and given a volume element $\mathrm{d}V$ of this system around a common point M and containing the amount of material $\mathrm{d}n$. We associate it the extensive quantity $\mathrm{d}X$ proportional to $\mathrm{d}n$ such that:

$$\mathrm{d}X = X_m \mathrm{d}n \Leftrightarrow X_m = \frac{\mathrm{d}X}{\mathrm{d}n} \tag{13.4.15}$$

so that X_m is an intensive quantity (ratio of two extensive quantities according to what was seen in the section of Thermodynamics) which we will name by definition the "associated molar size" to X.

We conclude that:

$$X = \int X_m \mathrm{d}n \tag{13.4.16}$$

the integral applying on the whole monophasic system.

In the case of a uniform phase, X_m being constant at any point, we can simply write the latter as:

$$X = nX_m \tag{13.4.17}$$

Remark

Basically the idea is to say that the mass of a single-phase chemical system is proportional to the molar mass of it to closely to a given integer factor representing the number of its constituents (or the number of moles to be more exact).

D5. When the system is heterogeneous, we use the concept of "mole fraction", defined by:

$$\boxed{x_i = \frac{n_i}{n}} \tag{13.4.18}$$

x_i being the mole fraction of a species A_i whose the quantity of material (the number of moles for example) is n_i with $n = \sum_i n_i$ being the total quantity of matter of the studied phase.

As a result, for all chemical species of the studied phase, $\sum_i x_i = 1$ which means that if there are n chemical species, it is enough to know $n-1$ molar titles to know them all.

If the studied phase is a gas and assuming a perfect gas according to Boyle's law (approximation of the Van der Waals equation proved in the section of Statistical Mechanics at page 3907)(see page 3907) we have:

$$P_iV = n_iRT \qquad \text{and} \qquad PV = nRT \tag{13.4.19}$$

we therefore have the possibility in the case of gaseous phases to express the mole fraction as:

$$\boxed{x_i = \frac{n_i}{n}\frac{nRT}{nRT} = \frac{P_iV}{PV} = \frac{P_i}{P}} \tag{13.4.20}$$

Remark

We can do obviously the same for the volume V.

D6. We define the "mass content associated with the species A_i" by the ration:

$$\boxed{w_i = \frac{m_i}{m}} \tag{13.4.21}$$

with $m = \sum_i m_i$ being the total mass of the studied phase. We also have of course $\sum_i w_i = 1$.

D7. We define the "volumic molar concentration" or "molarity" the ratio (do not confuse the notation with the specific heat):

$$\boxed{c_i = \frac{n_i}{V}} \tag{13.4.22}$$

Remark

There are other composition variables used much less used than x_i or c_i. We can cite the "mass concentration density" m_i/V, the "molality" (ratio of the amount of material of the species A_i by the total mass of solvent), etc.

D8. We say that a (perfect) gas is in the "standard state" if its pressure is equal to the standard pressure:

$$\boxed{P^\circ = 1\ [\text{bar}] = 10^5\ [\text{Pa}] \cong 1\ [\text{atm}]} \tag{13.4.23}$$

D9. We name "standard molar quantity" of a constituent X_m° the value of the molar quantity of this same component taken in the standard state, that is to say under the pressure P°.

Remarks

R1. Any standard molar quantity is obviously intensive: the pressure being set by the standard state , it depends only on the temperature.

R2. Any standard quantity is denoted with the superscript "°". V_m° is then standard molar volume. For cons, the standard molar quantity is not always specified with the small index m, we must sometimes be careful with what is handled in the equations (as always anyway!).

In the case of the ideal gas, the molar volume is calculated using the ideal gas equation of state. Then we get:

$$\boxed{V_m^\circ = \frac{RT}{P^\circ}} \tag{13.4.24}$$

We see of course that the standard molar volume of an ideal gas depends on the temperature.

If we do that calculation at the "standard conditions of temperature and pressure" (abbreviated STP), that is to say at a temperature of 273.15 [K] (i.e. 0 [°C]) and a pressure of 1 [atm] (i.e. $101,325$ [kPa]), then we find a volume of 22.4 [L·mol^{-1}] which is a well known value by chemists.

Remarks

R1. In a wide range of temperatures and pressures, the molar volume of real gases is generally not very different from that of an ideal gas.

R2. In the case of a condensed state, we do not have in general a state equation but we can measure the molar volume..

We can define then by extension other standard quantities resulting from those we had defined in the section Thermodynamics:

1. The "standard molar internal energy" (intensive quantity as expressed by molar unit) and denoted by U_m°.

2. The "standard molar enthalpy" (intensive quantity as expressed by molar unit) with:

$$H_m^\circ = U_m^\circ + P^\circ V_m^\circ = U_m^\circ + RT \tag{13.4.25}$$

It is important that the reader notice that the enthalpy depends only on the temperature (and the internal energy).

Enthalpies of combustion for many substances have been measured. A few of these are listed in the table below. Many readily available substances with large enthalpies of combustion are used as fuels, including hydrogen, carbon (as coal or charcoal), and hydrocarbons (compounds containing only hydrogen and carbon), such as methane, propane, and the major components of gasoline.

Substance	**Combustion Reaction**	**Combustion Molar Enthalpy $\Delta H^\circ_{c,m}$ in [kJ $\cdot$ mole^{-1}] at 25°**
carbon	$C(s) + O_2(g) \rightarrow CO_2(g)$	-393.5
hydrogen	$H_2(g) + \frac{1}{2}O_2(g) \rightarrow H_2O(l)$	-285.8
magnesium	$Mg(s) + \frac{1}{2}O_2(g) \rightarrow MgO(s)$	-601.6
sulphur	$S(s) + O_2(g) \rightarrow SO_2(g)$	-296.8
carbon monoxide	$CO(g) + \frac{1}{2}O_2(g) \rightarrow CO_2(g)$	-283.0
methane	$CH_4(g) + 2O_2(g) \rightarrow CO_2(g) + 2H_2Ol$	-890.8
acetylene	$C_2H_2(g) + \frac{5}{2}O_2(g) \rightarrow 2CO_2(g) + H_2O(l)$	-1301.1
ethanol	$C_2H_5OH(l) + 3O_2(g) \rightarrow 2CO_2(g) + 3H_2O(l)$	-1366.8
methanol	$CH_3OH(l) + \frac{3}{2}O_2(g) \rightarrow CO_2(g) + 2H_2O(l)$	-726.1
isooctane	$C_8H_{18}(l) + \frac{25}{2}O_2(g) \rightarrow 8CO_2(g) + 9H_2O(l)$	-5461

Table 13.5: **Different molar enthalpy of combustion (source: OpenStax)**

Remark

For condensed states the standard volume is very low in S.I. units so that $H_m^\circ \cong U_m^\circ$. However, it is very difficult to speak of pressure for so condensed states so this approximation has to be used with caution.

If we now consider an extensive function X (as for example the volume!) defined on a chemical gaseous evolving system. We can a priori express X based on two intensive variables T, P (because an extensive function is always a product or ratio of two intensive quantities, or a sum of extensive quantities) and of the different quantity of materials n_i, n_i' of A_i, A_i' such that:

$$X = X(T, P, \ldots, n_i, \ldots) \tag{13.4.26}$$

If all products (reagents and resulting one) are in their standard state, the extensive function, therefore denoted X°, gets the form:

$$X^\circ = X(T, \ldots, n_i, \ldots) \tag{13.4.27}$$

where the pressure is no longer involved as attached to its standard value. The gas is then described by its temperature and the quantity of its constituents!

However, if we consider an infinitesimal evolution of the system at constant temperature and pressure (because we assume a very slow transformation) the different quantities of materials vary therefore following the exact total differential (see section of Differential Calculus and Integral page 1466):

$$\mathrm{d}X_T^\circ=\sum_i \frac{\partial X^\circ}{\partial n_i}\mathrm{d}n_i \tag{13.4.28}$$

where obviously are taken into account, as T and P are supposed constant, only the quantity of materials that could vary (yes don't forget we are doing chemistry!!!).

We can then define artificially (nothing prevents us to do so, it's not false!) the intensive standard molar quantity that depends only on the temperature:

$$X_i^\circ=\frac{\partial X^\circ}{\partial n_i} \tag{13.4.29}$$

Therefore:

$$\mathrm{d}X_T^\circ=\sum_i X_i^\circ \mathrm{d}n_i \tag{13.4.30}$$

but we have also defined in the section Analytical Chemistry the material balance equation (see page 6244):

$$\mathrm{d}n=v\mathrm{d}\xi \tag{13.4.31}$$

expressing, for recall, the variation in the quantity of matter of one of the compounds of a chemical reaction relatively to its stoichiometric ratio (constant) and the progress of the reaction. We therefore have:

$$\mathrm{d}X_T^\circ=\left(\sum_i X_i^\circ v_i\right)\mathrm{d}\xi \tag{13.4.32}$$

and also that:

$$\begin{aligned}\mathrm{d}X_T^\circ&=\sum_i \frac{\partial X^\circ}{\partial n_i}\mathrm{d}n_i=\sum_i \frac{\partial X^\circ}{v_i\partial \xi}v_i\mathrm{d}\xi=\left(\sum_i \frac{\partial X^\circ}{\partial \xi}\right)\mathrm{d}\xi=\left(X_i^\circ v_i\right)\mathrm{d}\xi\\ \Rightarrow \frac{\mathrm{d}X_T^\circ}{\mathrm{d}\xi}&=\sum X_i^\circ v_i=\sum_i \frac{\partial X^\circ}{\partial \xi}\end{aligned} \tag{13.4.33}$$

By definition, we name this algebraic sum "standard quantity reaction associated with the extensive function X" and denote it by (notation badly chosen by chemists in our point of view...):

$$\Delta_r X^\circ=\sum_i X_i^\circ v_i \tag{13.4.34}$$

which is an intensive quantity that depends only on the temperature and represents a relative change (hence the subscript r!). This relation can also be written:

$$\boxed{\Delta_r X^\circ=\sum_i X_i^\circ v_i=\sum_i \frac{\partial X^\circ}{\partial \xi}=\frac{\mathrm{d}X_T^\circ}{\mathrm{d}\xi}} \tag{13.4.35}$$

In general, chemists name "Lewis operator", denoted Δ_r, the derivative of a quantity X (standardized or not), with respect to the progress of the reaction ξ with constant temperature and pressure.

Remark

The symbol Δ_r appears with the letter r in subscript to show that this is a relative reaction quantity. In other words, it is the standard variation of the molecular quantity during the concerned reaction for a given reaction progress of one mole at a pressure of 1 bar for a perfect gas.

We must also not forget that the stoichiometric coefficients of the reactants are positive and those of the resulting products are negative (see section of Analytical Chemistry page 6242).

There are two reaction quantities that play important roles in chemistry:

1. The internal molar energy of reaction, named often "internal energy of standard reaction" of a chemical system:

$$\boxed{\Delta_r U^\circ = \sum_i U_i^\circ v_i = \frac{\mathrm{d}U_T^\circ}{\mathrm{d}\xi}} \tag{13.4.36}$$

2. The molar enthalpy of reaction, often named more "standard enthalpy of reaction" of a chemical system:

$$\boxed{\Delta_r H^\circ = \sum_i H_i^\circ v_i = \frac{\mathrm{d}H_T^\circ}{\mathrm{d}\xi}} \tag{13.4.37}$$

13.4.2.1 Standard enthalpy of reaction

Therefore we can consider the following two cases after knowing the relation (see section Thermodynamics page 3643):

$$H_i^\circ = U_i^\circ + V_i^\circ P^\circ \tag{13.4.38}$$

1. If the A_i are in a condensed state, since the internal pressure does not apply we have:

   $$H_i^\circ \cong U_i^\circ \tag{13.4.39}$$

   which still remains to be taken with precaution following the scenarios!

2. If the A_i are in the gaseous state (assumed perfect gas):

   $$H_i^\circ \cong U_i^\circ + RT \tag{13.4.40}$$

We conclude that only gas will intervene in this relation:

$$\Delta_r H^\circ = \sum_i H_i^\circ v_i = \sum_i (U_i^\circ + RT) = \Delta_r U^\circ + \sum_i v_i RT \tag{13.4.41}$$

That we write conventionally:

$$\boxed{\Delta_r H^\circ = \Delta_r U^\circ + \Delta_r v_g RT} \qquad (13.4.42)$$

It follows that in the special case where:

$$\Delta_r v_g = 0 \qquad (13.4.43)$$

(which is in fact an unfortunate notation... for the algebraic sum of the stoichiometric ratio that would equal to zero) for a given temperature then we have:

$$\Delta_r H^\circ = \Delta_r U^\circ \qquad (13.4.44)$$

where it must be remembered that the stoichiometric coefficients of the products are counted as positive, while those of the reactants are counted as negative (see section Analytical Chemistry page 6242).

Thus, the variation of the enthalpy function corresponds to the variation of the quantity of heat absorbed or emitted in an isobaric transformation at a given temperature T. This is why it is sometimes denoted $\Delta_r H_{T,P^\circ}$.

A chemical reaction that has an enthalpy reaction (which is for recall the instantaneous change in enthalpy during a reaction) that is negative is said to be "exothermic", since it releases heat into the environment (constant pressure obliged by the definition of enthalpy reaction!), then a chemical reaction whose reaction enthalpy is positive is say to be "endothermic" since it then requires a supply of heat to occur (so the vocabulary is the same as in the section of Thermodynamics).

Thus, according to the preceding developments, if we denote with an index p the products and with an index i the reactants, we often find the standard enthalpy of reaction as follows if the stoichiometric coefficients are counted as positive:

$$\boxed{\Delta_r H_{T,P^\circ} = \sum_p v_p H_p^\circ - \sum_p v_r H_r^\circ} \qquad (13.4.45)$$

Into this form, then we see well that the standard reaction enthalpy corresponds to the difference partial molar enthalpies between the products and reactants of the transformation. This is nothing more than the "Hess's law" set in the 119th century (holocene calendar) by the Swiss chemist Henri Hess. This law states that the total enthalpy change during the complete course of a chemical reaction is the same whether the reaction is made in one step or in several steps and can be understood as an expression of the principle of conservation of energy, also expressed in the first law of thermodynamics, and the fact that the enthalpy of a chemical process is independent of the path taken from the initial to the final state (i.e. enthalpy is a state function).

Because in a system at equilibrium, the initial energy is always greater than or equal to the final energy (all systems tend to move towards to a more stable state with minimum energy as we have study it in the section of Thermodynamics), then the standard enthalpy of reaction $\Delta_r H^\circ$ may be only negative or zero.

If a chemical reaction at constant pressure and at a specific temperature gives only a single chemical compound (product) then the standard enthalpy of reaction is named "standard enthalpy of formation" and is denoted by $\Delta_f H^\circ$.

In fact, the interest of prior-previous relation is that the chemist can simply, without having to know the quantities of material involved, determine just by knowing the stoichiometric coefficients of an isobaric gas or condensed chemical reaction (if he agrees that it will then be an approximation for the latter case) that the instantaneous variation of the molar internal energy during the progress of the reaction at a given temperature is equal to the instantaneous variation of the molar enthalpy .

Two different situations arise then:

1. The difference between the instantaneous variation of the molar internal energy and the molar enthalpy is zero: therefore, the chemical reaction (at a given temperature) does not instantaneously occupies a larger volume and thus don't loss energy to push ("unnecessarily") the pressure of the gas surrounding the studied reaction (this can be seen as a money saving in terms of energy in the chemical industry). In this case, the standard enthalpy of reaction is simply equal to the heat of reaction at constant pressure Q_p.
2. The difference between the instantaneous variation of the molar internal energy and the molar enthalpy is positive: Therefore, the chemical reaction (at the given temperature) instantly occupies a greater volume and thus loses some energy to push ("unnecessarily") the pressure of the gas surrounding the studied reaction (this can be seen as a waste of money in terms of energy efficiency in the chemical industry).

Remark

Obviously, it is possible to imagine a company that takes advantage of the change in volume of a reaction (case 2 above) that pushes the surrounding gas with a piston system to then produce mechanical energy... so it would be possible in certain situations to lose much less money (verbatim energy ...).

However a small difficulty arise, ... the standard enthalpy of a simple pure body (body formed of a single type of atom) can not be calculated in absolute terms because it depends on the internal energy which is very difficult to calculate (you must use the tools of quantum physics which raise insurmountable problems even in the beginning of the 121st century according to holocene calendar). This means we must define an arbitrary scale of molar enthalpies by setting an arbitrary zero enthalpy and adopted internationally (which is unfortunately not the case as far as we know!).

Thus, in order to set up tables of standard molars enthalpy, he was chosen to define the scale of enthalpy as follows: the standard molar enthalpy of a simple steady pure body in the standard state is equal to 0 at 298 [K]. It follows that the enthalpy of formation of a simple standard pure body is always equal to zero.

✍**Example:**

Given the reaction:

$$\mathrm{PCl_5} \rightleftharpoons \mathrm{PCl_3} + \mathrm{Cl_2} \tag{13.4.46}$$

That is to say, the dissociation of chlorine and phosphorus pentachloride in phosphorus trichloride. The tables give us at the temperature of $T = 1000$ [K] the following value of the standard molar enthalpy of this reaction:

$$\Delta_r H_m^\circ = 156 \, [\text{kJ} \cdot \text{mol}^{-1}] \tag{13.4.47}$$

The variation of the value of the molar enthalpy of reaction being positive, it follows that the reaction is endothermic (requires a heat input hence the dissociation temperature of 1000 [K]) and therefore the product is more volatile than the initial reactant.

We have the following algebraic sum of the stoichiometric coefficients of the reaction:

$$1 \cdot \text{PCl}_5 \rightleftharpoons 1 \cdot \text{PCl}_3 + 1 \cdot \text{Cl}_2 \tag{13.4.48}$$

That is (which is dimensionless since enthalpy is in molar value!):

$$\Delta_r v_g = -1 + 1 + 1 = 1 \tag{13.4.49}$$

therefore the reaction increase the pressure by creating an additional mole per mole of reactant.

Since:

$$\Delta_r H_m^\circ = \Delta_r U_m^\circ + \Delta_r v RT = \Delta_r U^\circ + 1 \cdot RT \tag{13.4.50}$$

then it comes:

$$\Delta_r U^\circ = 148 \, [\text{kJ} \cdot \text{mol}^{-1}] \tag{13.4.51}$$

This is then the part of internal energy absorbed by the system on the $156 \, [\text{kJ} \cdot \text{mol}^{-1}]$. The remainder (difference) is has just been used to push the surrounding atmosphere of the chemical reactor.

13.4.2.1.1 Kirchhoff's Enthalpy Law

Kirchhoff's Enthalpy Law describes the enthalpy of a reaction's variation with temperature changes. In general, enthalpy of any substance increases with temperature, which means both the products and the reactants' enthalpies increase. The overall enthalpy of the reaction will change if the increase in the enthalpy of products and reactants is different.

In other words, in a more practical way, the latent heat - energy required to evaporate a liquid - is not the same at every temperature! The difference between the Gas and Liquid energy levels increases at higher temperatures. Thus, the Kirchhoff's Enthalpy law enables the calculation of a new latent heat from an existing one with a known temperature change.

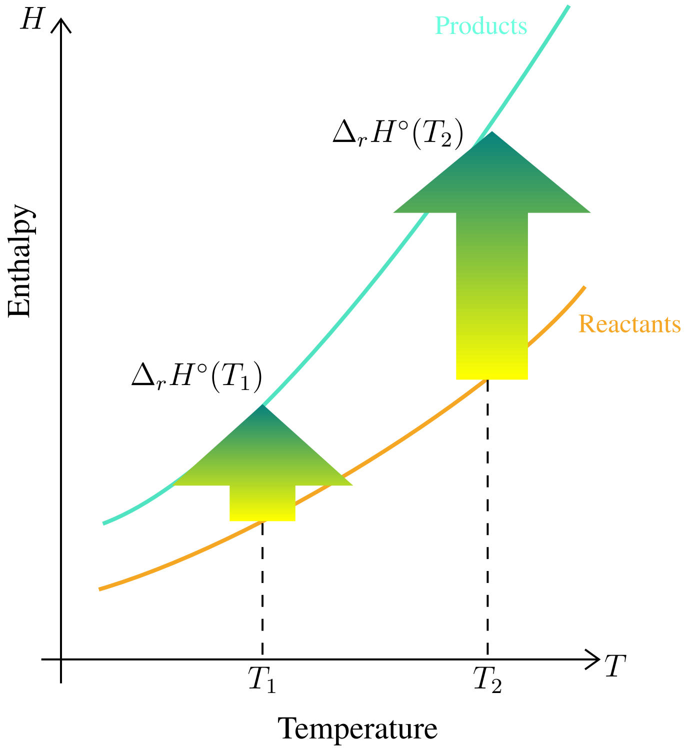


Figure 13.42: **Kirchhoff's enthalpy law illustration**

So the Kirchhoff enthalpy law idea is to express the variations of the enthalpy of reaction (molar or not) in function of the temperature from the knowledge of the heat capacity at constant pressure of the gaseous reactants.

He have built in previous developments the following relation:

$$\Delta_r H^\circ = \sum_i H_i^\circ v_i = \frac{\mathrm{d}H_T^\circ}{\mathrm{d}\xi} \tag{13.4.52}$$

which is the standard enthalpy of reaction at a given temperature in a system with a standard pressure.

We had also mentioned earlier above that Δ_r, for recall, is somewhat an unfortunate notation for the differential (Lewis) operator of progress of the reaction $\mathrm{d}/\mathrm{d}\xi$.

If we focus on the influence of the temperature T on $\Delta_r H^\circ$ we have just to write the exact differential:

$$\frac{\Delta_r H^\circ}{\mathrm{d}T} = \frac{\mathrm{d}}{\mathrm{d}T}\left(\sum_i H_i^\circ v_i\right) \tag{13.4.53}$$

since the algebraic variation of the standard enthalpy by definition depends only on the temperature.

The stoichiometric coefficients v_i are not dependent of the temperature at least until this latter does not changes the essence itself of the studied transformation.

We then have under this approximation (assumption):

$$\frac{\Delta_r H^\circ}{\mathrm{d}T}=\frac{\mathrm{d}}{\mathrm{d}T}\left(\sum_i H_i^\circ v_i\right)=\sum_i v_i\frac{\mathrm{d}H_i^\circ}{\mathrm{d}T} \tag{13.4.54}$$

Now we have defined in the section of Thermodynamics (see page 3622) the heat capacity at constant pressure which is written:

$$C_P=\left(\frac{\partial Q}{\partial T}\right)_P=\frac{\partial H}{\partial T} \tag{13.4.55}$$

So if the conditions are standard (the enthalpy therefore depends only on the temperature), we get is the exact differential:

$$C_{P,i}^\circ=\frac{\mathrm{d}H_i^\circ}{\mathrm{d}T} \tag{13.4.56}$$

Then we have:

$$\frac{\mathrm{d}\left(\Delta_r H^\circ\right)}{\mathrm{d}T}=\sum_i v_i\frac{\mathrm{d}H_i^\circ}{\mathrm{d}T}=\sum_i v_i C_{P,i}^\circ=\Delta_r C_P^\circ \tag{13.4.57}$$

We can of course integrate the latter relations to get the common form use in practice and available in many books:

$$\int_{T_0}^{T}\mathrm{d}\left(\Delta_r H^\circ\right)=\int_{T_0}^{T}\Delta_r C_P^\circ \mathrm{d}T \tag{13.4.58}$$

Then we have:

$$\boxed{\Delta_r H^\circ(T)=\Delta_r H^\circ(T_0)+\int_{T_0}^{T}\Delta_r C_P^\circ \mathrm{d}T} \tag{13.4.59}$$

where T_0 is a particular temperature for which $\Delta H^\circ(T_0)$ is known.

In a temperature range very close to T_0 chemists sometimes approximate the variation as being linear. That is equivalent to put:

$$\Delta_r C_P^\circ \cong \alpha \tag{13.4.60}$$

It then immediately comes from the prior-previous relation:

$$\Delta_r H^\circ(T)=\Delta_r H^\circ(T_0)+\alpha\int_{T_0}^{T}\mathrm{d}T=\Delta_r H^\circ(T_0)+\alpha(T-T_0) \tag{13.4.61}$$

Remark

Quite often, the variation of the enthalpy of reaction with temperature is negligible!

✍**Example:**

For the reaction (graphite + oxygen yielding to carbon dioxide) we would like to know $\Delta_r H^\circ$ at 1000 [K]:

$$\mathrm{C}+\mathrm{O}_2 \rightarrow \mathrm{CO}_2 \qquad (13.4.62)$$

For this, it is given in the tables for this reaction at 298 [K]:

$$\Delta_r H_m^\circ(298) = -393.5\,[\mathrm{kJ}\cdot\mathrm{mol}^{-1}] \qquad (13.4.63)$$

and:

$$c_{P,\mathrm{C}}^\circ = 8.5\,[\mathrm{J}\cdot\mathrm{K}^{-1}\cdot\mathrm{mol}^{-1}] \quad c_{P,\mathrm{O}_2}^\circ = 29.4\,[\mathrm{J}\cdot\mathrm{K}^{-1}\cdot\mathrm{mol}^{-1}] \quad c_{P,\mathrm{CO}_2}^\circ = 37.1\,[\mathrm{J}\cdot\mathrm{K}^{-1}\cdot\mathrm{mol}^{-1}] \qquad (13.4.64)$$

We write in lowercase the heat capacities above as there are enough subscripts to not add a third one (m) that mean these are molar heat capacities.

Remark

When the enthalpy of reaction is given at the reference temperature (nowadays...) at 298 [K] chemists then speak as we have already mention earlier above the "standard enthalpy of formation".

The value of the molar enthalpy of reaction being negative, it follows that the reaction is exothermic (it is tendency of nature to favour exothermic reactions to stabilize systems in their minimal energy states).

We then have immediately:

$$\begin{aligned}\Delta_r H_m^\circ(T) &= \Delta_r H_m^\circ(T_0) + \int_{T_0}^{T} \Delta_r c^\circ \mathrm{d}T = \Delta_r H_m^\circ(T_0) + \int_{T_0}^{T} \left(c_{P,\mathrm{C}}^\circ - c_{P,\mathrm{O}_2}^\circ - c_{P,\mathrm{CO}_2}^\circ\right)\mathrm{d}T \\ &\cong \Delta_r H_m^\circ(T_0) + \left(c_{P,\mathrm{C}}^\circ - c_{P,\mathrm{O}_2}^\circ - c_{P,\mathrm{CO}_2}^\circ\right)\int_{T_0}^{T}\mathrm{d}T \\ &= \Delta_r H_m^\circ(T_0) + \left(c_{P,\mathrm{C}}^\circ - c_{P,\mathrm{O}_2}^\circ - c_{P,\mathrm{CO}_2}^\circ\right)(T-T_0) \\ &= -393,500 + (37.1-8.5-29.4)(1,000-298) = -394,060\,[\mathrm{J}\cdot\mathrm{mol}^{-1}]\end{aligned} \qquad (13.4.65)$$

Thus the variation is of $-560\,[\mathrm{kJ}\cdot\mathrm{mol}^{-1}]$, that is a variation of about $+0.1\%$. It follows that the higher the temperature increase, more is the reaction exothermic. In fact, the choice of this particular temperature of $1,000$ [K] is not innocent because it is from this temperature that experiments shows that the reaction also produces carbon monoxide.

We can also conclude that some exothermic reactions and having a enthalpy of reaction that decreases rapidly with temperature can blow up!

Finally, let us indicate that in practice we often use the term "calorific power" or "heat of combustion", which is simply the enthalpy of reaction per unit mass of fuel or the energy obtained by the combustion a kilogram of fuel.

Thus, for Gasoline, we have following what give tables (under the assumption that this number is correct):

$$\Delta_r H^\circ(298) = -47.3\,[\text{MJ}\cdot\text{kg}^{-1}] \tag{13.4.66}$$

And we can have fun by calculating the amount of Gasoline needed to accelerate a car of 1000 [kg] from 0 to 100 $[\text{km}\cdot\text{h}^{-1}]$ with a yield of $\eta = 35\%$ at a temperature of 293 [K]. Thus we have:

$$M = \frac{E_c}{\Delta_r H^\circ(T)\eta} = \frac{\dfrac{1}{2}mv^2}{\Delta_r H^\circ(298)\eta} \cong \frac{392\cdot 10^3}{47.3\cdot 10^6\cdot 35\%} \cong 23.67\,[\text{g}] \tag{13.4.67}$$

and to get the amount of fuel in litres the tables give us the for Gasoline density about 700 $[\text{kg}\cdot\text{m}^{-3}]$ which gives finally a volume in litres of:

$$V \cong \frac{0.00828}{700}\cdot 1000 = 0.033\,[\text{L}] \tag{13.4.68}$$

14.1. Numerical Methods/Analysis

THE numerical analysis is a mathematical discipline. It is interested in both theoretical foundations as the implementation methods to resolve by purely numerical calculations and empirical approach, mathematical analysis problems.

Definition (#14.1.551): "Numerical Methods/Analysis" is the study of algorithms or empirical scientific methods for solving or analysing mathematical continuous or discrete problems. This means that it mainly deals to respond numerically to real or complex variables questions like numerical linear algebra over the real or complex fields, looking for numerical solutions of differential equations and other problems occurring in the physical sciences or financial/statistical engineering.

Some continuous mathematical problems can be solved exactly by an algorithm. These algorithms are then named "direct methods". Examples are the elimination of Gauss-Jordan for solving a system of linear equations or the simplex algorithm of linear programming (see further below). However, for some problems no direct method are known (and is even proved that for a class of problems known as "NP complete" - see further below - there is no direct calculation with finished algorithm in a polynomial time). In such cases, it is sometimes possible to use an iterative method to attempt to determine an approximation of the solution. Such a method starts from a guessed value or roughly estimated one and finds successive approximations that should converge to the solution under certain conditions. Even when a direct method exists, however, an iterative method may be preferable because it is often more effective and often more stable (in particular it allows most often to correct minor errors in intermediate calculations).

The use of numerical analysis has been greatly facilitated by modern computers. The Increasing availability and power of computers since the second half of the 120th century (holocene calendar) allowed the application of numerical methods in many scientific, technical and economic, often with revolutionary, accurate and significant effects.

What is the meaning of life?
I don't know. The computers are down.

In numerical simulations of physical systems (multi-physics), the initial conditions are very important in solving differential equations (see the various sections of this textbook where chaotic effects appears). The fact that we can not know them exactly implies that the results of calculations can never be perfectly accurate (we know this fact very well for the weather forecasting which is the most glaring example known). This effect is a consequence of the results of fundamental physics (based on pure mathematics) which demonstrates that we can not perfectly know a system by performing measurements since it directly disrupts it (Heisenberg uncertainty principle as see in the section of Quantum Wave Theory) and these disturbances are the subject of Chaos Theory (classical or quantum).

With new computer tools available in the early 121st century (holocene calendar), it became practical and exciting to know the numerical methods to have fun with some softwares or programming languages (OpenGL, 3D Studio Max, Blender, Maple™, MATLAB®, Mathematica®, COMSOL Multiphysics®, R, C++, Python™, etc.) to simulate 2D or 3D physical systems graphically.

Remarks

R1. Many numerical methods used in computer science are based on arguments which we have already been studied in other sections of this textbook. We won't come back on this methods.

R2. This section being on the boundary between engineering and Applied Mathematics, we decided to give some application examples of developed tools with various programming languages or software.

R3. Many of the techniques presented below are available as complete code in the C++ book [423] that we strongly recommend to the reader.

Definitions (#14.1.552):

D1. An "algorithm" is a finite sequence of rules to be applied in a specific order in a finite number of data to arrive in a finite number of steps (including the amount, or conversely the execution time is defined by the term "cost") to a certain result, independently of the data type.

D2. The algorithms are integrated into computers through "programs" (including stuff like "functions", "objects", "classes", "methods", "properties", "pointers", etc. but this is more related to a programming language course) that are the realization (implementation) of an algorithm using a given language (on a given architecture). This is the implementation of the principle.

Axioms of programming (anecdotal):

A1. More we write code, more errors we will produce.

A2. There are no programs without possible errors (due to the program itself, to the underlying electronics or most often to the user himself).

Remark

Basically there a is minimum steps to follow when developing an algorithm and its corresponding code. A very good process to follow is the one proposed by the ISO/CEI 9126 norm.

Theorem 14.1. There exist an infinite number of algorithms.

Proof 14.1.1. For every integer $i \geq 1$, consider the following algorithm A_i : Declare variable x, then assign x the value i. Terminate.

Every algorithm defined, as above, terminates in finite time. Every algorithm defined above is distinct.

Notice that we have defined an algorithm, one for each positive integer (in technical language, there is a correspondence between the family of algorithms we defined above and $\mathbb{Z}^+$). There are infinitely many positive integers, therefore, there are infinitely many algorithms (for which at least a subset of them include the family of the algorithms we defined above).

■ Q.E.D.

When developing a scientific algorithm, it may be interesting, rigorous and even an obligation in very high level cases to analyse the "complexity" of the algorithm. Without going too far, let's see what it is exactly:

14.1.1 Computer Representation of Numbers

In a classical computer numbers are represented by binary digits 0 and 1. Computers employ binary arithmetic for performing operations on numbers. Since it gets cumbersome to display large numbers in binary form computers usually display them in hexadecimal or octal or decimal system. All of these number systems are positional systems. In a positional system a number is represented by a set of symbols. Each of these symbols denote a particular value depending on its position. The number of symbols used in a positional system depends on its 'base'. Let us now discuss about various positional number systems:

14.1.1.1 Decimal System

The decimal system uses 10 as its base value and employs ten symbols 0 to 9 in representing numbers. Let us consider a decimal number 7402 consisting of four symbols 7,4,0,2. In terms of base 10 it can be expressed as follows:

$$7402 = 7 \times 10^3 + 4 \times 10^2 + 0 \times 10^1 + 2 \times 10^0$$

So each of the symbols from a set of symbols denoting a number is multiplied with power of the base (10) depending on its position counted from the right. The count always begins with 0.

In general a decimal number $d_m d_{m-1} \ldots d_1 d_0$ consisting of $(m+1)$ symbols can be expressed as:

$$d_m \times 10^m + d_{m-1} \times 10^{m-1} + \ldots . + d_1 \times 10^1 + d_0 \times 10^0 = \sum_{i=0}^{m} d_i 10^i$$

where $0 \leq d_i \leq 9$ with $i = 0, 1, \ldots, m$

Similarly, a fractional part of a decimal number can be expressed as $\sum_{i=1}^{m} d_i 10^{-i}$

14.1.1.2 Binary system

Binary system is the positional system consisting of two symbols i.e. $\{0,1\}$, named "bits", and '2' as its base. Any binary number $d_m d_{m-1} \ldots d_1 d_0$ actually represents a decimal value given by

$$d_m 2^m + d_{m-1} 2^{m-1} + \ldots + d_0 2^0 = \sum_{i=0}^{m} d_i 2^i$$

where $d_i = 0 \quad or \quad 1, \quad i = 0, 1, ..m.$

Consider the binary number 10101. The decimal equivalent of 10101 is given by

$$\begin{aligned}(10101)_2 &= 1 \times 2^4 + 0 \times 2^3 + 1 \times 2^2 + 0 \times 2^1 + 1 \times 2^0 \\ &= 16 + 0 + 4 + 0 + 1 = (21)_{10}\end{aligned}$$

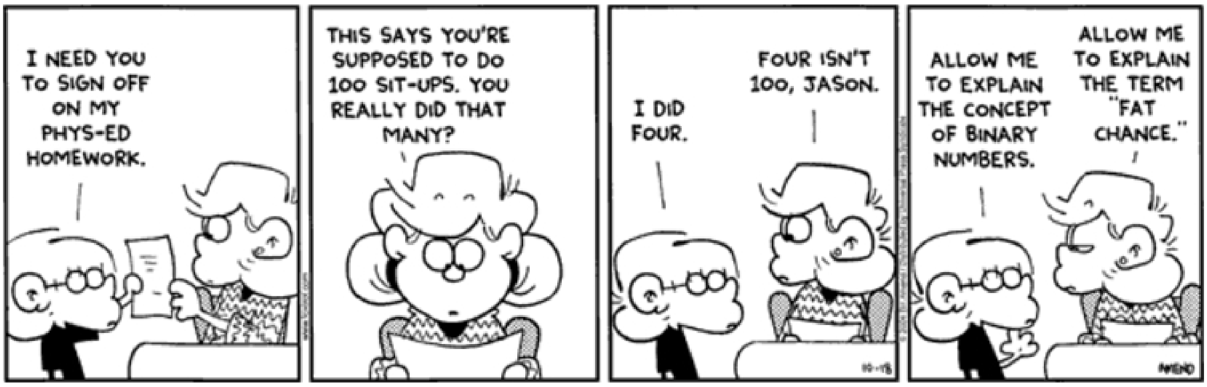
Here are the representation of some integer positive values in binary notation:

1	1	13	1101	25	11001
2	10	14	1110	26	11010
3	11	15	1111	27	11011
4	100	16	10000	28	11100
5	101	17	10001	29	11101
6	110	18	10010	30	11110
7	111	19	10011	31	11111
8	1000	20	10100	32	100000
9	1001	21	10101	33	100001
10	1010	22	10110	34	100010
11	1011	23	10111	35	100011
12	1100	24	11000	36	100100

Notice that:

- The number of different values representable in n bits is 2^n

- An n-bit binary number $X = x_{n-1}x_{n-2}\cdots x_1x_0$ can represent any integer value in the range $0 \leq X \leq 2^n - 1$ (e.g., if $n = 3$, then $0 \leq X \leq 7$). Note that $n+1$ bits are needed to represent the value $X = 2^n$
- The highest (left-most) bit x_{n-1} of an n-bit number is named the "most significant bit" (MSB) and the lowest bit (right-most) x_0 the "least significant bit" (LSB)



I NEED YOU TO SIGN OFF ON MY PHYS-ED HOMEWORK.
THIS SAYS YOU'RE SUPPOSED TO DO 100 SIT-UPS. YOU REALLY DID THAT MANY?
I DID FOUR.
FOUR ISN'T 100, JASON.
ALLOW ME TO EXPLAIN THE CONCEPT OF BINARY NUMBERS.
ALLOW ME TO EXPLAIN THE TERM "FAT CHANCE."

It should be obvious at this level for the reader that:

- 1000 has 10 bits because $512 \leq 1000 \leq 1024$, or $2^9 \leq 1000 \leq 2^{10} - 1$
- 1344 has 11 bits because $1024 \leq 1344 \leq 2047$, or $2^{10} \leq 1344 \leq 2^{11} - 1$
- 2527 has 12 bits because $2048 \leq 2527 \leq 4095$, or $2^{11} \leq 2527 \leq 2^{12} - 1$
- 5019 has 13 bits because $4096 \leq 5019 \leq 8191$, or $2^{12} \leq 5019 \leq 2^{13} - 1$
- 9999 has 14 bits because $8192 \leq 9999 \leq 16383$, or $2^{13} \leq 9999 \leq 2^{14} - 1$

Hence the minimum number of bit required b_{min} for a d digit integer is computed simply by using the specific number formula on the minimum d digit value:

$$b_{\text{min}} = \lfloor \log_2(10^{d-1}) \rfloor + 1 \qquad (14.1.1)$$

So for example, in 12018 (holocene calendar) the biggest prime number (important in cryptography) discovered had $23,249,425$ digits, thus corresponding using the above relation to $b_{\text{min}} = 25$.

What we have seen so far works only for integer (i.e. "fixed point numbers"). What about decimal numbers??? This is what we will focus on right now!

14.1.1.2.1 Floating Point (Real Numbers)

The encoding scheme for floating point numbers is more complicated than for fixed point. The basic idea is the same as used in scientific notation, where a mantissa is multiplied by ten raised to some exponent. For instance, $5.4321 \cdot 10^6$, where 5.4321 is the mantissa and 6 is the exponent. Scientific notation is exceptional at representing very large and very small numbers. For example: $1.2 \cdot 10^{50}$, the number of atoms in the Earth, or $2.6 \cdot 10^{-23}$, the distance a turtle crawls in one second, compared to the diameter of our galaxy. Notice that numbers represented in scientific notation are normalized so that there is only a single nonzero digit left of the decimal point. This is achieved by adjusting the exponent as needed.

Floating point representation is similar to scientific notation, except everything is carried out in base two, rather than base ten. While several similar formats are in use, the most common is ANSI/IEEE Std. 754-1985. This standard defines the format for 16 bits number named "half-precision", 32 bit numbers named "single precision", as well as 64 bit numbers named "double precision". As shown in the figure below, the 32 bits used in single precision are divided into three separate groups: bits 0 through 22 form the mantissa, bits 23 through 30 form the exponent, and bit 31 is the sign bit. These bits form the floating point number, v, by the following relation:

$$v = (-1)^S \cdot (1 + M) \cdot 2^{E-127} \tag{14.1.2}$$

More generally:

$$v = (-1)^S \cdot (2^0 + M) \cdot 2^{E-\text{bias}} \tag{14.1.3}$$

Also sometimes denoted:

$$\begin{aligned} \text{Real Value} &= (-1)^{\text{sign}} * (1.b_{22}b_{21}\ldots b_0)_2 \cdot 2^{(b_{30}b_{29}\ldots b_{23})_2 - 127} \\ &= \text{sign}(1\text{-bit}) \cdot \text{ binary fraction bits } (23\text{-bit}) * (8\text{-bit unsigned integer exponent}, e-127) \\ &= (-1)^{\text{sign}} \cdot \left(1 + \sum_{i=1}^{23} b_{23-i} 2^{-i}\right) \cdot 2^{(e-127)} \end{aligned} \tag{14.1.4}$$

So the main relation is:

$$\boxed{v = (-1)^S \cdot (2^0 + M) \cdot 2^{E-\text{bias}} = (-1)^{\text{sign}} \cdot \left(1 + \sum_{i=1}^{23} b_{23-i} 2^{-i}\right) \cdot 2^{(e-127)}} \tag{14.1.5}$$

In other words, $M = 1 + b_{22}2^{-1} + b_{21}2^{-2} + b_{20}2^{-3} \ldots$. If bits 0 through 22 are all zeros, M takes on the value of one. If bits 0 through 22 are all ones, M is just a hair under two, i.e., $2 - 2^{-23}$.

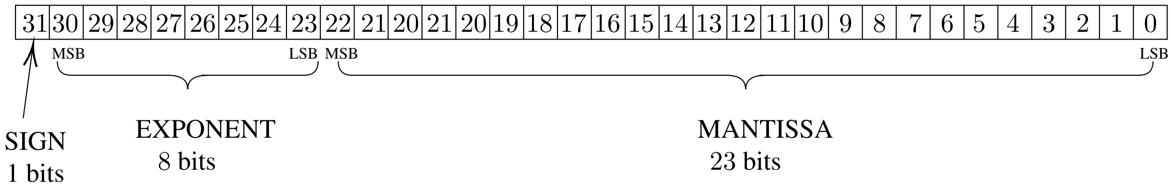


Figure 14.1: **Floating point (real numbers) in simple precision**

Or for the half-precision system:

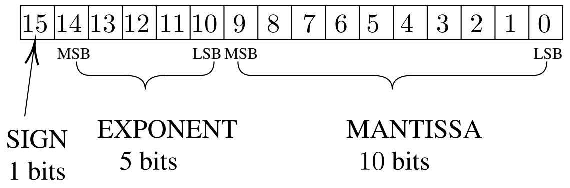

Figure 14.2: **Floating point (real numbers) in half precision**

The term: $(-1)^S$, simply means that the sign bit, S, is 0 for a positive number and 1 for a negative number. The variable, E, is the number between 0 and 255 represented by the eight exponent bits. Subtracting 127 from this number allows the exponent term to run from 10^{-127} to 10^{128} other words, the exponent is stored in offset binary with an offset of 127.

The mantissa, M, is formed from the 23 bits as a binary fraction. For example, the decimal fraction: 2.783 , is interpreted: $2+7/10+ 8/100+3/1000$. The binary fraction: 1.0101 , means: $1+0/2+1/4+0/8+1/16$. Floating point numbers are normalized in the same way as scientific notation, that is, there is only one nonzero digit left of the decimal point (named a" binary point" in base 2). Since the only nonzero number that exists in base two is 1, the leading digit in the mantissa will always be a 1, and therefore does not need to be stored. Removing this redundancy allows the number to have an additional one bit of precision. The 23 stored bits, referred to by the notation: $b_{22}, b_{21}, b_{21}, \ldots, b_0$, form the mantissa according to:

$$M = 1.b_{22}b_{21}b_{20}b_{19}\ldots b_2b_1b_0 \qquad (14.1.6)$$

Using this encoding scheme, the largest number that can be represented is: $\pm\,(2-2^{-23})\cdot 2^{128} = \pm 6.8\cdot 10^{38}$. Likewise, the smallest number that can be represented is: $\pm 1.0\cdot 2^{-127} = \pm 5.9\cdot 10^{-39}$. The IEEE standard reduces this range slightly to free bit patterns that are assigned special meanings. In particular, the largest and smallest numbers allowed in the standard are $\pm 3.4\cdot 10^{38}$ and $\pm 1.2\cdot 10^{-38}$ respectively. The freed bit patterns allow three special classes of numbers:

- ± 0 is defined as all of the mantissa and exponent bits being zero.
- $\pm\infty$ is defined as all of the mantissa bits being zero, and all of the exponent bits being one.
- A group of very small unnormalized numbers between $\pm 1.2\cdot 10^{-38}$ and $\pm 1.4\cdot 10^{-45}$.

These are lower precision numbers obtained by removing the requirement that the leading digit in the mantissa be a one. Besides these three special classes, there are bit patterns that are not assigned a meaning, commonly referred to as NANs (Not A Number).

The IEEE standard for double precision simply adds more bits to the single precision format. Of the 64 bits used to store a double precision number, bits 0 through 51 are the mantissa, bits 52 through 62 are the exponent, and bit 63 is the sign bit. As before, the mantissa is between one and just under two, i.e., $M = 1 + b_{51}2^{-1} + b_{50}2^{-2} + b_{49}2^{-3}\ldots$. The 11 exponent bits form a number between 0 and 2047 , with an offset of 1023, allowing exponents from

2^{-1023} to 2^{1024}. The largest and smallest numbers allowed are $\pm 1.8 \cdot 10^{308}$ and $\pm 2.2 \cdot 10^{-308}$, respectively. These are incredibly large and small numbers! It is quite uncommon to find an application where single precision is not adequate. You will probably never find a case where double precision limits what you want to accomplish.

Caution! Let's have a look at a number which is fine for us, but has the floating point issue for the personal computer: $1/10$. For us Homo Sapiens, $1/10$ is 0.1, it's easy, only one decimal! For a digital computer, $1/10$ in floating precision is $0.0001100110011001101\ldots$ These decimals have a recurring combination of numbers, i.e. 0011. The computer will not calculate every single decimals as it is infinite! It has to stop at some point and round the number of decimals. This rounding is the floating point lack of precision. For comparison, in base 10, we can't precisely define $1/3$, which is 0.3333 recurring 3. Overall, many spreadsheet and business intelligence softwares decimal issue is caused by a limitation of floating point precision. This is not an error per se, but can cause one. Understanding the logic of decimals-rounding will help you find the solution applicable to your situation.

14.1.1.2.2 Binary arithmetic (for fixed point/integers)

Here are the addition facts that you need when adding numbers in binary notation:

$$\begin{aligned} 0+0&=0\\ 0+1&=1\\ 1+1&=10 \end{aligned} \tag{14.1.7}$$

Doing binary addition is like doing decimal addition excepted that we work on a binary set.

$$\begin{array}{r} {\scriptstyle 1\;1111\;111} \\ 0\,1100\,1001 \\ +\,0\,1111\,1111 \\ \hline 1\,1100\,1000 \end{array}$$

Here are the subtractions facts that you need when subtracting numbers in binary notation:

$$\begin{aligned} 1-1&=0\\ 1-0&=0\\ 10-1&=1 \end{aligned} \tag{14.1.8}$$

The fact that $10-1=1$ will lead to borrowing since you can not take 1 from 0 for a certain place value, and so you must borrow from the 1 in the next place value, much like how you need to borrow in decimal notation:

$$\begin{array}{r} {\scriptstyle 111} \\ 1001 \\ -\,0110 \\ \hline 0011 \end{array}$$

We will come back more in details on binary arithmetic during our study of Boolean Algebra in the section of Logical Systems.

14.1.1.3 Hexadecimal System

The Hexadecimal system is the positional system consisting of sixteen symbols, 0,1,2,...,9,A,B,C,D,E,F, and '16' as its base. Here the symbols A denotes 10, B denotes 11 and so on. The decimal equivalent of the given hexadecimal number $d_m d_{m-1} \ldots d_0$ is given by:

$$\sum_{i=0}^{m} d_i \cdot (16)^i \tag{14.1.9}$$

For example consider $(15ACB)_{16}$:

$$\begin{aligned}(15ACB)_{16} &= 1 \cdot 16^4 + 5 \cdot 16^3 + 10 \cdot 16^2 + 12 \cdot 16^1 + 11 \cdot 16^0 \\ &= 65536 + 5 \cdot 4096 + 10 \cdot 256 + 12 \cdot 16 + 11 \cdot 1 \\ &= 65536 + 20480 + 2560 + 192 + 11 = (88779)_{10}\end{aligned} \tag{14.1.10}$$

We can convert a binary number directly to a hexadecimal number by grouping the binary digits, starting from the right, into sets of four and converting each group to its equivalent hexadecimal digit. If in such a grouping the last set falls short of four binary digits then do the obvious thing of prefixing it with adequate number of binary digit '0'. For example let us find the hexadecimal equivalent of $(111\,011\,0101\,0010\,1110)_2$:

$$(\underline{0011} \quad \underline{1011} \quad \underline{0101} \quad \underline{0010} \quad \underline{1110})_2 = (3B52E)_{16} \tag{14.1.11}$$

The vice versa is also true.

14.1.1.4 Octal System

The octal system is the positional system that uses 8 as its base and $\{0, 1, \ldots, 7\}$ as its symbol set of size 8. The decimal equivalent of an octal number $(d_m d_{m-1} \ldots d_0)_8$ is given by:

$$\left(\sum_{i=0}^{m} d_i 8^i\right)_{10} \tag{14.1.12}$$

For example consider $(6741)_8$:

$$\begin{aligned}(6741)_8 &= 6 \cdot 8^3 + 7 \cdot 8^2 + 4 \cdot 8^1 + 1 \cdot 8^0 \\ &= 6 \cdot 512 + 7 \cdot 64 + 4 \cdot 8 + 1 \\ &= 3072 + 448 + 32 + 1 = (3553)_{10}\end{aligned} \tag{14.1.13}$$

We can get the octal equivalent of a binary number by grouping the binary digits, starting from the right, into sets of three binary digits and converting each of these sets to its octal equivalent.

If such a grouping results in a last set having less number of digits it may be prefixed with adequate number of binary digit 0.

As an example the octal equivalent of $(1010\,110\,111\,001)_2$.

So we have:

$$\begin{aligned}(1010\,110\,111\,001)_2 &= (001 \quad 010 \quad 110 \quad 111 \quad 001)_2 \\ &= (12671)_8\end{aligned} \tag{14.1.14}$$

14.1.1.5 Conversion of decimal system to non-decimal system:

To convert a decimal number to a number of any other system we should consider the integer and fractional parts separately and follow the following procedure:

Conversion of integer part:

1. Consider the integer part of a given decimal number and divide it by the base b of the new number system. The remainder will constitute the rightmost digit of the integer part of the new number.
2. Next divide the quotient again by the base b. The remainder will constitute second digit from the right in the new system

Continue this process until we end up with a zero-quotient. The last remainder is the leftmost digit of the new number.

Conversion of fractional part:

1. Consider the fractional part of the given decimal number and multiply it with the base b of the new system. The integral part of the product constitutes the leftmost digit of the fractional part in the new system.
2. Now again multiply the fractional part resulting in step (a) by the base b of the new system. The integral part of the resultant product is the second digit from the left in the new system.

Repeat the above step until we encounter a zero-fractional part or a duplicate fractional part. The integer part of this last product will be the rightmost digit of the fractional part of the new number.

✍**Example:**

We want to convert 54.45 into its binary equivalent.

1. Consider the integer part i.e. 54 and apply the steps listed under conversion of integer part i.e.
2. conversion of fractional part:

		Product	integral part	Binary number
0.45×2	=	0.90	0	$(.01\overline{1100})_2$
0.9×2	=	1.80	1	
0.8×2	=	1.6	1	
0.6×2	=	1.2	1	
0.2×2	=	0.4	0	
0.4×2	=	0.8	0	
0.8×2	=	1.6	1	
0.6×2	=	1.2	1	
0.2×2	=	0.4	0	
0.4×2	=	0.8	0	
0.8×2	=	1.6	1	
...		...	...	
...		...	...	

Therefore:

$$(0.45)_{10} = (.01\overline{1100})_2 \tag{14.1.15}$$

and finally:

$$(54.45)_{10} = (110110.01\overline{1100})_2 \tag{14.1.16}$$

Here the overbar denotes the repetition of the binary digits.

Using binary system as an intermediate stage we can easily convert octal numbers to hexadecimal numbers and vice-versa:

✍**Examples:**

E1. $(423)_8 = (100 \quad 010 \quad 011)_2$
$\quad = (0001 \quad 0001 \quad 0011)_2 = (113)_{16}$

E2. $(93AF)_{16} = (1001 \quad 0011 \quad 1010 \quad 1111)_2$
$\quad = (010 \quad 010 \quad 011 \quad 101 \quad 011 \quad 110)_2$
$\quad = (223536)_8$

In the above two examples we have grouped the binary digits suitably either to quadruplets or triplets to convert octal to hexadecimal and hexadecimal to octal numbers respectively.

14.1.2 Algorithm Complexity

Definition (#14.1.553): The "complexity" of an algorithm is the measure of the number of fundamental operations it performs in the worst case on a dataset.

Measure the exact complexity is most of time irrelevant because often too complex given the size of the programs (too big algorithms). To avoid calculating in detail the complexity of an algorithm, we identify the fundamental operations. These basic operations can be: an assignment, a comparison between two variables, an arithmetic operation between two variables, etc.

Thus, the classical used hypothesis for the calculation of the complexity are:

H1. The four fundamental operations have the same time cost: $+\equiv-\equiv\times\equiv\div$

H2. A memory access has a cheaper time cost than an arithmetic operation.

H3. A comparison check has a cheaper time cost than an arithmetic operation.

H4. We work with only one single processor.

Definitions (#14.1.554):

D1. We note D_n the sets of data of size n and $T(n)$ the cost (in time) of the algorithm on the data or the data set of size n.

D2. The "complexity at the best" is given by the function:

$$T_{\text{min}}(n)=\text{min}_{d\in D_n}C(d) \tag{14.1.17}$$

This is the smallest time that will need an algorithm to run on a data set (lines of code) of fixed size, here equal to n, that the cost (duration) execution is $C(d)$. This is a lower bound on the complexity of the algorithm on a data set of size n.

D3. The "complexity at worst" (the most interesting for the practitioner because it is the one to minimize!):

$$T_{\text{max}}(n)=\text{max}_{d\in D_n}C(d) \tag{14.1.18}$$

This is the biggest time that will need an algorithm to run on a data set (lines of code) of fixed size, here equal to n, that the cost (duration) execution is $C(d)$. This is a upper bound on the complexity of the algorithm on a data set of size n. The algorithm will always finish at this time or before but never after.

D4. The "average complexity":

$$T_{\text{avg}}(n)=\frac{\sum\limits_{d\in D_n}C(d)}{D_n} \tag{14.1.19}$$

This is the average of the complexities of the algorithm on the data sets of size n (strictly speaking, we must obviously take into account the probability of occurrence of each of the data sets). This average reflects the general behaviour of the algorithm if extreme cases are rare or complexity varies slightly depending on the data. However, the complexity in practice on a particular data set may be significantly greater than the average complexity; in this case the average complexity does not give a good indication of the behaviour of the algorithm.

D5. The "order of complexity" is defined as the complexity at worst of an algorithms that contains several terms (additions or subtractions) so that we only keep the term that is growing the fastest. Thus, an algorithm having a complexity of type:

$$An^2+Bn+n! \tag{14.1.20}$$

will be said to have a complexity of order $\mathcal{O}(n!)$. This is the "big $\mathcal{O}$ notation". It is a member of a family of notations invented by Paul Bachmann, Edmund Landau, and others, collectively named "Bachmann–Landau notation" or "asymptotic notation".

Remark

Just as worst cases are given in terms of upper bounds, best cases are given in terms of lower bounds, which are specified with "big Ω notation". A best case of $\Omega(n)$ would mean that the function is always at least linear, but could grow faster.

✍**Examples:**

Consider N as the size of the data. For a decimal number this is the numbers N of digits. Consider two decimal numbers like $0.a_1a_2a_3\ldots$ and $0.b_1b_2b_3\ldots$

E1. Addition has linear complexity because in developed way addition is expressed as (see section Numbers page 211):

$$\sum_{1\leq n\leq N} a_n10^{-n}+\sum_{1\leq n\leq N} b_n10^{-n}=\sum_{1\leq n\leq N}(a_n+b_n)10^{-n} \tag{14.1.21}$$

E2. Multiplication has quadratic complexity because in developed way multiplication is expressed as:

$$\sum_{1\leq k\leq N} a_k10^{-k}+\sum_{1\leq l\leq N} b_l10^{-l}=\sum_{1\leq n\leq N}\left(\sum_{k+l=n} a_kb_l\right)10^{-n} \tag{14.1.22}$$

Definition (#14.1.555): An algorithm is said to be an "optimal algorithm" if its complexity has the minimal complexity among all other algorithms in its class.

As we made it understand implicitly earlier, we focus almost exclusively on the time complexity of the algorithms. Sometimes it is interesting to focus on other of their characteristics, such as space complexity (size of the memory used), the bandwidth required, etc.

For the result of the analysis of an algorithm to be relevant, we must have a model of a machine on which the algorithm will be implemented (as a program). We usually take as a reference, the "random access machine (RAM)" with a single processor where instructions are executed one after the other, without concurrent operations and without stochastic processes (in contrast to possible future quantum computers).

Most common algorithms can be classified into a number of broad classes of complexity whose order $\mathcal{O}$ varies somehow:

1. The algorithms with "constant complexity $\mathcal{O}(1)$" that just do a boolean control (comparison).
2. The algorithms with "linear complexity $\mathcal{O}(n)$" and those in complexity in $\mathcal{O}(n\log(n))$ that are considered as fast.
3. The algorithms with "polynomial complexity in $\mathcal{O}(n^k)$" (for $k>3$ are considered as slow).
4. The algorithms with "sub-linear complexity" whose complexity is usually of the order $\mathcal{O}(\log(n))$
5. The algorithms with "factorial complexity" whose complexity is usually of the order $\mathcal{O}(n!)$

and so on... (we give here definition only for complexity for which we already have given a detailed example or will give examples further below).

It is important to see that (focusing only on complexities we have seen with examples or will see later below) for $n>4$:

$$\boxed{\mathcal{O}(1)<\mathcal{O}(\log(n))<\mathcal{O}(n)<\mathcal{O}(n\ln(n))<\mathcal{O}(n^2)<\mathcal{O}(e^n)<\mathcal{O}(n!)<\mathcal{O}(n^n)} \quad (14.1.23)$$

Remark

In practice a good complexity is considered as being of order $\mathcal{O}(n^k)$ for $k>3$. Poor complexity is considered as being of type $\mathcal{O}(e^n),\mathcal{O}(n!)$ or equation.

For people that like better visual stuff:

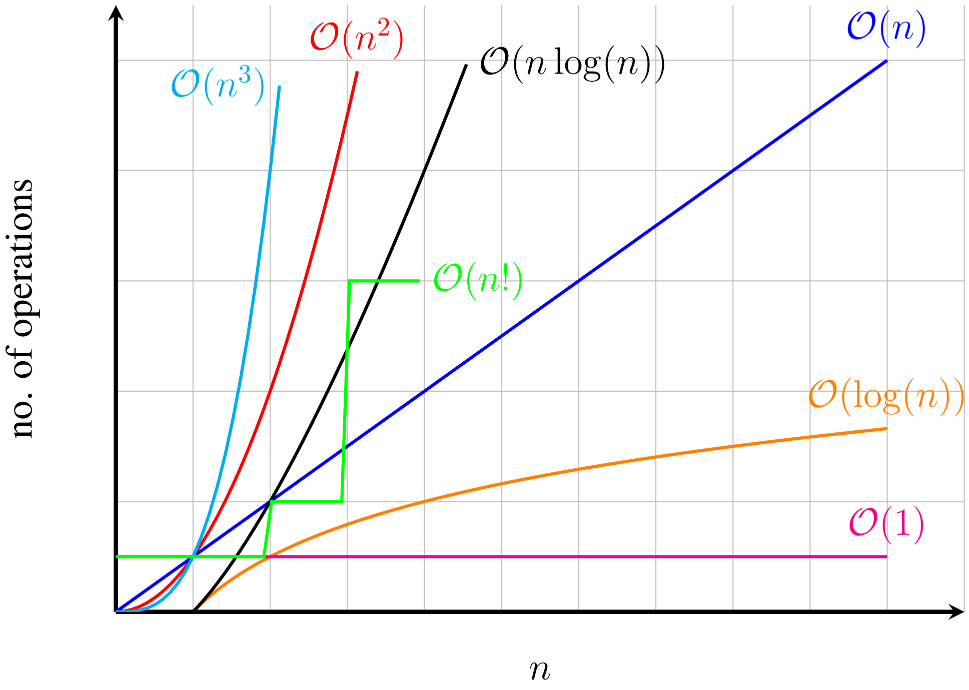

Figure 14.3: Big $\mathcal{O}$ notation complexities plot

n	1	$\log(n)$	$n\cdot\log(n)$	n^2	n^3	$n!$
1	1	0	0	1	1	1
2	1	0.30	0.60	4	8	2
3	1	0.48	1.43	9	27	6
4	1	0.60	2.41	16	64	24
5	1	0.70	3.49	25	125	120
6	1	0.78	4.67	36	216	720
7	1	0.85	5.92	49	343	5,040
8	1	0.90	8.13	64	512	40,320
9	1	0.95	8.59	81	729	362,880
10	1	1.00	10.00	100	1,000	3,628,800
20	1	1.30	26.02	400	8,000	$2.42\cdot 10^{18}$

We already saw above an example with linear complexity (addition of scalars) and of polynomial (quadratic) complexity (with multiplication of scalars).

Let us see some other very common examples. The first example use the results of the previous examples:

✍**Examples:**

E1. Evaluation of a polynomial:

$$P(x)=a_0+a_1x+a_2x^2+\ldots+a_nx^n \quad (14.1.24)$$

The direct estimate of the value of $P(x)$ leads to a complexity:

$$C_{P(x)}=\mathcal{O}\left((n)_{\text{additions}}+\left(1+2+3+\ldots+(n+1)=\frac{n(n+1)}{2}\right)_{\text{products}}\right)=\mathcal{O}(n^2) \tag{14.1.25}$$

E2. Another important example is the inversion matrix problem that is used a lot in supercomputer megaflops benchmark (sometimes named "LINPACK test"). As you can see in the MATLAB® companions book there is a division by n^3 as the matrix inversion complexity is of order n^3. Indeed:

At the beginning, when the first row has length n, it takes n operations to zero out any entry in the first column (one division, and $n-1$ multiply-subtracts to find the new entries along the row containing that entry. To get the first column of zeroes therefore takes $n(n-1)$ operations.

In the next column, we need $(n-1)(n-2)$ operations to get the second column zeroed out.

In the third column, we need $(n-2)(n-3)$ operations.

The sum of all of these operations is:

$$\sum_{i=1}^{n} i(i-1)=\sum_{i=1}^{n} i^2-\sum_{i=1}^{n} i=\frac{n(n+1)(2n+1)}{6}-\frac{n(n+1)}{2} \tag{14.1.26}$$

which goes as $\mathcal{O}(n^3)$.

Thanks to William George Horner we have a more efficient algorithm that uses a factorization of the polynomial in the form:

$$P(x)=a_0+x(a_1+x(a_2+\ldots x(a_{n-1}+xa_n))) \tag{14.1.27}$$

We can see almost easily that this factorization holds the same number of additions to (n) but reduces the number of multiplications to (n).

The resulting complexity is $\mathcal{O}(n)$. The gain is unquestionably important. In addition, this factorization avoids computing power.

Let us see now another well known example that almost all students that have learned scripting a little bit already know:

✍**Example:**

The famous example of algorithmic complexity is the search for an information in a sorted column (list). A simple algorithm named "dichotomous search", also named "binary search", is to take the cell to mid-column and see if we find the desired value. Otherwise, research must continue on the same method in the top or bottom of the column (depending on the lexicographical order).

The algorithm is recursive and allows at each step, to divide by two the size of the search space.

If this size is initially of n cells in the column, it is of size $\dfrac{n}{2}$ in step 1, of size $\dfrac{n}{2^2}$ in step 2, and more generally of size $\dfrac{n}{2^k}$ in step k.

At worst, the search ends when there is only one cell in the column to explore, i.e. when k is such that $n < 2^k$.

We deduce the maximum number of steps: it is the smallest k such that $n < 2^k$, written in another way $\log_2(n) < k$, i.e. the sub-linear complexity:

$$T_{\text{max}} = k = \log_2(n) \tag{14.1.28}$$

That result is strongly related to a famous guess game. The game is that if you have a set of integers $\{1, 2, \ldots, n\}$. Host picks at random one of the numbers and gives you k chances to guess it. After each guess the host says "higher", "lower", or "correct". The question is what is the optimal strategy (number of guesses)?

If we use binary search algorithm with guesses lower or higher on every turn, the maximum number of guesses that is required to guess a number between $1 - n$ is $\lceil \log_2(n) \rceil$ and this must be less than k to guarantee that we guess the number within k guesses. So:

$$\lceil \log_2(n) \rceil \leq k \tag{14.1.29}$$

Therefore:

$$\lfloor \log_2(n) \rfloor + 1 \leq k \tag{14.1.30}$$

Hence:

$$n \leq 2^{k-1} \tag{14.1.31}$$

So we have just proved that if $n \leq 2^{k-1}$ then there is a strategy that guarantees we will guess the number by the kth guess.

The result of this last example is to compared with a sequential search (useful when sorting is too costly in resources). For example, in a column of $25,000$ data the complexity is $\mathcal{O}(n)$ thus $25,000$ while with the dichotomous method, the sub-linear complexity gives $\log_2(25,000) = 15$. The gain is considerable (at the condition that data is sorted)!

Other complexity that the reader must absolutely know are some elementary Linear Algebra calculations (see the section of the same name)! So without proof (because normally trivial given the previous examples) if we consider two square matrices A and B of dimensions n the main operations have the following complexities:

- Read the components (nested loops): $\mathcal{O}(n^2)$

- Calculation of the trace: $\text{tr}(A)=\sum_{i=1}^{n} a_{ii} \rightarrow \mathcal{O}(n)$
- Addition $A+B=C$ so that $c_{ij}=a_{ij}+b_{ij} \rightarrow \mathcal{O}(n^2)$
- Product $A \cdot B=c$ so that $c_{ij}=\sum_{k=1}^{n} a_{ik}b_{kj} \rightarrow \mathcal{O}(n^3)$
- Solving the travelling salesman problem via brute-force search is $\mathcal{O}(n!)$.
- Determinant (by the direct method of Cramer as detailed in the section of Linear Algebra page 1977). We can thus show that the complexity order of the determinant of a square matrix of dimensions n is n products, $n-1$ additions plus n times the complexity of the determinant of a matrix of dimensions $n-1$ so that finally we have: det(A) $=\mathcal{O}(n \cdot n!)$

Assuming that the computer performs an elementary operation in equation seconds (which is already a good computer), we obtain the following calculations time for several values of n for the determinant:

n	5	10	15	20	50
t	$6 \cdot 10^{-7}$ [s]	0.04 [s]	5.5 [h.]	$1,543$ [y.]	$4.8 \cdot 10^{46}$ [y.]

Table 14.1: **Various costs**

hence the need to make sometimes a time complexity calculation before starting an algorithm (unless you are working exclusively for future generations, provided that there will still be future generations...).

To close this subject let us indicate that there are other notations than just the big $\mathcal{O}$ and the big Ω. So let us give a summary and at the same time the definition for the other one:

- $f(x)=\mathcal{O}(g(x))$ means that the growth rate of $f(x)$ is asymptotically less than or equal to the growth rate of $g(x)$
- $f(x)=\Omega(g(x))$ means that the growth rate of $f(x)$ is asymptotically greater than or equal to the growth rate of $g(x)$
- $f(x)=\wr(g(x))$ means that the growth rate of $f(x)$ is asymptotically less than the growth rate of $g(x)$.
- $f(x)=\omega(g(x))$ means that the growth rate of $f(x)$ is asymptotically greater than the growth rate of $g(x)$
- $f(x)=\Theta(g(x))$ means that the growth rate of $f(x)$ is asymptotically equal to the growth rate of $g(x)$

Remark

Here's a simple way to remember which notation means what. All of the big $\mathcal{O}$ notations can be considered to have a bar. When looking at a Ω, the bar is at the bottom, so it is an (asymptotic) lower bound. When looking at a Θ, the bar is obviously in the middle. So it is an (asymptotic) tight bound. When handwriting $\mathcal{O}$, you usually finish at the top, and draw a squiggle. Therefore $\mathcal{O}(g(x))$ is the upper bound of the function. To be fair, this one doesn't work with most fonts, but it is the original justification of the names.

14.1.2.1 NP-Completude

We will introduce now for the general culture the concept of "NP-completeness", that is to say that we will try to define without too much formalism (as usual in this textbook).

First let us introduce two non-formal definitions of a Turing machine.

Definitions (#14.1.556):

D1. An algorithm is said to be a "deterministic Turing machine" when the set of its rules prescribes at most one action to be performed for any given situation.

D2. A "non-deterministic Turing machine" may have a set of rules that prescribes more than one action for a given situation. For example, a non-deterministic Turing machine may have both "If you are in state 2 and you see an 'A', change it to a 'B' and move left" and "If you are in state 2 and you see an 'A', change it to a 'C' and move right" in its rule set.

Now let us define what type of problems are frequently considered:

Definitions (#14.1.557):

D1. "Logarithmic problems L" contains all algorithms (problems) that can be solved by a deterministic Turing machine using a logarithmic amount of computation time.

D2. "Polynomial problems P" contains all algorithms (problems) that can be solved by a deterministic Turing machine using a polynomial amount of computation time.

D3. "Non-deterministic polynomial time problems NP" are the set algorithms (problems) where the result instances can be controlled in a polynomial time complexity by a non-deterministic Turing machine.

It should be noted at this stage of the discussion that the class P is included in the NP class so that P $\subset$ NP. Indeed if we know a polynomial algorithm to solve a problem then we can at worst check the solution with a polynomial complexity algorithm also.

But a difficult question is the following reciprocal: if a problem is NP (known solution can be controlled in polynomial time) but it seems we can not found yet an algorithm in a polynomial time (or less) to find the solution, does it always exist a polynomial algorithm to find the solution so that $P = NP$ that thus bring us to write P $\subseteq$ NP?

In other words: If the solution of a problem can be quickly verified as being the correct one, can the solution also be found quickly?

✍**Examples:**

E1. The problem of finding a Hamiltonian cycle (cycle that passes once and only once by all the vertices of the graph - see section Graphs Theory page 3019) in a graph belongs to NP since, given a known cycle it is trivial to check in linear time $\mathcal{O}(n)$ it contains a well and once each vertex but found the cycle is at worst a factorial complexity $\mathcal{O}(n!)$.

E2. Factoring an integer n in product of prime factors (important in cryptography) is a NP problem. Indeed, given the prime factors $p_1, p_2, \ldots, p_n$ it is trivial to control the solution $n = p_1, p_2, \ldots, p_n$ as it is of order $\mathcal{O}(n^2)$. But we do not know if it exist a polynomial algorithm to find the prime numbers (to find the solution). So we do not know if the problem of finding prime numbers of an integer is a P-problem.

Remark

Apparently (we were not able to find the proof of this result and neither had opportunity to do so) the complexity of the best factorization algorithm for prime numbers is in the year 12007 (holocene calendar) of the type:

$$\mathcal{O}\left(\exp\left[\left(\frac{64}{9}\log(n)\right)^{\frac{1}{3}}\right]\log(\log(n))^{\frac{2}{3}}\right) \tag{14.1.32}$$

therefore there is still work to do (if a reader could provide us with the details that led to this result, we are interested).

A problem x that is in NP is also in NP-Complete if and only if every other problem in NP can be quickly (i.e. in polynomial time) transformed into x.

In other words a problem x is "NP-Complete NPC" if:

1. x is in NP
2. Every problem in NP is reducible to x

So, what makes NP-Complete so interesting is that if any one of the NP-Complete problems was to be solved quickly, then all NP problems can be solved quickly.

A NPC problem is complete in that it contains most of the complexity of problems belonging to NP, and a polynomial solution to this problem involves a polynomial solution to all NP type problems.

In other words: NPC problems have an exponential complexity and they all have the same complexity class (modulo polynomials).

Finally, what is important to understand and retain about this idea is that if we find one day a polynomial algorithm for one of these really difficult problems that are the NPC problems, then in one stroke NP becomes equal to P and all difficult problems become easy such that:

$$\boxed{\mathrm{N}=\mathrm{NP}} \tag{14.1.33}$$

In other words: can we find in a polynomial time what can be proved (controlled) in polynomial time?

Remark

This issue is so important in computing science to reduce energy consumptions and time computations that it belongs (arbitrarily) to the 7 millennium problems, whose resolution is prized $1 million by the Clay Mathematics Institute.

Ok this definitions given let us now study of some typical applications of numerical methods which are very often used in the industry. We will go from simple to more complicated and not forgetting that many methods that are not in this section can sometimes be found in other sections of the book!

14.1.3 Integer Part

The biggest integer less than or equal to a real number x is expressed in this textbook by $[x]$, which will be read "integer part of x" and according to the norm ISO 80000-2:2009 *Mathematical signs and symbols to be used in the natural sciences and technology* it should denoted as: int x.

The number M is an integer if and only if $[M]=M$. Similarly, the natural number $A\in\mathbb{N}$ is divisible in the natural set by the natural number $B\in\mathbb{N}$ if and only if:

$$\left[\frac{A}{B}\right]=\frac{A}{B} \tag{14.1.34}$$

We also denote by $\{x\}$ the fractional part of x such that:

$$\{x\}=x-[x] \tag{14.1.35}$$

That is to say:

$$x=[x]+\{x\} \tag{14.1.36}$$

with $|\{x\}|<1$.

Consider $x,y\in\mathbb{R}$. Then we have the following properties (normally most of them don't need any proof):

P1. $[x]\leq x<[x]+1\Leftrightarrow 0\leq x-[x]<1$

P2. $[x]=\sum\limits_{n\leq x} 1$ for $x \geq 0$

P3. $[x+m]=[x]+m$ if $m \in \mathbb{Z}$

P4. $[x]+[y] \leq [x+y] \leq [x]+[y]+1$

Proof 14.1.2. A reader asked for the proof of this property. So let us see how to proceed. First we write:

$$x=n+\theta, y=m+\phi \tag{14.1.37}$$

where $n,m \in \mathbb{Z}$ and where $0 \leq \theta < 1$ and $0 \leq \phi < 1$. Thus:

$$\begin{aligned}[x]+[y]=n+m=[n+m]\leq [n+\theta+m+\phi]=[x+y]\\ =n+m+[\theta+\phi]\leq n+m+1=[x]+[y]+1\end{aligned} \tag{14.1.38}$$

By writing $x=n+\theta$, where $0 \leq 0 < 1$, we have:

$$-x=-n-1+1-\theta \tag{14.1.39}$$

where $0 < 1-\theta \leq 1$. It follows that:

$$[x]+[-x]=n+[-n-1+1-\theta]=n-n-1+[1-\theta]=0 \tag{14.1.40}$$

if $\theta=0$ and:

$$[x]+[-x]=n+[-n-1+1-\theta]=n-n-1+[1-\theta]=-1 \tag{14.1.41}$$

if $0<\theta<1$.

■ Q.E.D.

P5. $[-x]=-[x]$ if $x \in \mathbb{Z}$ otherwise $[-x]=-[x]-1$ if $x \notin \mathbb{Z}$

Proof 14.1.3. The proof is already given at the end of the proof of property P4.

■ Q.E.D.

P6. $\left[\dfrac{[x]}{m}\right]=\left[\dfrac{x}{m}\right]$ if $m \in \mathbb{N}$

Proof 14.1.4. For this proof we will write:

$$x=[x]+n \tag{14.1.42}$$

where $0<\theta<1$ and:

$$[x]=qm+r \tag{14.1.43}$$

where $0 \leq r < m$ (see section Number Theory page 338). So we get:

$$\left[\dfrac{x}{m}\right]=\left[\dfrac{qm+r+\theta}{m}\right]=q+\left[\dfrac{r+\theta}{m}\right]=q \tag{14.1.44}$$

because $0 \leq r+\theta \leq m$. Besides :

$$\left[\dfrac{x}{m}\right]=\left[\dfrac{n}{m}\right]=\left[q+\dfrac{r}{m}\right]=q \tag{14.1.45}$$

and thus we have the expected result.

■ Q.E.D.

P7. If $a \in \mathbb{N}$ then $\left\lfloor \dfrac{x}{a} \right\rfloor$ represents the number of integers less than or equal x that are divisible by a.

Proof 14.1.5. For the last part, we observe that if $a, 2a, \ldots, ma$ are all positive integers $\leq x$ that are divisible by a, it suffices to prove that $\left\lfloor \dfrac{x}{a} \right\rfloor = m$.

Since $(m+1)a > x$, then:

$$ma \leq x \leq (m+1)a \tag{14.1.46}$$

That is to say:

$$m \leq \frac{x}{m} \leq m+1 \tag{14.1.47}$$

and thus we have the expected result.

■ Q.E.D.

Remark

The rounding method of real values will be given in the section on Economy.

14.1.4 Heron's Square Root Algorithm

One of the first things that many people learn in an introduction to Computer Sciences course is the algorithm for calculating the square root of a number.

There is such a simple algorithm for this purpose named "Heron's algorithm" or "algorithm of Heron of Alexandria" or even "Babylonian method" which converge to the value of this square root.

Thus want to calculate the square root:

$$x = \sqrt{A} \tag{14.1.48}$$

Proof 14.1.6. Here is a pseudo-proof because historically the algorithm was built on purely intuitive considerations (since approximately year 9900 according to holocene calendar algebra did not exist...). In high-school classes the result is given as a definition and just convergence is observed.

Remark

The "convergence ratio" of a sequence $x^{(k)}$ to a constant x_0 is:

$$\lim_{k \to \infty} \frac{\Delta\left(x^{(k+1)}, x_0\right)}{\Delta\left(x^{(k)}, x_0\right)} \tag{14.1.49}$$

if this limit exists. If the convergence ratio is greater than 0 and less than 1, the sequence is said to "converge linearly". If the convergence ratio is 0, the sequence is said to "converge superlinearly".

So for the demonstration, we will proceed as follows:

$$\begin{aligned}
&x^2 = A\\
&\Rightarrow 2x^2 = x^2 + A\\
&\Rightarrow 2x = \frac{x^2+A}{x}\\
&\Rightarrow x = \frac{x^2+A}{2x} = \frac{x+\dfrac{A}{x}}{2}
\end{aligned} \tag{14.1.50}$$

And the trick is to write:

$$\boxed{x_{i+1} = \frac{x_i}{2} + \frac{A}{2x_i}} = \frac{1}{2}\left(x_i + \frac{A}{x_i}\right) \tag{14.1.51}$$

This is named a "fixed-point iteration" (related to the theorem of the same name proved in the section of Sequences and Series page 1780). It is used in mainly situations in computer science. We will encounter it quite a lot of time further below...!

■ Q.E.D.

Example:

We want to calculate:

$$\sqrt{10} = 3.162277660168\ldots \tag{14.1.52}$$

We take $A = 10$ and this gives us the following table of iterations:

Iteration	$\dfrac{x_i}{2}$	$\dfrac{A}{2x_i}$	x_{i+1}	**Gap**
1	5	0.5	5.50	$\cong 2$
2	2.750	0.90909	3.659090909	$\cong 0.49$
3	1.82954	1.3664	3.196005083	$\cong 0.033$
4	1.59800	1.5644	3.162455624	$\cong 0.0002$
5	1.58122	1.5810	3.162277665	$\cong 0.5\cdot 10^{-8}$

Table 14.2: **Iterations for Heron's square root algorithm**

In the case of the cubic root, the proof is similar and we obtain:

$$x_{i+1} = \frac{2x_i}{3} + \frac{A}{3x_i^2} \tag{14.1.53}$$

and so on...

We can prove algebraically that the babylonian method converge. Note that all $x_n > 0$ and:

$$x_{n+1}^2 = \frac{1}{4}\left(x_n + \frac{a}{x_n}\right)^2 = \frac{1}{4}\left(x_n - \frac{a}{x_n}\right)^2 + a \geq a \tag{14.1.54}$$

Thus, all x_n past the first satisfy $x_n^2 \geq a$. Therefore:

$$x_{n+1} - x_n = \frac{a - x_n^2}{2x_n} \leq 0 \tag{14.1.55}$$

says that $x_{n+1} \leq x_n$. Therefore, $\{x_n\}$ is a decreasing sequence, bounded below. Thus, the sequence converges. Furthermore, since the sequence converges:

$$\lim_{n\to+\infty} a - x_n^2 = \lim_{n\to+\infty} 2x_n(x_{n+1} - x_n) = 0 \tag{14.1.56}$$

Therefore:

$$\lim_{n\to+\infty} x_n^2 = a \tag{14.1.57}$$

To conclude it is perhaps interesting to know that the reader can find in the section of Number Theory the method used in the antiquity (at least an analogy) using continued fractions.

Remark

We will see later that this above method is a special case of Newton's method introduced further below page 6612.

14.1.5 Archimedes Algorithm

The calculation of the universal constant "pi" denoted by π is certainly the algorithm with the greatest interest since we found this constant almost everywhere in physics and mathematics (there are numerous books on the subject available on the market).

We recall that we did not give the value of π in the section on Geometry or in other sections of this textbook until now. So we will now tackle this task.

We define in geometry the number named "pi", independently of the metric used, as the ratio of half the circumference of a circle with its radius such that:

$$\boxed{\pi = \frac{P/2}{R}} \tag{14.1.58}$$

It seems that we own the first algorithm of the calculation of this constant by Archimedes (9713-9788 according to holocene calendar) and whose proof is given below:

Proof 14.1.7. Consider an n-polygon inscribed in a circle (we start with a square of n sides of length $2u_n$ and if we go from a square to an octogone, two times more side, the sides length becomes $2u_{2n}$ and so on...):

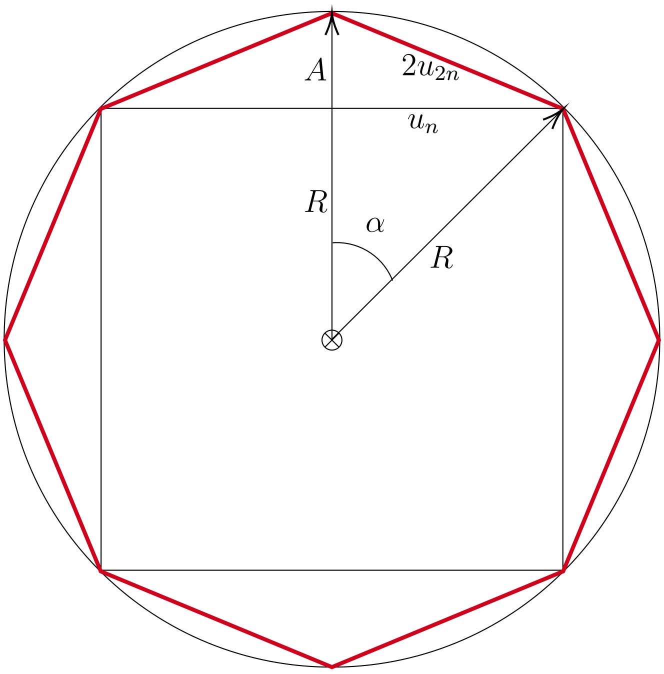

Figure 14.4: **The illustrated principle of Archimedes algorithm**

The principle of Archimedes algorithm is as follows:

Given the perimeter of a regular polygon of n sides inscribed in a circle of radius $R=1/2$ we can see in the figure above that by induction (see section Trigonometry page 2542):

$$P_n = 2nu_n \underset{n\to+\infty}{=} 2\sum R\alpha_i = 2R\sum \alpha_n = 2\frac{1}{2}\sum \alpha_n := \pi \tag{14.1.59}$$

We have for a n-polygon using basic trigonometry:

$$u_n = R\sin(\alpha) = \frac{1}{2}\sin\left(\frac{2\pi}{2n}\right) = \frac{1}{2}\sin\left(\frac{\pi}{n}\right) \tag{14.1.60}$$

and by using Pythagorean theorem:

$$(2u_{2n})^2 = u_n^2 + A^2 \tag{14.1.61}$$

with:

$$A = R - R\cos(\alpha) = \frac{1}{2} - \frac{1}{2}\cos\left(\frac{\pi}{n}\right) \tag{14.1.62}$$

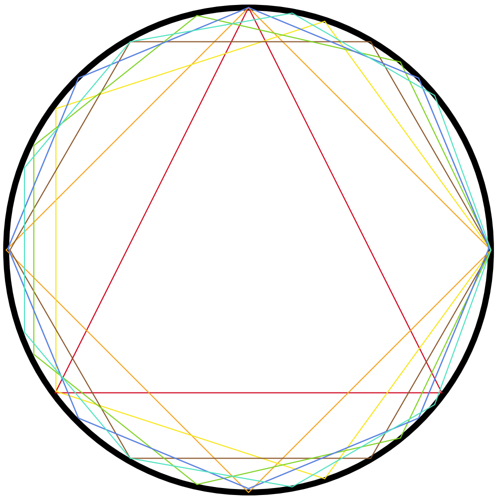
hence:

$$\begin{aligned}4u_{2n}^2 &= \left[\frac{1}{2}\sin\left(\frac{\pi}{n}\right)\right]^2 + \left[\frac{1}{2} - \frac{1}{2}\cos\left(\frac{\pi}{n}\right)\right]^2 = \frac{1}{4}\sin^2\left(\frac{\pi}{n}\right) + \frac{1}{4} - \frac{1}{2}\cos\left(\frac{\pi}{n}\right) + \frac{1}{4}\cos^2\left(\frac{\pi}{n}\right)\\ &= \frac{1}{4}\left[\sin^2\left(\frac{\pi}{n}\right) + \cos^2\left(\frac{\pi}{n}\right)\right] + \frac{1}{4} - \frac{1}{2}\cos\left(\frac{\pi}{n}\right) = \frac{2}{4} - \frac{1}{2}\cos\left(\frac{\pi}{n}\right)\\ &= \frac{1}{2} - \frac{1}{2}\sqrt{1-\sin^2\left(\frac{\pi}{n}\right)} = \frac{1}{2}\left[1 - \sqrt{1-\sin^2\left(\frac{\pi}{n}\right)}\right]\\ &= \frac{1}{2}\left(1-\sqrt{1-4u_n^2}\right)\end{aligned} \tag{14.1.63}$$

Therefore (keep in mind that this is the relation if we assume $R = 1/2$):

$$u_{2n} = \frac{1}{2}\sqrt{\frac{1}{2}\left(1-\sqrt{1-4u_n^2}\right)} \tag{14.1.64}$$

We then just need a computer and several iterations to evaluate with a good accuracy the value of π. Obviously, we use the Heron algorithm to calculate the square root...



■ Q.E.D.

For example for some iterations we have (it's simply by using Pythagoras theorem that we get immediately for the first row below u_n equal to $0.5 \cdot R \cdot \sqrt{2}$):

Sides (n)	u_n	**Perimeter** (estimated π)
4	$u_4 = 0.5 \cdot R \cdot \sqrt{2} = 0.353553$	$2 \cdot 4 \cdot u_4 = 2.828427125$
8	$u_8 = \dfrac{1}{2}\sqrt{\dfrac{1}{2}\left(1-\sqrt{1-4u_4^2}\right)} = 0.191342$	$2 \cdot 8 \cdot u_8 = 3.061467459$
16	$u_{16} = \dfrac{1}{2}\sqrt{\dfrac{1}{2}\left(1-\sqrt{1-4u_8^2}\right)} = 0.097545$	$2 \cdot 16 \cdot u_{16} = 3.121445152$
32	0.049009	3.136548491
64	0.024534	3.140331157
128	0.012271	3.141277251
256	0.006136	3.141513801
512	0.003068	3.14157294
1024	0.001534	3.141587725
2048	0.000767	3.141591422

where we have explicited the mechanism only of the first rows for pedagogical reasons.

Remark

There are a large number of algorithms to compute π. The one shown above, without being the most aesthetic, seems historically to be the first and most simple one.

14.1.6 Euler's Number e

Including the constant π, there are many other important mathematical constant that we need to generate with a computer (nowadays most constant values are stored as is and are not recalculated automatically). Among them, is the "Euler number" denoted by e (see section Functional Analysis page 2289). Let's see how to calculate this number.

Consider the Taylor series (see section Sequences and Series page 1696) for an infinitely differentiable function f given by:

$$f(u)=\sum_{i=0}^{+\infty}\frac{1}{n!}\frac{\mathrm{d}^n f(0)}{\mathrm{d}u^n}u^n \tag{14.1.65}$$

As (see section Differential and Integral Calculus page 1475):

$$\frac{\mathrm{d}^n e^u}{\mathrm{d}u^n}=e^u \tag{14.1.66}$$

Therefore we have:

$$f(u)=e^u=\sum_{i=0}^{+\infty}\frac{1}{n!}\frac{\mathrm{d}^n f}{\mathrm{d}u^n}(0)u^n=\sum_{i=0}^{+\infty}\frac{1}{n!}\frac{\mathrm{d}^n e^u}{\mathrm{d}u^n}(0)u^n=\sum_{i=0}^{+\infty}\frac{1}{n!}1u^n=\sum_{i=0}^{+\infty}\frac{u^n}{n!} \tag{14.1.67}$$

So finally:

$$\boxed{e=\sum_{i=0}^{+\infty}\frac{1}{n!}} \tag{14.1.68}$$

This relation provides an easy algorithm to calculate the Euler number to a given order n of precision.

14.1.7 Stirling's factorial approximation

Obviously, the factorial may be calculated with a simple iteration. However, this kind of method generates an exponential complexity algorithm which is not the best. Then there exists another method:

In mathematics, Stirling's approximation (or Stirling's formula) is an approximation for factorials. It is a very powerful approximation, leading to a very useful result in Statistical Mechanics (see section of the same name page 3554).

There are various approach that lead to different results. We will focus here on the only one that we will use later in theoretical physics and that is the worst easiest approximation.

Either the definition of the factorial:

$$n!=n(n-1)(n-2)\ldots 1 \tag{14.1.69}$$

And according to the properties of logarithms:

$$\ln(n!)=\sum_{m=1}^{n}\ln(m) \tag{14.1.70}$$

If n is very large (but very large) then the previous sum can be approximately written as an integral:

$$\ln(n!)=\sum_{m=1}^{n}\ln(m)\cong\int_{0}^{n}\ln(m)\mathrm{d}m \tag{14.1.71}$$

Solving this integral we get (see section Differential and Integral Calculus page 1534)

$$\ln(n!)\cong\int_{0}^{n}\ln(m)\mathrm{d}m=(m\ln(m)-m)\Big|_{0}^{n} \tag{14.1.72}$$

When $n\gg 1$, the lower limit is negligible and then (approximation that will be very useful in the section of Statistical Mechanics):

$$\ln(n!)\cong n\ln(n)-n\Leftrightarrow n!=e^{n(\ln(n)-1)} \tag{14.1.73}$$

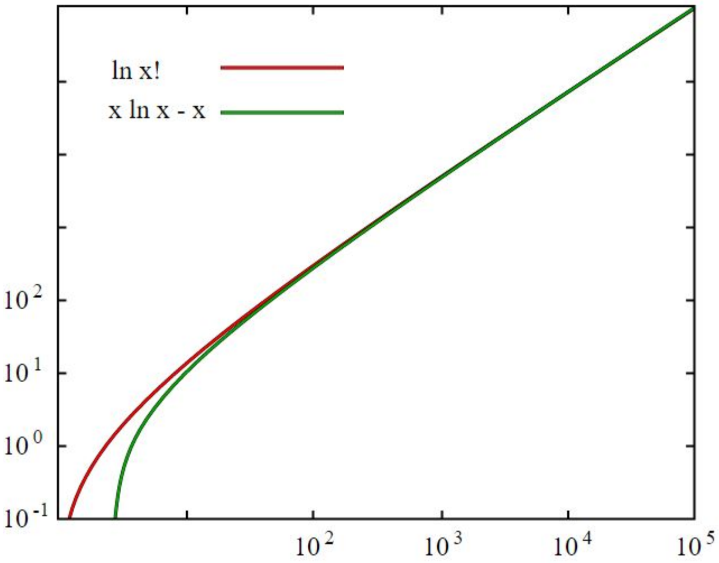


Figure 14.5: **Comparison of logarithmic formulations using Stirling formula**

After a small elementary simplification, we obtain:

$$\boxed{\ln(n!)\cong e^{n\ln(n)}e^{-n}=n^{n}\frac{1}{e^{n}}=\left(\frac{n}{e}\right)^{n}} \tag{14.1.74}$$

The latter relation is useful of course only if we assumes that Euler's constant is a value stored in the machine...

Let us consider the Gamma function (see section Differential and Integral Calculus page 1574):

$$\Gamma_{-1}(x)=\int_0^{+\infty} t^{x-1}e^{-t}\mathrm{d}t \tag{14.1.75}$$

and recall that for integers λ we have:

$$\Gamma(\lambda+1)=\lambda! \tag{14.1.76}$$

We get:

$$\Gamma(\lambda+1)=\int_0^{+\infty} t^{\lambda}e^{-t}\mathrm{d}t \tag{14.1.77}$$

Substituting $y=t/\lambda$ and letting $g(x)=y-\log(y)$ We get:

$$\Gamma(\lambda+1)=\lambda\int_0^{+\infty}(\lambda y)^y e^{-\lambda y}\mathrm{d}y=\lambda^{\lambda+1}\int_0^{+\infty} e^{-\lambda g(y)}\mathrm{d}y \tag{14.1.78}$$

Now we will use Laplace's method of integration (see section Differential and Integral Calculus page 1557) and for this we differentiate twice and get:

$$g'(y)=1-\frac{1}{y}\qquad g''(y)=\frac{1}{y^2} \tag{14.1.79}$$

so that $y^*=1$, $g(y^*)=1$ and $g''(y^*)=1$. Laplace's method now yields to:

$$\Gamma(\lambda+1)\cong\lambda^{\lambda+1}e^{-\lambda g(y^*)}\sqrt{\frac{2\pi}{\lambda g''(y^*)}}=\lambda^{\lambda+1/2}e^{-\lambda}\sqrt{2\pi} \tag{14.1.80}$$

The relation:

$$\boxed{\lambda!\cong\lambda^{\lambda+1/2}e^{-\lambda}\sqrt{2\pi}} \tag{14.1.81}$$

which is known as "Stirling's improved formula".

14.1.8 Linear Systems of Equations

There are many methods for solving systems of linear equations. Most of them have been developed to address particular systems. We will here study for the moment only one, named the "Gauss reduction method" or "Gauss pivot" or "Gauss reduction algorithm" or also "Gauss elimination" which is well suited for solving small systems of linear equations (up to 50 unknowns).

Remarks

R1. The validity of some of the operations that we will perform here to solve linear systems is proved in the section on Linear Algebra. In fact, to be brief, the whole method use vector spaces whose columns are linearly independent vectors.

R2. Recall that linear systems admit a solution if and only if the rank of the augmented matrix is less than or equal to the number of equations (see section Linear Algebra page 1938).

14.1.8.1 One equation with one unknown

We begin for sure with the easiest and smallest possible example... of one equation with one unknown:

$$ax=b \tag{14.1.82}$$

Where a and b are the coefficients of the equation and x is unknown. Solving this equation consists to determine x is according to a and b. If a is not equal to 0 then:

$$x=\frac{b}{a} \tag{14.1.83}$$

is the solution of the equation. If a is equal to zero and if b is different from 0 then the equation above admits no solution. If a and b are equal to zero, then the equation has infinitely many solutions.

14.1.8.2 Two equations with two unknowns

A linear system of two equations with two unknowns can be written as we know:

$$\begin{aligned}a_{11}x_1+a_{12}x_2&=b_1\\a_{21}x_1+a_{22}x_2&=b_2\end{aligned} \tag{14.1.84}$$

Where $a_{11},a_{12},a_{21},a_{22}$ are the coefficients of the equations, x_1 and x_2 are the unknowns.

Remark

The above-used notations have nothing to do with the tensor calculus!

To solve the system following the algorithm that interest us we proceed as follows:

Using elementary algebraic manipulations (addition or subtraction of the various equalities between themselves - operations authorized by the linear independence of vectors-lines) we transform the system into another with one unknown less for one of the both equations given by (for example):

$$\begin{aligned} a_{11}x_1+a_{12}x_2&=b_1\\ 0x_1+a'_{22}x_2&=b'_2 \end{aligned} \tag{14.1.85}$$

The transformation between the two systems:

$$\left.\begin{aligned} a_{11}x_1+a_{12}x_2 &= b_1\\ \\ a_{21}x_1+a_{22}x_2 &= b_2 \end{aligned}\right\} \Rightarrow \left\{\begin{aligned} a_{11}x_1+a_{12}x_2 &= b_1\\ \\ 0x_1+a'_{22}x_2 &= b'_2 \end{aligned}\right. \tag{14.1.86}$$

is simply done by multiplying each coefficient of the first equality by $\dfrac{a_{21}}{a_{11}}$ and subtracting the second line with the resulting equation. This procedure is named "row reduction" or "(naive) Gaussian elimination".

In our case, the element a_{11} is named the "pivot" or "leading coefficient". In others words, if the L_i is the notation for the each line number of the system, what we made is:

$$L_2-\frac{a_{21}}{a_{11}}L_1\rightarrow L_2 \tag{14.1.87}$$

Then, we solve the equation with only one unknown:

$$a'_{22}x_2=b'_2\Leftrightarrow x_2=\frac{b'_2}{a'_{22}} \tag{14.1.88}$$

We can therefore conclude with:

$$a_{11}x_1+a_{12}x_2=b_1\Rightarrow a_{11}x_1+a_{12}\frac{b'_2}{a'_{22}}=b_1\Leftrightarrow x_1=\frac{b_1-a_{12}\dfrac{b'_2}{a'_{22}}}{a_{11}} \tag{14.1.89}$$

But this is not the real algorithm. The real one use the augmented form:

$$\left[\begin{array}{cc|c} a_{11} & a_{12} & b_1\\ a_{21} & a_{22} & b_2 \end{array}\right] \tag{14.1.90}$$

Now we apply $L_2-\dfrac{a_{21}}{a_{11}}L_1\rightarrow L_2$ and $L_1-\dfrac{a_{12}}{a_{22}}L_2\rightarrow L_1$ such that:

$$\left[\begin{array}{cc|c} a_{11}-\dfrac{a_{12}}{a_{22}}a_{21} & 0 & b_1-b_2\dfrac{a_{12}}{a_{22}}\\ 0 & a_{22}-\dfrac{a_{21}}{a_{11}}a_{12} & b_2-b_1\dfrac{a_{21}}{a_{11}} \end{array}\right] \tag{14.1.91}$$

As you can see the matrix has been put in diagonal form! Now to continue, we write:

$$\left[\begin{array}{cc|c} a'_{11} & 0 & b'_1\\ 0 & a'_{22} & b'_2 \end{array}\right] \tag{14.1.92}$$

Now we just apply $\dfrac{1}{a'_{11}}L_1 \rightarrow L_1$ and $\dfrac{1}{a'_{12}}L_2 \rightarrow L_2$ such that:

$$\left[\begin{array}{cc|c} 1 & 0 & \dfrac{b'_1}{a'_{11}} \\ 0 & 1 & \dfrac{b'_2}{a'_{22}} \end{array}\right] \tag{14.1.93}$$

Finally:

$$x_1 = \frac{b'_1}{a'_{11}} \quad \text{and} \quad x_2 = \frac{b'_2}{a'_{22}} \tag{14.1.94}$$

In pseudocode (non-unique and very likely not optimized):

Algorithm 4: Gaussian elimination (naive) pseudocode algorithm

```
Data: $A$,$\vec{b}$
Result: $A'$,$\vec{b}'$
for $j = 1, 2, \ldots, n-1$ do
    for $i = j+1, j+2, \ldots, n$ do
        $m_{ij} = a_{ij}/a_{jj}$;
        for $k = j+1, j+2, \ldots, n$ do
            $a_{ik} = a_{ik} - m_{ij}a_{jk}$;
        $b_i = b_i - m_{ij}b_j$
```

14.1.8.3 Three equations with three unknowns

Now consider the case of the linear systems of three equations with three unknowns:

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + a_{13}x_3 &= b_1 \\ a_{21}x_1 + a_{22}x_2 + a_{23}x_3 &= b_2 \\ a_{31}x_1 + a_{32}x_2 + a_{33}x_3 &= b_3 \end{aligned} \tag{14.1.95}$$

We can subsequently by elementary operations (see section Linear Algebra page 1929 and the previous case) reduce this linear system in the following echelon form system:

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + a_{13}x_3 &= b_1 \\ 0x_1 + a''_{22}x_2 + a''_{23}x_3 &= b''_2 \\ 0x_1 + 0x_2 + a''_{33}x_3 &= b''_3 \end{aligned} \tag{14.1.96}$$

And therefore we can trivially solve the last line:

$$x_3 = \frac{b''_3}{a''_{33}} \tag{14.1.97}$$

And afterwards the second line:

$$x_2 = \frac{b''_2 - a''_{23}x_3}{a''_{22}} = \frac{b''_2 - a''_{23}\dfrac{b''_3}{a''_{33}}}{a''_{22}} \tag{14.1.98}$$

And finally:

$$x_1=\frac{b_1-a_{13}x_3-a_{12}x_2}{a_{11}}=\frac{b_1-a_{13}\dfrac{b_3''}{a_{33}''}-a_{12}\dfrac{b_2''-a_{23}''\dfrac{b_3''}{a_{33}''}}{a_{22}''}}{a_{11}} \tag{14.1.99}$$

Let us return to the systems transformations. It is carried out in two stages:

1. In the first line, we choose a_{11} as the pivot and we eliminate the coefficients a_{21} and a_{31} as follows:

   We have to multiply each coefficient of the first line by $\dfrac{a_{21}}{a_{11}}$ and subtract this result of the second line and therefore a_{21} disappears.

   Similarly, by multiplying the coefficients of the first line by $\dfrac{a_{31}}{a_{11}}$, and subtracting the result obtained from the third line, a_{31} disappears.

   The linear system of equations can therefore be written as:

   $$\begin{aligned}a_{11}x_1+a_{12}x_2+a_{13}x_3&=b_1\\0x_1+a_{22}'x_2+a_{23}'x_3&=b_2'\\0x_1+a_{32}'x_2+a_{33}''x_3&=b_3'\end{aligned} \tag{14.1.100}$$

2. The second step is to treat the linear system of two equations with two unknowns formed by the second and third lines of the previous system and that, in choosing a_{22}' as pivot. This method of resolution can seem complicated but it has the advantage of being generalized and be applied to solve linear systems of n equations in n unknowns.

✍**Example:**

Let us see an example taken on Wikipedia (helps to copy/paste boring LaTeX...):

$$\begin{cases}2x+y-z=8 & (L1)\\-3x-y+2z=-11 & (L2)\\-2x+y+2z=-3 & (L3)\end{cases} \tag{14.1.101}$$

Now we put:

$$\begin{aligned}L_2+\frac{3}{2}L_1&\rightarrow L_2\\L_3+L_1&\rightarrow L_3\end{aligned} \tag{14.1.102}$$

Therefore we get:

$$\begin{cases}2x+y-z=8\\\frac{1}{2}y+\frac{1}{2}z=1\\2y+z=5\end{cases} \tag{14.1.103}$$

Now we put:

$$L_3+-4L_2 \rightarrow L_3 \tag{14.1.104}$$

Therefore we get:

$$\begin{cases} 2x+\ y-\ z=8 \\ \frac{1}{2}y+\frac{1}{2}z=1 \\ -\ z=1 \end{cases} \tag{14.1.105}$$

To continue we put:

$$\begin{gathered} L_2+\frac{1}{2}L_3 \rightarrow L_2 \\ L_1-L_3 \rightarrow L_1 \end{gathered} \tag{14.1.106}$$

Therefore we get:

$$\begin{cases} 2x+\ y=7 \\ \frac{1}{2}y=\frac{3}{2} \\ -z=1 \end{cases} \tag{14.1.107}$$

We put:

$$\begin{gathered} 2L_2 \rightarrow L_2 \\ -L_3 \rightarrow L_3 \end{gathered} \tag{14.1.108}$$

Therefore we get:

$$\begin{cases} 2x+y=7 \\ y=3 \\ -z=1 \end{cases} \tag{14.1.109}$$

And finally we put:

$$\begin{gathered} L_1-L_2 \rightarrow L_1 \\ \frac{1}{2}L_1 \rightarrow L_1 \end{gathered} \tag{14.1.110}$$

To get:

$$\begin{cases} x=2 \\ y=3 \\ -z=1 \end{cases} \tag{14.1.111}$$

So this is again an application of the row reduction method (or Gaussian elimination).

For sure when you know that such systems can be solved using just a matrix inversion with a vector multiplication (see section Linear Algebra page 1929) all that stuff will be almost useless for most employees working in non-maths jobs.

Remark

If the procedure of solution showed earlier above gives a row where $0=$ 'something non-zero' or $0=0$, then it means that the system has no solution and respectively infinitely many solutions. We will see in the section of Linear Algebra that this is explained by the fact that the matrix of the system is a singular matrix (i.e. there is no inverse).

By the way... two matrix applications that have the same dimensions (number of rows and columns) but different components that can be obtained one from each other by linear operations are said to be "equivalent matrices". For example, taken from the example above, the matrix equivalent to the system, i.e.:

$$\begin{bmatrix} 2 & 1 & -1 \\ -3 & -1 & 2 \\ -2 & 1 & 2 \end{bmatrix} \tag{14.1.112}$$

is equivalent to:

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix} \tag{14.1.113}$$

What is denoted:

$$\begin{bmatrix} 2 & 1 & -1 \\ -3 & -1 & 2 \\ -2 & 1 & 2 \end{bmatrix} \equiv \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix} \tag{14.1.114}$$

14.1.8.4 n equations with n unknowns

To simplify the writing, the coefficients will always be noted a_{ij} and not a'_{ij}, a''_{ij}, etc. at each stage of the calculation.

Given the linear system (we could also represent it as an augmented matrix to simplify the notations):

$$\begin{aligned} a_{11}x_1+a_{12}x_2+\ldots+a_{1n}x_n&=b_1\\ a_{21}x_1+a_{22}x_2+\ldots+a_{2n}x_n&=b_2\\ &\ldots\\ &\ldots\\ a_{n1}x_1+a_{n2}x_2+\ldots+a_{nn}x_n&=b_n \end{aligned} \tag{14.1.115}$$

We will choose a_{11} as the pivot to eliminate $a_{21}, a_{31}, \ldots, a_{n1}$. Then, removing $a_{32}, a_{42}, \ldots, a_{n2}$ is performed by taking a_{22} as a pivot. Last pivot to consider is obviously $a_{n-1,n-1}$, it helps eliminate $a_{n,n-1}$. The system then takes the form:

$$\begin{aligned} a_{11}x_1+a_{12}x_2+\ldots+a_{1n}x_n&=b_1\\ 0\cdot x_1+a_{22}x_2+\ldots+a_{2n}x_n&=b_2\\ &\ldots\\ &\ldots\\ 0\cdot x_1+0\cdot x_2+\ldots+a_{nn}x_n&=b_n \end{aligned} \tag{14.1.116}$$

And we can therefore solve the last equation, then the fore last equation, and so on up to the first one.

This method must however be fine-tuned to avoid pivots with 0 values. The trick is therefore to switch the order in which the equations are written to choose the pivot coefficient whose absolute value is the largest. Thus, in the first column, the better is pivot is the coefficient such that a_{j1}:

$$|a_{j1}|>|a_{i1}| \quad \forall i \tag{14.1.117}$$

It is taken to a_{11} by permutation of first lines and j-th lines. Removal of the rest of the first column can then be performed. Then, we begin again with the $n-1$ remaining equations.

✍**Example:**

A last example with 4 unknowns with a different representation that may help (we hope so!). Consider the following linear system:

$$\begin{bmatrix} 1 & -2 & 1 & 2 & 8\\ 2 & 3 & -2 & 3 & 14\\ 4 & -1 & 3 & -1 & 7\\ 3 & 2 & -4 & 5 & 5 \end{bmatrix}\cdot\begin{bmatrix} x\\ y\\ z\\ t \end{bmatrix}=\begin{bmatrix} 8\\ 14\\ 7\\ 5 \end{bmatrix} \tag{14.1.118}$$

Let us apply the Gauss elimination algorithm:

$$
\begin{gathered}
\begin{array}{rrrrrlll}
1 & -2 & 1 & 2 & 8 & |(-2) & |(-4) & |(-3) \\
2 & 3 & -2 & 3 & 14 & \leftarrow + & & \\
4 & -1 & 3 & -1 & 7 & \leftarrow & + & \\
3 & 2 & -4 & 5 & 5 & \leftarrow & & +
\end{array}
\\[2ex]
\begin{array}{rrrrrll}
1 & -2 & 1 & 2 & 8 & & \\
0 & 7 & -4 & -1 & -2 & |(-1) & |(-\frac{8}{7}) \\
0 & 7 & -1 & -9 & -25 & \leftarrow + & \\
0 & 8 & -7 & -1 & -9 & \leftarrow & +
\end{array}
\\[2ex]
\begin{array}{rrrrrl}
1 & -2 & 1 & 2 & 8 & \\
0 & 7 & -4 & -1 & -2 & \\
0 & 0 & 3 & -8 & -23 & |\,\frac{17}{3} \\
0 & 0 & -17 & 1 & -47 & \leftarrow +
\end{array}
\\[2ex]
\begin{array}{rrrrr}
1 & -2 & 1 & 2 & 8 \\
0 & 7 & -4 & -1 & -2 \\
0 & 0 & 3 & -8 & -23 \\
0 & 0 & 0 & -\frac{133}{3} & \frac{-532}{3}
\end{array}
\end{gathered}
\tag{14.1.119}
$$

And the last steps should be obvious to the reader (if not we can detail them on request as always!).

To summarize, given a $n \times n$ matrix A and n-vector $\vec{b}$, the following algorithm reduces the system of linear equations $A\vec{x} = \vec{b}$ to an equivalent upper triangular system. A and $\vec{b}$ are overwritten with the coefficients and right-hand side, respectively, of the reduced system.

Algorithm 5: Gaussian elimination

```
Input: $A$,$\vec{b}$
for $j = 1, 2, \ldots$ to $n-1$ do
    for $i = j+1, j+2, \ldots$ to $n$ do
        $m_{ij} = a_{ij}/a_{jj}$;
        for $k = j+1, j+2, \ldots$ to $n$ do
            $a_{ik} = a_{ik} - m_{ij}a_{jk}$;
        $b_i = b_i - m_{ij}b_j$
```

14.1.9 Polynomials

The basics polynomials with real coefficients has been studied in the section of Calculus quite in details (see page 1368). Here we will address only the digital aspect of some problems related to polynomials (that is to say elementary algorithms or formulas useful for some operations not included by default in most computer programming languages).

Apart from the addition and subtraction of polynomials which we assume as trivial (aside the optimization of the complexity aside as the Horner scheme), we will see how to multiply and divide two polynomials.

Let's first see how to multiply two polynomials.

Let:

$$\begin{aligned} f(x) &= a_0 + a_1 x + a_2 x^2 + \ldots + a_n x^n \\ g(x) &= b_0 + b_1 x + b_2 x^2 + \ldots + b_m x^m \end{aligned} \tag{14.1.120}$$

Therefore:

$$\begin{aligned} f(x)g(x) &= a_0 b_0 + (a_0 b_1 + a_1 b_0)x + (a_0 b_2 + a_1 b_1 + a_2 b_0)x^2 + \ldots \\ &= c_0 + c_1 x + c_2 x^2 + \ldots \end{aligned} \tag{14.1.121}$$

With for $k = 0, 1, 2, \ldots, n+m$:

$$\boxed{c_k = \sum_{i=0} a_i b_{k-i} \qquad k \in \{0, 1, 2, \ldots, n+m\}} \tag{14.1.122}$$

it was easy...

The second case of interests to us now is the Euclidean division of polynomials (see section Calculus page 1374).

Let us take again:

$$\begin{aligned} f(x) &= a_0 + a_1 x + a_2 x^2 + \ldots + a_n x^n \\ g(x) &= b_0 + b_1 x + b_2 x^2 + \ldots + b_m x^m \end{aligned} \tag{14.1.123}$$

but with the condition that $n \geq m$ that is to say $\text{deg}(f(x)) < \text{deg}(g(x))$.

The division can be written as we know (see the section of Number Theory or Calculus at page 1374):

$$f(x) = g(x)q(x) + r(x) \tag{14.1.124}$$

with:

$$\text{deg}(r(x)) < \text{deg}(g(x)) \tag{14.1.125}$$

otherwise $r(x)=0$.

It is normally known beforehand (since proved in the section Calculus again at page 1374) that we have:

$$\deg(q(x))=n-m \tag{14.1.126}$$

and:

$$\deg(r(x))<m \tag{14.1.127}$$

We have therefore by definition $q(x)$ that is the quotient of the division and $r(x)$ the remainder of the Euclidean division of $f(x)$ by $g(x)$.

Therefore, nothing prevents us from writing in the most general possible way:

$$\begin{aligned}q(x)&=q_0+q_1x+a_2x^2+\ldots+q_{n_m}x^{n-m}\\ r(x)&=r_0+r_1x+r_2x^2+\ldots+r_{m-1}x^{m-1}\end{aligned} \tag{14.1.128}$$

To prove the expression of different q_i, we have preferred for educational reasons to use a specific example (see below) whose result will be generalized.

✍**Example:**

Let:

$$\begin{aligned} f(x) &= a_0 + a_1 x + a_2 x^2 + a_3 x^3 + a_4 x^4 \\ g(x) &= b_0 + b_1 x + b_2 x^2 \end{aligned} \tag{14.1.129}$$

So of what we have said before, we get (starting point):

$$\begin{aligned} q(x) &= q_0 + q_1 x + q_2 x^2 \\ r(x) &= r_0 + r_1 x \end{aligned} \tag{14.1.130}$$

Using the fact that (as a reminder):

$$f(x) = g(x)q(x) + r(x) \tag{14.1.131}$$

So we have almost immediately:

$$\begin{aligned} q_2 &= \frac{a_4}{b_2} \\ r_1(x) &= (a_3 - q_2 b_1)x^3 + (a_2 - q_2 b_0)x^2 + a_1 x + a_0 = c_3 x^3 + c_2 x^2 + c_1 x + c_0 \end{aligned} \tag{14.1.132}$$

Then (still proceeding in the same way):

$$\begin{aligned} q_1 &= \frac{c_3}{b_2} \\ r_2(x) &= (c_1 - q_1 b_1)x^2 + (c_1 - q_1 b_0)x + c_0 = c'_2 x^2 + c'_1 x + c'_0 \end{aligned} \tag{14.1.133}$$

And finally:

$$\begin{aligned} q_0 &= \frac{c'_2}{b_2} \\ r_3(x) &= r(x) = (c'_1 - q_0 b_1)x + (c'_0 - q_0 b_0) = c''_1 x + c'_1 x + c''_0 \end{aligned} \tag{14.1.134}$$

So in general:

$$q_{n-m} = \frac{a_n}{b_m} \tag{14.1.135}$$

As:

$$f(x) = g(x)q(x) + r(x) \Leftrightarrow r(x) = f(x) - q(x)g(x) \tag{14.1.136}$$

The first remainder is then:

$$\begin{aligned} r_1(x) &= f(x) - q_{n-m}g(x) \\ &= \underbrace{(a_n - q_{n-m}b_m)}_{=0}x^n + (a_{n-1} - q_{n-m}b_{m-1})x^{n-1} + (a_{n-2} - q_{n-m}b_{m-2})x^{n-2} + \ldots \\ &+ (a_{n-m} - q_{n-m}b_0)x^{n-m} + a_{n-m-1}x^{n-m-1} + \ldots + a_0 \\ &= c_{n-1}x^{n-1} + c_{n-2}x^{n-2} + \ldots + c_0 \end{aligned} \tag{14.1.137}$$

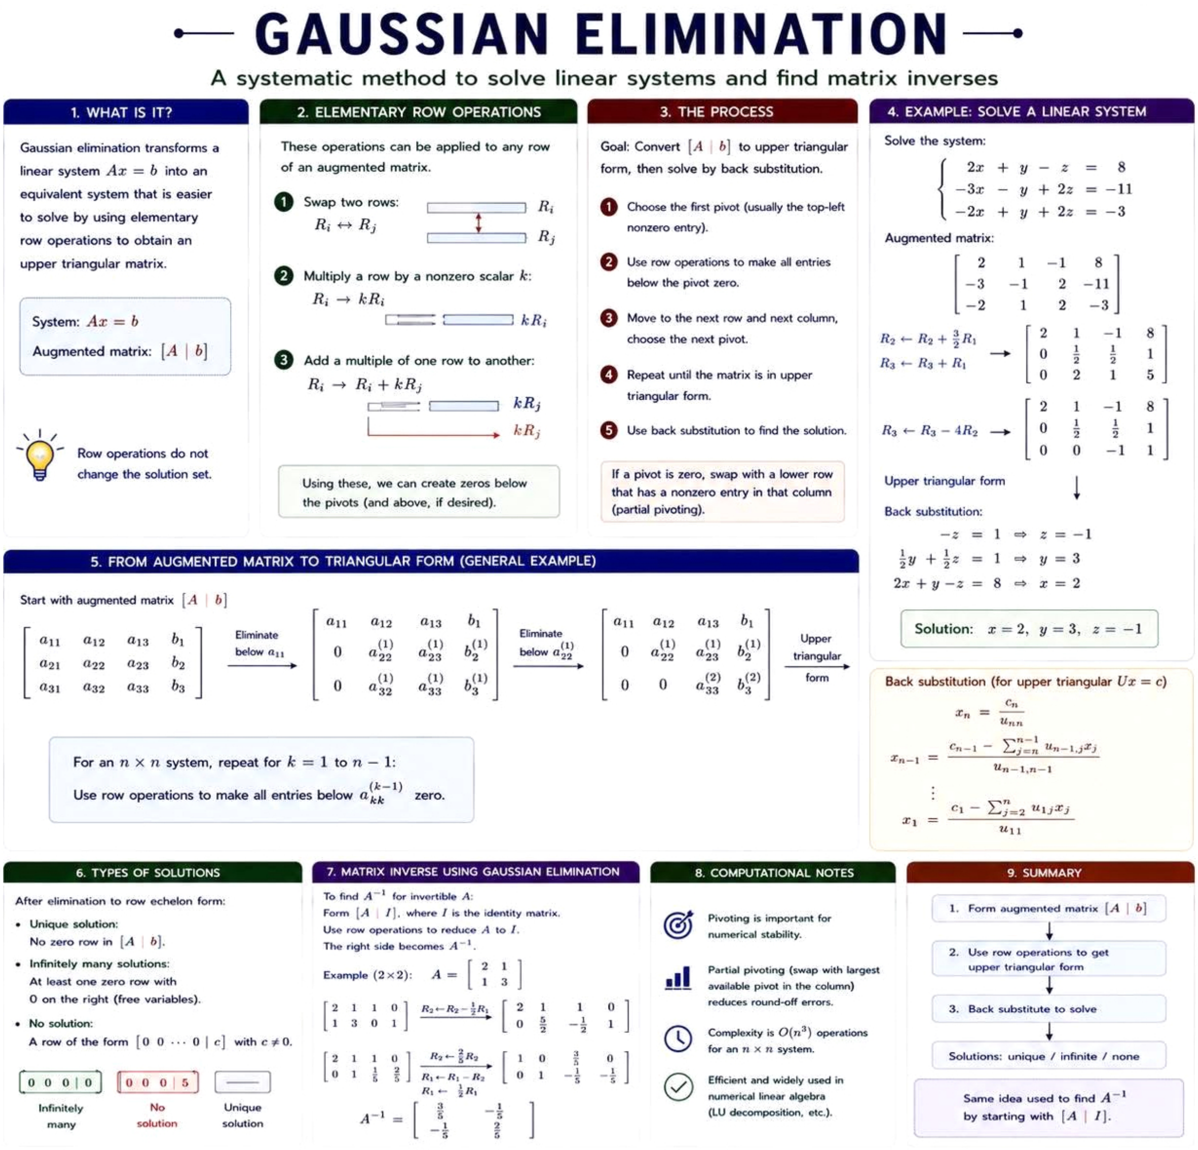
After:

$$q_{n-m-1}=\frac{c_{n-1}}{b_m} \tag{14.1.138}$$

The second remainder is then:

$$\begin{aligned}
r_2(x)&=r_1(x)-q_{n-m-1}g(x)\\
&=\underbrace{(c_{n-1}-q_{n-m-1}b_m)}_{=0}x^{n-1}+(c_{n-2}-q_{n-m-1}b_{m-1})x^{n-2}+(c_{n-3}-q_{n-m-1}b_{m-2})x^{n-3}+\ldots\\
&+(c_{n-m-1}-q_{n-m-1}b_0)x^{n-m-1}+c_{n-m-2}x^{n-m-2}+\ldots+c_0\\
&=c'_{n-2}x^{n-2}+c'_{n-3}x^{n-3}+\ldots+c'_0
\end{aligned} \tag{14.1.139}$$

and so on... we continue until $\deg(r_k(x))<m$.



GAUSSIAN ELIMINATION

A systematic method to solve linear systems and find matrix inverses

1. WHAT IS IT?

Gaussian elimination transforms a linear system $Ax=b$ into an equivalent system that is easier to solve by using elementary row operations to obtain an upper triangular matrix.

System: $Ax=b$

Augmented matrix: $[A \mid b]$

Row operations do not change the solution set.

2. ELEMENTARY ROW OPERATIONS

These operations can be applied to any row of an augmented matrix.

① Swap two rows: $R_i \leftrightarrow R_j$

② Multiply a row by a nonzero scalar k: $R_i \rightarrow kR_i$

③ Add a multiple of one row to another: $R_i \rightarrow R_i + kR_j$

Using these, we can create zeros below the pivots (and above, if desired).

3. THE PROCESS

Goal: Convert $[A \mid b]$ to upper triangular form, then solve by back substitution.

① Choose the first pivot (usually the top-left nonzero entry).

② Use row operations to make all entries below the pivot zero.

③ Move to the next row and next column, choose the next pivot.

④ Repeat until the matrix is in upper triangular form.

⑤ Use back substitution to find the solution.

If a pivot is zero, swap with a lower row that has a nonzero entry in that column (partial pivoting).

4. EXAMPLE: SOLVE A LINEAR SYSTEM

Solve the system:

$$\begin{cases} 2x + y - z = 8\\ -3x - y + 2z = -11\\ -2x + y + 2z = -3\end{cases}$$

Augmented matrix:

$$\begin{bmatrix} 2 & 1 & -1 & 8\\ -3 & -1 & 2 & -11\\ -2 & 1 & 2 & -3\end{bmatrix}$$

$$\begin{array}{l} R_2 \leftarrow R_2+\frac{3}{2}R_1\\ R_3 \leftarrow R_3+R_1\end{array} \rightarrow \begin{bmatrix} 2 & 1 & -1 & 8\\ 0 & \frac{1}{2} & \frac{1}{2} & 1\\ 0 & 2 & 1 & 5\end{bmatrix}$$

$$R_3 \leftarrow R_3-4R_2 \rightarrow \begin{bmatrix} 2 & 1 & -1 & 8\\ 0 & \frac{1}{2} & \frac{1}{2} & 1\\ 0 & 0 & -1 & 1\end{bmatrix}$$

Upper triangular form ↓

Back substitution:

$$\begin{aligned} -z &= 1 \Rightarrow z=-1\\ \tfrac{1}{2}y+\tfrac{1}{2}z &= 1 \Rightarrow y=3\\ 2x+y-z &= 8 \Rightarrow x=2\end{aligned}$$

Solution: $x=2,\ y=3,\ z=-1$

5. FROM AUGMENTED MATRIX TO TRIANGULAR FORM (GENERAL EXAMPLE)

Start with augmented matrix $[A \mid b]$

$$\begin{bmatrix} a_{11} & a_{12} & a_{13} & b_1\\ a_{21} & a_{22} & a_{23} & b_2\\ a_{31} & a_{32} & a_{33} & b_3\end{bmatrix} \xrightarrow{\text{Eliminate below } a_{11}} \begin{bmatrix} a_{11} & a_{12} & a_{13} & b_1\\ 0 & a_{22}^{(1)} & a_{23}^{(1)} & b_2^{(1)}\\ 0 & a_{32}^{(1)} & a_{33}^{(1)} & b_3^{(1)}\end{bmatrix} \xrightarrow{\text{Eliminate below } a_{22}^{(1)}} \begin{bmatrix} a_{11} & a_{12} & a_{13} & b_1\\ 0 & a_{22}^{(1)} & a_{23}^{(1)} & b_2^{(1)}\\ 0 & 0 & a_{33}^{(2)} & b_3^{(2)}\end{bmatrix} \xrightarrow[\text{form}]{\text{Upper triangular}}$$

For an $n \times n$ system, repeat for $k=1$ to $n-1$:

Use row operations to make all entries below $a_{kk}^{(k-1)}$ zero.

Back substitution (for upper triangular $Ux=c$)

$$\begin{aligned} x_n &= \frac{c_n}{u_{nn}}\\ x_{n-1} &= \frac{c_{n-1}-\sum_{j=n}^{n-1} u_{n-1,j}x_j}{u_{n-1,n-1}}\\ &\vdots\\ x_1 &= \frac{c_1-\sum_{j=2}^{n} u_{1j}x_j}{u_{11}}\end{aligned}$$

6. TYPES OF SOLUTIONS

After elimination to row echelon form:

- Unique solution:
  No zero row in $[A \mid b]$.
- Infinitely many solutions:
  At least one zero row with 0 on the right (free variables).
- No solution:
  A row of the form $[0\ 0 \cdots 0 \mid c]$ with $c \neq 0$.

Infinitely many

No solution

Unique solution

7. MATRIX INVERSE USING GAUSSIAN ELIMINATION

To find A^{-1} for invertible A:
Form $[A \mid I]$, where I is the identity matrix.
Use row operations to reduce A to I.
The right side becomes A^{-1}.

Example (2×2): $A=\begin{bmatrix} 2 & 1\\ 1 & 3\end{bmatrix}$

$$\begin{bmatrix} 2 & 1 & 1 & 0\\ 1 & 3 & 0 & 1\end{bmatrix} \xrightarrow{R_2\leftarrow R_2-\frac{1}{2}R_1} \begin{bmatrix} 2 & 1 & 1 & 0\\ 0 & \frac{5}{2} & -\frac{1}{2} & 1\end{bmatrix}$$

$$\begin{bmatrix} 2 & 1 & 1 & 0\\ 0 & 1 & \frac{1}{5} & \frac{2}{5}\end{bmatrix} \xrightarrow[\substack{R_1\leftarrow R_1-R_2\\ R_1\leftarrow \frac{1}{2}R_1}]{R_2\leftarrow \frac{2}{5}R_2} \begin{bmatrix} 1 & 0 & \frac{3}{5} & 0\\ 0 & 1 & -\frac{1}{5} & -\frac{1}{5}\end{bmatrix}$$

$$A^{-1}=\begin{bmatrix} \frac{3}{5} & -\frac{1}{5}\\ -\frac{1}{5} & \frac{2}{5}\end{bmatrix}$$

8. COMPUTATIONAL NOTES

Pivoting is important for numerical stability.

Partial pivoting (swap with largest available pivot in the column) reduces round-off errors.

Complexity is $O(n^3)$ operations for an $n \times n$ system.

Efficient and widely used in numerical linear algebra (LU decomposition, etc.).

9. SUMMARY

1. Form augmented matrix $[A \mid b]$
↓
2. Use row operations to get upper triangular form
↓
3. Back substitute to solve
↓
Solutions: unique / infinite / none

Same idea used to find A^{-1} by starting with $[A \mid I]$.

14.1.10 Regression Techniques

Regressions are very useful and very important tools for statisticians, engineers, computer scientists, marketing analysts, physicists, physicians, economists wishing to establish a law of correlation between two (or more) variables, do a qualitative analysis, an extrapolation or even to separate signal form noise (as every point outside the regression will be considered as being noise).

There are many regression methods: the simple solution of first degree equations (when only two points of measurement are known) to equations that permits to obtain from a large number of points information that are essential to the establishment of a linear regression, polynomial, logistic or other law (or function).

Let us give a list of the most used regressions techniques used in business and administrations (whose mathematical models are not all shown in this section yet but will be when we will have more time):

1. **Simple Linear Regression (SLR) model**[1] with one (**Univariate Linear Regression (CLR)**) or more variables (**Multiple Linear Regression (MLR)**) based on the method of least[2] squares with binary or continuous variables with response variable and coefficients[3] belonging to $\mathbb{R}$. Presented in detail in this section of the book (implicitly this model contains the interactions between variables and also some non-linear models).

2. **Gaussian linear regression model** (statistical approach of linear regression based on the method of least squares) with binary or continuous variables with response variable also belonging to $\mathbb{R}$. When a regression model assumes that the errors are normally distributed, we speak commonly of **general linear model**. Presented in detail in this section of the book. A gaussian linear regression model is a special case of the generalized linear model (GLM).

3. **Weighted least squares regression model** is used in the case where the assumption $\mathrm{V}(\varepsilon_i)=\sigma_\varepsilon^2$ of Gaussian linear regression is not satisfied. The purpose is to apply a transformation trick using simple weights (see further below for more details), to keep this assumption valid.

4. **Nonlinear regression models** with binary or continuous variables with response variable in $\mathbb{R}$. Presented in detail in this section of the if they can be reduced to linear case or not but then no interactions of explanatory variables. Otherwise based on quasi-Newton techniques type or Gauss-Newton presented also this section.

5. **Polynomial regression model by the method of B-splines** or of the collocation polynomial with response variable in $\mathbb{R}$. The most common case is to restrict ourselves to the

---

[1] Also named **Classical Linear Regression (CLR)**

[2] Don't confuse "estimation methods" like OLS (ordinary least squares), TLS (total least squares), ML (maximum likelihood), REML (restricted maximum likelihood), PQL (penalized quasi-likelihood) with "regression methods"!

[3] If the coefficients are required to be non-negative, we speak then of **Non-Negative Least Squares** and if we require the coefficient to be in some bounds then we speak of **Bounded-Variable Least-Squares** or **Constrained Least Squares**.

restriction of third order splines and then we speak of **restricted cubic splines regression (RCS)**. Presented in detail in this section of the book.

6. **Logistic regression models** (binomial/multinomial/ordinal regressions) with binary, nominal variables (categorical) or ordinal or continuous with response variable bounded between 0 and 1. Presented summarily and naively in this section of the book. A logistic, probit or robit (robust version of the logit model) regression model is a special case of the generalized linear model (GLM).

7. **Logic regression model** is a (generalized) regression methodology that is primarily applied when most of the covariates in the data to be analysed are binary. The goal of logic regression is to find predictors that are Boolean (logical) combinations of the original predictors.

8. **Principal Component Regression (PCR)** instead of regressing the dependent variable on the explanatory variables directly, the principal components of the explanatory variables are used as regressors. Therefore PLS can reduces the number of predictors (dimensional reduction) to a smaller set of uncorrelated components and performs least squares regression on these components.

9. **Partial Least squares Regression (PLR)** is a statistical method that bears some relation to principal components regression. They differ in the methods used in extracting factor scores. In short, principal components regression produces like weight matrix reflecting the covariance structure between the predictor variables, while partial least squares regression produces like a weight matrix reflecting the covariance structure between the predictor and response variables.

10. **Counting Poisson regression** (Poisson MLE, PMLE, GLM, Poisson-quasi-Lindley) or **negative binomial regression** (binomial MLE and QGPMLE) model with binary, nominal (categorical) or ordinal or continuous variables with positive integer answer in $\mathbb{N}$. All the regression models that do not assume the errors to me normally distributed, but following other well-known statistical distributions, are known under the name of **Generalized Linear regression Models (GLM)**.

11. **Beta regression** is commonly used by practitioners to model variables that assume values in the standard unit interval $[0,1]$. It is based on the assumption that the dependent variable is beta-distributed and that its mean is related to a set of regressors through a linear predictor with unknown coefficients and a link function. A beta regression model is also a special case of the generalized linear model (GLM).

12. **Simplex regression** is actually (12019 according to holocene calendar) considered as a more robust and flexible alternative to the beta regression dedicated of rates or proportions. This regression is based on the simplex distribution, hence it's name...

13. **Orthogonal linear regression model** (or Deming regression) that is used as complement to the paired T-test to check the stability of the measuring instruments in laboratories. This is a case where the explanatory and dependent variables are tainted with uncertainty. Notice that at the opposite of all regression techniques listed above and below that have no assumptions about the distribution of the predictor (independent) variables, the orthogonal linear regression is as far as we know, the only regression technique that has an assumption of the distribution of the predictor!

14. **Total linear regression model** (also named Total Least Squares (TLS)) that is a generalization of Deming and Orthogonal linear regression. TLS aims to minimize the total geometric distance between the data points and the best-fit line rather than just the vertical distance as in Ordinary Least Squares (OLS).

15. **Quantile regression model** (very useful in the medical and economic fields) based on the same idea as the regression by the method of least squares, but where we do not minimizes the sum of squared errors from the average, but the sum of absolute errors from a given quantile (median or other). It's also used sometimes to get rid of extreme values.

16. **Theil–Sen estimator method** also named Sen's slope estimator or Slope selection method or Single median method or Kendall robust line-fit method or Kendall–Theil robust line... that is a very simple method for robustly fitting a line to a set of points (simple linear regression) that chooses the median a_M of the slopes of all lines through pairs of two-dimensional sample points. For the estimate of the intercepts the USGS recommends the following calculation $b = y_M - a_M x_M$. That's all... it's quite simple in fact.

17. **Least Absolute Deviation (LAD) regression model** that use absolute values rather than square errors. But absolute values are difficult to work with in mathematics (especially Calculus) as absolute values results in discontinuous derivatives that cannot be treated analytically

18. **LOESS (LOcally Estimated Scatterplot Smoothing)** and **LOWESS (LOcally WEighted Scatterplot Smoothing)** are two strongly related nonparametric regression methods. These methods are purely numerical (does therefore not provide any unique formula) and are performed by fitting simple models to localized subsets (we speak then of "segmented regression"). In fact, one of the chief attractions of this method is that is not required to specify a global function of any form to fit a model to the data, only to fit segments of the data.

19. **Multivariate adaptive regression splines (MARS)** (the term "MARS" is trademarked and licensed to Salford Systems. In order to avoid trademark infringements, many open source implementations of MARS are named "Earth"...) and as it names describes it well... is uses splines to interpolate and also extrapolate know data.

20. **Bayesian linear regression model** is an approach to linear regression in which the statistical analysis is undertaken within the context of Bayesian inference, that means we have some prior knowledge about the regression coefficients and the error term.

21. **Ridge regression model**[4] that use a trick on the information matrix X^TX (see further below) by adding a constant in it. But the constraints of usage are quite boring (no intercept and coefficients normalized) that make it quite difficult to interpret. In fact it is a special case of a regression family named **regularized linear regression models** and the underlying mathematical trick can be applied ton any general linear model (simple linear regression, logistic regressions, etc.).

22. **Least Absolute Shrinkage and Selection Operator model (LASSO)**[5] that is based on the same ideas as that of the Ridge regression model and therefore also a special case

---

[4] Technically speaking it's not a regression but a method of regularization! It's only a procedure affecting (sometimes improving) the method of fitting. It can be applied to almost any kind of regression.

[5] Technically speaking it's also not a regression but a method of regularization!

of the Regularized Linear Regression models family (the only point that differs with the Ridge is that the theoretical model has somewhere a exponent equal to 1 for LASSO when for it is equal to 2 for Ridge).

23. **Elastic net regression model**[6] is only a mathematical mixture of the LASSO and Ridge regression. This model therefore also belongs to the family of Regularized Linear Regression models.

24. **Two-Stage Least Squares (2SLS) Regression** is used when the dependent variable's error terms are correlated with the independent variables. Additionally, it is useful when there are feedback loops in the model. In a first stage this regression builds instrumental variables that are uncorrelated with the error terms to compute estimated values of the problematic predictor(s), and then in a second stage uses those computed values to estimate a linear regression model of the dependent variable. This technique is used mainly in **Structural equation modelling (SEM)**.

25. **Moderated Multiple Regression (MMR)** is used when one of the explicative variable has an interaction with another variable (product) that is continuous or dichotomous. The variable that interacts with the normal explicative variable is named the "moderator variable". A common error in practice is to make a confusion between Moderated Multiple Regression and a nested hierarchical model (i.e. Nested ANOVA).

26. **Independent Component Regression (ICR)** is just a simple linear regression but based on a previous dimensional reduction of the exogenous variables based on an independent component analysis (ICA). That means the final model used the most explaining variance independent component as exogenous variables. Indeed, the reader must remember that PCA creates uncorrelated components but "uncorrelated" doesn't mean "independent" (!!!) as we have proved it in the section Statistics.

27. **Support Vector Machine regression (SVMr)** use the concept of Support Vector Machine classification technique to evaluate existing values and interpolate new one.

28. **Bootstrap or Jackknife regression model**[7] using all previous models and then by resampling techniques (see further below) gives the possibility to have robust estimators that could in some situations be hard to get analytically.

29. **Isotonic regression** is a technique of fitting a free-form line to a sequence of observations under the following constraints: the fitted free-form line has to be non-decreasing (or non-increasing) everywhere, and it has to lie as close to the observations as possible.

30. **Cox regression model** is a non-parametric technique based on the assumption of constant proportional hazard to analyse the survival rate in clinical trials.

31. **Threshold Regression Models** is a parametric technique used to relax the assumption of constant proportional hazard of the Cox regression and therefore obviously also used to analyse the survival rate in clinical trials.

... and ... for a given number of these approaches we differentiate mathematical models taking into account the censored data and uncensored data, constraints coefficients (like the fact that they should be non-negative, like non-negative least square NNLS, or sum up to 1 or any other specific constraint that we categorize under the name of Bounded-Variable Least Squares (BVLS) or Constrained Least Square). This makes a bunch of theories/models to study in final and this is why this subsection is one of the biggest of the whole book and that some models are given in some other sections of the book (especially in the Statistics section).

---

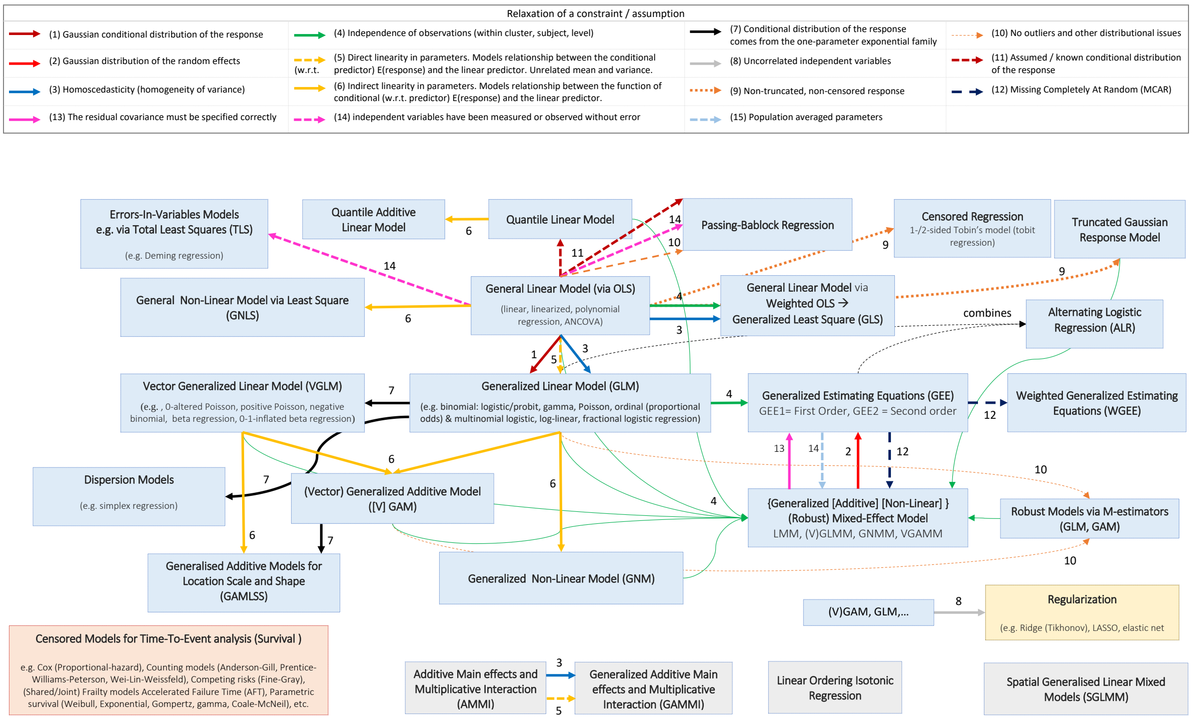
[6] Technically speaking it's also not a regression but a method of regularization!

[7] Technically speaking they are not "regression models" but methods related to the process of estimation!

Remark

There are also submodels families. Like the Panel Ordinary Least Squares (Panel OLS), linear mixed models (LMM) that includes fixed effects models (FE models) and random effects models (RE models) and mixed effect models (ME models) and longitudinal regression models. There is also Nonlinear Mixed Model (NLMM) that includes all linear mixed models, and Generalized Linear Models (to not be confuse with "general linear models) that includes NLMM. And also convex regression, etc.

Here is a figure that summarize quite well the different regressions and their relationships (thanks to Adrian Olszweski for having authorized us to reproduce it!):



Relaxation of a constraint / assumption
(1) Gaussian conditional distribution of the response
(4) Independence of observations (within cluster, subject, level)
(7) Conditional distribution of the response comes from the one-parameter exponential family
(10) No outliers and other distributional issues
(2) Gaussian distribution of the random effects
(w.r.t.
(5) Direct linearity in parameters. Models relationship between the conditional predictor) E(response) and the linear predictor. Unrelated mean and variance.
(8) Uncorrelated independent variables
(11) Assumed / known conditional distribution of the response
(3) Homoscedasticity (homogeneity of variance)
(6) Indirect linearity in parameters. Models relationship between the function of conditional (w.r.t. predictor) E(response) and the linear predictor.
(9) Non-truncated, non-censored response
(12) Missing Completely At Random (MCAR)
(13) The residual covariance must be specified correctly
(14) independent variables have been measured or observed without error
(15) Population averaged parameters

Figure 14.6: Synoptic summary and relationships between various regression models (author: Adrian Olszweski)

For a more exhaustive list of regression techniques and their relationships, the reader can refer to the Data Science mind map at page 6770.

Caution!!!!!!!!! There is a huge difference in science by only adjusting a mathematical function (having no real physical variables) to observations, and modelling observations with a physical model, i.e. including real physical variables and physics laws (the first one is naive, and most of time wrong, and the second one is obviously robust and most of time less wrong)!

Finally, note that in the linear regression, explanatory variables form a linear expression but that does not mean they are themselves linear. Thus, if we consider the two expressions below:

$$\begin{aligned} y &= a + be^{x_1} + c\log(x_2) \\ y &= a + x_1^{\beta_1} + x_2 e^{\beta_2} \end{aligned} \tag{14.1.140}$$

the first is linear in the parameters but the second is not!

Finally, a word on a technique sometimes used for qualitative interpretation of the influential of explanatory variables trough their coefficients for simple or multivariate linear regressions:

When the amplitudes of some explanatory variables (continuous!) have very different orders of magnitudes this raises a big problem of interpretation of the influence of each variable by reading their coefficient and also generates problems of calculations precision in algorithms because of differences in size order and thus also generates rounding errors!

The traditional idea is then to center-reduce all the values of explanatory variables which helps greatly to interpretation of the influence of these variables (but we must then leave out the interpretation of the numerical value of the response variable). But take care to a common trap!!! Once the theoretical model obtained from normalized (center-reduced) variables, the new values to explain should be obtained by having previously centered-reduced the new explanatory values but by subtracting the old average and reducing by the old standard deviations of respectively each of the injected explanatory variable in the model!

14.1.10.1 Univariate linear regression model

We will present here several algorithms (methods) useful and known in experimental science (we have already discussed about some of them during our study of statistics). The goal is to express the linear relation between two variables x (explanatory variable) and y (response variable) independently by a "linear model LM" as simple as possible (otherwise it would take hundreds of pages to introduce the topic!).

Remark

Writing this textbook we have hesitated a long time to put regression techniques in the Statistics section. But because in practice the choice of the type of regression is empirical it has seem to us most convenient to put this subject here.

Definition (#14.1.558): In univariate regression we have:

D1. x is the independent variable or "explanatory variable" also named "covariate" or "predictor" (in economics "exogenous variable"...). The x values are set by the experimenter and are assumed to be known without error.

D2. y is the dependent variable or "explained variable" (e.g. the answer of the analyser) also named in economy "endogenous variable". y values are most of time measured with an error (bias) of measurement. One goal of regression is to estimate precisely this error.

We seek a relation of the form:

$$y=f(x)=ax+b \tag{14.1.141}$$

This is the equation of a straight line (affine function), hence the term "linear regression" where a is named in the study framework of regression techniques: "regression coefficient" instead of "slope" as seen in previous sections.

In real life, linear relations are an exception because most phenomenon are nonlinear in reality and even non-continuous in certain situations... Furthermore, it is not because they are linear in a given interval of measurements that are still linear at a smaller-scale or larger scale (zoom bias)!

However, in practice we make transformation to linearise functions either by elementary algebraic transformations like those used by spreadsheets softwares (e.g. Microsoft® Excel®) as for example the linearisation of a logarithmic function by making a simple change of variables:

$$y=a\underbrace{\ln(x)}_{:=x}+b=ax+b \tag{14.1.142}$$

or as:

$$y=a\underbrace{e^x}_{:=x}+b=ax+b \tag{14.1.143}$$

or as:

$$y=a\underbrace{\sin(x)}_{:=x}+b=ax+b \tag{14.1.144}$$

or for power and exponential functions by also making a small algebraic manipulation with the properties of logarithms as proved in the section of Functional Analysis at page 2284 (under the assumption that a is strictly positive):

$$\begin{gathered}y=ax^b\Rightarrow\ln(y)=\ln(ax^b)=\ln(a)+\ln(x^b)=b\ln(x)+\ln(a)\\ y=ae^{bx}\Rightarrow\ln(y)=\ln(ae^{bx})=\ln(a)+\ln(e^{bx})=bx+\ln(a)\end{gathered}\tag{14.1.145}$$

or by making Taylor series approximations (see section Sequences and Series page 1696).

Caution! One of the biggest misconception and myth by data scientistis (but not by statisticians) is that for linear regression the independent variables need to have linear relationship with the y variable. No! Linear regression refers to the fact that the equation is linear in the coefficients, not necessarily the predictor themselves. This means that the model can handle predictors that are transformed (e.g. squared, logarithmic) as long as the equation remains linear in the parameters. For example, a quadratic model (with squared terms) still falls under linear regression as long as the model is linear in therms of the coefficients (betas)!

We will see during our study of Multiple Linear Regression further below at page 6384 how to deal with polynomial regression and Fourier series regression.

Remark

If we seek to determine the value of y for an unmeasured x and lying beyond the original interval of measurement, then we speak of "extrapolation" or in more complicated cases of "forecast with prediction interval for x". We will see that further below.

14.1.10.1.1 Regression line

In the common way to make an univariate linear regression of the type:

$$y=f(x)=ax+b\tag{14.1.146}$$

there exist multiple methods.

This first and most simple method in our point of view relies on the properties of covariance and mean (see section Statistics page 597) and is widely used among others in elementary finance (but in fact in any filed where there are some statistics).

Consider X,Y two variables, one of which depends on the other (often it is y that depends on x). According to the covariance bilinearity property (see section Statistics page 602) we recall that we have from:

$$\text{cov}(X,Y)=\text{E}(XY)+\text{E}(X)\text{E}(Y)\tag{14.1.147}$$

the following relation:

$$\begin{aligned}\text{cov}(X,Y)&=\text{cov}(X,aX+b)\\&=\text{E}(aX^2+bX)-\text{E}(X)\text{E}(aX+b)=\text{E}(aX^2)+\text{E}(bX)-\text{E}(X)(\text{E}(aX)+\text{E}(b))\\&=\text{E}(aX^2)+\text{E}(bX)-\text{E}(X)(\text{E}(aX)+\text{E}(b))\\&=a\text{E}(X^2)+b\text{E}(X)-\text{E}(X)(a\text{E}(X)+b)=a\text{E}(X^2)+b\text{E}(X)-a\text{E}(X)^2-b\text{E}(X)\\&=a\left(\text{E}(X^2)-\text{E}(X)^2\right)=a\text{cov}(X,X)=a\text{V}(X)\end{aligned} \tag{14.1.148}$$

So it comes for the regression coefficient (we will reuse this relation during our study of yield of a portfolio according to Sharpe model in the section Economy):

$$a=\frac{\text{cov}(X,Y)}{\text{V}(X)} \tag{14.1.149}$$

Either in a more explicit form which that we will use later (using the relation determined earlier at page 6323):

$$\boxed{a=\frac{\text{E}(x_k-\bar{x})(y_k-\bar{y})}{\dfrac{1}{n}\displaystyle\sum_k(x_k-\bar{x})^2}=\frac{\dfrac{1}{n}\displaystyle\sum_k(x_k-\bar{x})(y_k-\bar{y})}{\dfrac{1}{n}\displaystyle\sum_k(x_k-\bar{x})^2}=\frac{\displaystyle\sum_k(x_k-\bar{x})(y_k-\bar{y})}{\displaystyle\sum_k(x_k-\bar{x})^2}} \tag{14.1.150}$$

To determine the intercept we use the properties of the expected mean as proved in the section Statistics (see page 585):

$$\text{E}(Y)=\text{E}(aX+b)=\text{E}(aX)+\text{E}(b)=a\text{E}(X)+b \tag{14.1.151}$$

Therefore we have b as:

$$\boxed{b=\text{E}(Y)-a\text{E}(X)} \tag{14.1.152}$$

14.1.10.1.2 Ordinary Least Squares Method (OLSM)

Due to the error on y, the experimental points, of coordinates (x_k,y_k) do not lie exactly on the theoretical line. We can therefore find the equation of the experimental line passing closest to these points.

The "least squares method" (LSM) will be under the particular study we are interested in, to look for the values of the parameters a,b that minimize the sum of squares of residual e_i (also named as we already know "Sum of Squared Residuals" (SSR) or "Sum of Squared Errors" (SSE)) between the observed values y_k and the theoretical calculated values y'_k. We then speak sometimes about the "least squares method of ordinate deviations"...:

$$\text{SSR}=\sum_{k=1}^{n}(y_k-y'_k)^2 \tag{14.1.153}$$

where n is the number of measured points and the theoretical values given by:

$$y'_k = ax_k + b \tag{14.1.154}$$

Therefore written explicitly:

$$\text{SSR} = \sum_{k=1}^{n} (y_k - ax_k - b)^2 := \Phi(a,b) \tag{14.1.155}$$

This relation shows the sum of squared deviations as a function of the parameters a, b. When this function is minimal (extremal), the derivatives with respect to these parameters cancels:

$$\begin{cases} \dfrac{\partial \Phi(a,b)}{\partial a} = -2\displaystyle\sum_{k=1}^{n} x_k (y_k - ax_k - b)) = 0 \\ \dfrac{\partial \Phi(a,b)}{\partial b} = -2\displaystyle\sum_{k=1}^{n} (y_k - ax_k - b)) = 0 \end{cases} \tag{14.1.156}$$

Remark

This method of minimum research (optimization) is named "method of Lagrange multipliers" in the world of Economy (we will detail this method further below). In our example SSR is the scalar value that will be used as Lagrange multiplier.

Therefore after simplification and rearrangement:

$$\begin{cases} b\displaystyle\sum_{k=1}^{n} x_k + a\sum_{k=1}^{n} x_k^2 = \sum_{k=1}^{n} x_k y_k \\ bn + a\displaystyle\sum_{k=1}^{n} x_k = \sum_{k=1}^{n} y_k \end{cases} \tag{14.1.157}$$

The above system is named "normal equations". This is a linear system of two equations with two unknowns. Let us write to simplify the notation:

$$\bar{x} = \frac{1}{n}\sum_{k=1}^{n} x_k \qquad \bar{y} = \frac{1}{n}\sum_{k=1}^{n} y_k \tag{14.1.158}$$

The system becomes:

$$\begin{cases} bn\bar{x} + a\displaystyle\sum_{k=1}^{n} x_k^2 = \sum_{k=1}^{n} x_k y_k \\ b + a\bar{x} = \bar{y} \end{cases} \tag{14.1.159}$$

From the second line we get without surprise:

$$b = \bar{y} - a\bar{x} = \text{E}(Y) - a\text{E}(X) \tag{14.1.160}$$

By replacing in the first line, we get:

$$\begin{aligned}
&(\bar{y}-a\bar{x})n\bar{x}+a\sum_{k=1}^{n}x_k^2=\sum_{k=1}^{n}x_ky_k \Leftrightarrow n\bar{x}\bar{y}-na\bar{x}^2+a\sum_{k=1}^{n}x_k^2=\sum_{k=1}^{n}x_ky_k\\
&\Leftrightarrow a=\frac{\displaystyle\sum_{k=1}^{n}x_ky_k-n\bar{x}\bar{y}}{\displaystyle\sum_{k=1}^{n}x_k^2-n\bar{x}^2}=\frac{\displaystyle n\sum_{k=1}^{n}x_ky_k-\sum_{k=1}^{n}x_k\sum_{k=1}^{n}y_k}{\displaystyle n\sum_{k=1}^{n}x_k^2-\left(\sum_{k=1}^{n}x_k\right)^2}
\end{aligned}\tag{14.1.161}$$

From there we get from the second line:

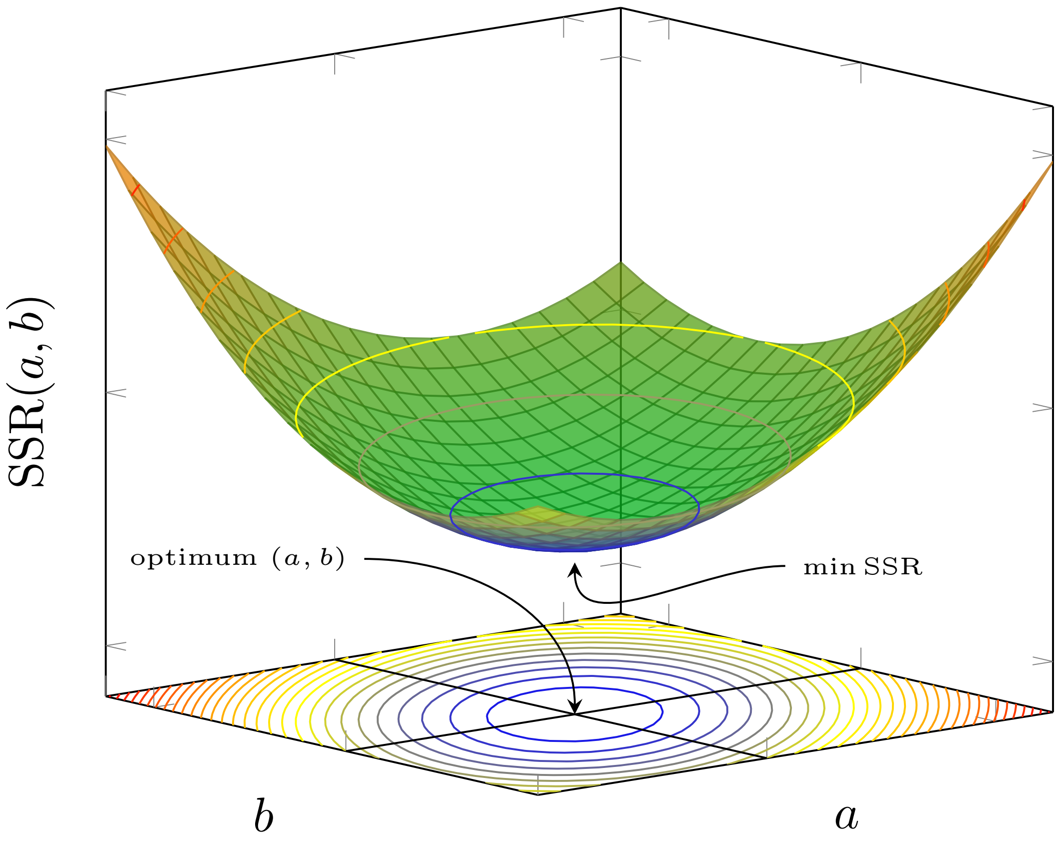
$$\begin{aligned}
b&=\frac{1}{n}\sum_{k=1}^{n}y_k-\frac{\displaystyle n\sum_{k=1}^{n}x_ky_k-\sum_{k=1}^{n}x_k\sum_{k=1}^{n}y_k}{\displaystyle n\sum_{k=1}^{n}x_k^2-\left(\sum_{k=1}^{n}x_k\right)^2}\frac{1}{n}\sum_{k=1}^{n}x_k\\
&=\frac{\displaystyle\left(n\sum_{k=1}^{n}x_k^2-\left(\sum_{k=1}^{n}x_k\right)^2\right)\frac{1}{n}\sum_{k=1}^{n}y_k-\left(n\sum_{k=1}^{n}x_ky_k-\sum_{k=1}^{n}x_k\sum_{k=1}^{n}y_k\right)\frac{1}{n}\sum_{k=1}^{n}x_k}{\displaystyle n\sum_{k=1}^{n}x_k^2-\left(\sum_{k=1}^{n}x_k\right)^2}\\
&=\frac{\displaystyle\sum_{k=1}^{n}x_k^2\sum_{k=1}^{n}y_k-\sum_{k=1}^{n}x_k\sum_{k=1}^{n}x_ky_k}{\displaystyle n\sum_{k=1}^{n}x_k^2-\left(\sum_{k=1}^{n}x_k\right)^2}
\end{aligned}\tag{14.1.162}$$

Thus, the terms of the slope and intercept of the straight line equation are:

$$\boxed{a=\frac{\displaystyle n\sum_{k=1}^{n}x_ky_k-\sum_{k=1}^{n}x_k\sum_{k=1}^{n}y_k}{\displaystyle n\sum_{k=1}^{n}x_k^2-\left(\sum_{k=1}^{n}x_k\right)^2}\qquad b=\frac{\displaystyle\sum_{k=1}^{n}x_k^2\sum_{k=1}^{n}y_k-\sum_{k=1}^{n}x_k\sum_{k=1}^{n}x_ky_k}{\displaystyle n\sum_{k=1}^{n}x_k^2-\left(\sum_{k=1}^{n}x_k\right)^2}}\tag{14.1.163}$$

The last two relations are used by a majority of spreadsheet softwares such as in the English version of Microsoft® Excel® 11.8346 when using the `REGRESSION( )` function. The term b (the y-intercept) may be obtained directly with the `INTERCEPT( )` function and a with the `SLOPE( )` function and the whole with the `LINEST( )` function.

In reality most softwares use the general case to find (a, b) based on the Newton-Gradient descent (see page 6678) where it seeks for the minimum of the SSR as illustrated below:



Here for information an interesting little list of some very practical case with this spreadsheet software (because requested a lot):

- For a straight line:

  a: = `SLOPE(y, x)`
  b: = `INTERCEPT(y, x)`

- For a logarithmic function (we see here again the change of variable given at the before):

  a: = `INDEX(LINEST(y, LN (x)), 1)`
  b: = `INDEX(LINEST(y, LN (x)), 1, 2)`

- For a power function (once again we see the change of variable given at the beginning):

  a: = `EXP(INDEX(LINEST(LN(y),LN(x)),1,2))`
  b: = `INDEX(LINEST(LN(y),LN(x)),1)`

- For an exponential function (we also find the change of variable given at the beginning):

  a: = `EXP(INDEX(LINEST(LN(y),x),1,2))`
  b: = `INDEX(LINEST(LN(y),x),1)`

Remark

We must keep in mind that the line of least squares, which can best summarize the cloud of observations points by minimizing SSR, necessarily passes through the center of gravity of the cloud, that is to say, by an average point that corresponds rarely to an observation (mean average of abscissas and ordinates).

Caution! Keep in mind that least squared and linear regression are note the same! Least squares is a method to estimate the parameters. Linear regression is a model. Least squares is one method used to estimate the parameters in Linear Regression. There are other methods as well like Maximum Likelihood that we will see later!

14.1.10.1.3 Univariate Regression Variance Analysis

Before starting it is important that the reader abandons immediately the possible reflex that would be to try to bring by successive analogies the regression ANOVA we will see right now to the categorical ANOVA we have studied in the section Statistics (see page 1001)!

Let us start with:

$$y=ax+b \tag{14.1.164}$$

Either in discrete form:

$$y_k=ax_k+b \tag{14.1.165}$$

As well as by the construction of the least squares method we have the following relation:

$$\bar{y}_k=a\bar{x}_k+b \tag{14.1.166}$$

Now we assume that each measured value is attached by an error such that:

$$y_k=ax_k+b+e_k \tag{14.1.167}$$

Either by subtracting the last two relations:

$$y_k-\bar{y}=a(x_k-\bar{x})+e_k\Leftrightarrow e_k=(y_k-\bar{y})-a(x_k-\bar{x}) \tag{14.1.168}$$

Now let us go through an intermediate result. Remember that we obtained earlier:

$$\begin{cases}\dfrac{\partial\Phi(a,b)}{\partial a}=-2\displaystyle\sum_{k=1}^{n}x_k(y_k-ax_k-b))=0\\ \dfrac{\partial\Phi(a,b)}{\partial b}=-2\displaystyle\sum_{k=1}^{n}(y_k-ax_k-b))=0\end{cases} \tag{14.1.169}$$

And therefore:

$$\begin{cases}\displaystyle\sum_{k=1}^{n}x_k(y_k-ax_k-b))=0\\ \displaystyle\sum_{k=1}^{n}(y_k-ax_k-b))=0\end{cases} \tag{14.1.170}$$

By replacing b by its value:

$$b=\bar{y}-a\bar{x} \tag{14.1.171}$$

We therefore get:

$$\begin{cases}\displaystyle\sum_{k=1}^{n}x_k(y_k-ax_k-\bar{y}+a\bar{x}))=\sum_{k=1}^{n}x_k((y_k-\bar{y})-a(x_k-\bar{x}))=0\\ \displaystyle\sum_{k=1}^{n}(y_k-ax_k-\bar{y}+a\bar{x}))=\sum_{k=1}^{n}((y_k-\bar{y})-a(x_k-\bar{x}))=0\end{cases} \tag{14.1.172}$$

Multiplying the second line above by $\bar{x}$ and by subtracting from the first we get:

$$\sum_{k=1}^{n} x_k((y_k-\bar{y})-a(x_k-\bar{x}))-\bar{x}\sum_{k=1}^{n}((y_k-\bar{y})-a(x_k-\bar{x})) \tag{14.1.173}$$

Therefore after rearrangement:

$$\sum_{k=1}^{n}(x_k-\bar{x})((y_k-\bar{y})-a(x_k-\bar{x}))=0 \tag{14.1.174}$$

Now we go back to:

$$y_k-\bar{y}=a(x_k-\bar{x})+e_k \tag{14.1.175}$$

If we put it all square and summing for all observations, we get:

$$\sum_{k=1}^{n}(y_k-\bar{y})^2=a^2\sum_{k=1}^{n}(x_k-\bar{x})^2+2a\sum_{k=1}^{n}(x_k-\bar{x})e_k+\sum_{k=1}^{n}e_k^2 \tag{14.1.176}$$

Therefore:

$$\sum_{k=1}^{n}(y_k-\bar{y})^2=a^2\sum_{k=1}^{n}(x_k-\bar{x})^2+2a\sum_{k=1}^{n}(x_k-\bar{x})((y_k-\bar{y})-a(x_k-\bar{x}))+\sum_{k=1}^{n}e_k^2 \tag{14.1.177}$$

But we have shown just before the double product was equal to zero. Therefore:

$$\sum_{k=1}^{n}(y_k-\bar{y})^2=a^2\sum_{k=1}^{n}(x_k-\bar{x})^2+\sum_{k=1}^{n}e_k^2 \tag{14.1.178}$$

This last relation is named "ANOVA equation" or "variance analysis equation". In fact, it is the sums of squares. We would need to divide it by n to obtain biased variances.

This last relation is often written:

$$\boxed{\text{SST}=\text{SSE}+\text{SSR}} \tag{14.1.179}$$

where SST is the "total sum of squares", SSE the "sum of square errors" and SSR "sum of squares residuals".

$$\begin{aligned}\sum_{k=1}^{n}(y_k-\bar{y})^2&=\sum_{k=1}^{n}(ax_k-a\bar{x})^2+\sum_{k=1}^{n}e_k^2=\sum_{k=1}^{n}(ax_k+b-a\bar{x}-b)^2+\sum_{k=1}^{n}e_k^2\\&=\sum_{k=1}^{n}(ax_k+b-\bar{y})^2+\sum_{k=1}^{n}e_k^2\end{aligned} \tag{14.1.180}$$

Let us note now the estimated y_k that minimize the errors such that the error is null in a different way and let us named that the "a priori linear model":

$$\hat{y}_k=ax_k+b \tag{14.1.181}$$

Hence the equality we will reuse several times (it is just previous relations without error term):

$$a^2\sum_{i=k}^{n}(x_k-\bar{x})^2:=\sum_{i=k}^{n}(\hat{y}_k-\bar{y})^2 \tag{14.1.182}$$

It is indeed important in practice to differentiate the a priori model that does not take into account the errors of the real model that does!

Because of the previous equality the relation:

$$\sum_{k=1}^{n}(y_k-\bar{y})^2=\sum_{k=1}^{n}(ax_k-a\bar{x})^2+\sum_{k=1}^{n}e_k^2 \tag{14.1.183}$$

Can be written:

$$\sum_{k=1}^{n}(y_k-\bar{y})^2=\sum_{i=k}^{n}(\hat{y}_k-\bar{y})^2+\sum_{k=1}^{n}e_k^2 \tag{14.1.184}$$

More explicitly:

$$\boxed{\sum_{k=1}^{n}(y_k-\bar{y})^2=\sum_{i=k}^{n}(\hat{y}_k-\bar{y})^2+\sum_{k=1}^{n}(y_k-\hat{y}_k)^2} \tag{14.1.185}$$

This last relation can be represented graphically as follows:

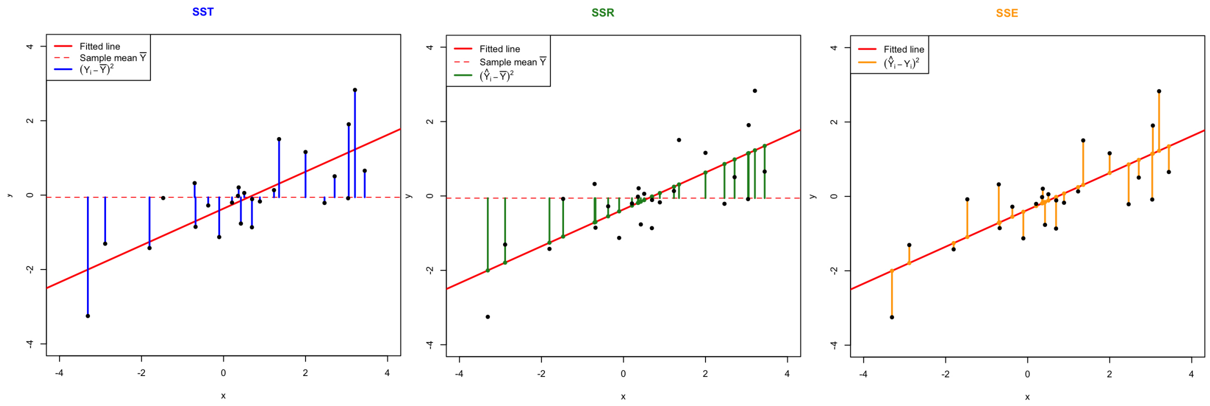


Figure 14.7: **Graphical representation of respectively SST, SSE, SSR**

The last relation is sometimes denoted also in the literature in a most educational way as follows:

$$\sum_{k=1}^{n}(y_k-\bar{y})^2=\sum_{i=k}^{n}(f_k-\bar{y})^2+\sum_{k=1}^{n}(y_k-f_k)^2 \tag{14.1.186}$$

which is just another way to write the variance decomposition (implicit variance):

$$\text{SST}=\text{SSE}+\text{SSR} \tag{14.1.187}$$

and it then comes immediately the relation sometimes used in practice to calculate residues (knowing the calculated values and measured values):

$$\sum_{k=1}^{n}e_k^2=\sum_{i=k}^{n}(y_k-\bar{y})^2-\sum_{i=k}^{n}(\bar{y}_k-\bar{y})^2 \tag{14.1.188}$$

It is important to remember that the above relation between SST, SSE and SSR are valid only in the case of a linear model!

It is also important to note that in this particularly variance decomposition we have:

$$\sum_{k=1}^{n} e_k^2 \neq \sum_{i=k}^{n}(y_k-\hat{y})^2 \tag{14.1.189}$$

Remember now that we have proved in the section Statistics, we found that the correlation coefficient was given (defined) by:

$$R_{X,Y}=\frac{\text{cov}(X,Y)}{\sqrt{\text{V}(X)\text{V}(Y)}} \Rightarrow R_{X,Y}^2=\frac{(\text{cov}(X,Y))^2}{\text{V}(X)\text{V}(Y)}=\frac{(\text{cov}(X,Y))^2}{\sigma_X^2\sigma_Y^2} \tag{14.1.190}$$

Or else since we have shown above that (remember that the indicated variance is an estimated variance in practice!):

$$a=\frac{\text{cov}(X,Y)}{\text{V}(X)} \tag{14.1.191}$$

We can therefore write the correlation coefficient in the form:

$$R_{X,Y}^2=\frac{(\text{cov}(X,Y))^2}{\text{V}(X)\text{V}(Y)}=\frac{a^2\text{V}(X)^2}{\text{V}(X)\text{V}(Y)}=\frac{a^2\text{V}(X)}{\text{V}(Y)} \tag{14.1.192}$$

So we deduce from this using the relations established in the section of statistics:

$$\begin{aligned}R_{X,Y}^2&=\frac{(\text{cov}(X,Y))^2}{\text{V}(X)\text{V}(Y)}=\frac{(\text{E}((x_k-\bar{x})(y_k-\bar{y}))^2}{\text{E}((x_k-\bar{x})^2)\text{E}((y_k-\bar{y})^2)}=\frac{\left(\dfrac{1}{n}\sum_k(x_k-\bar{x})(y_k-\bar{y})\right)^2}{\dfrac{1}{n}\displaystyle\sum_k(x_k-\bar{x})^2\frac{1}{n}\sum_k(y_k-\bar{y})^2}\\&=\frac{\left(\displaystyle\sum_k(x_k-\bar{x})(y_k-\bar{y})\right)^2}{\displaystyle\sum_k(x_k-\bar{x})^2\sum_k(y_k-\bar{y})^2}\end{aligned} \tag{14.1.193}$$

Remember that we proved above that:

$$a=\frac{\displaystyle\sum_k(x_k-\bar{x})(y_k-\bar{y})}{\displaystyle\sum_k(x_k-\bar{x})^2} \quad \text{and} \quad a^2\sum_{i=k}^{n}(x_k-\bar{x})^2:=\sum_{i=k}^{n}(\hat{y}_k-\bar{y})^2 \tag{14.1.194}$$

Therefore:

$$R_{X,Y}^2=\frac{\left(\displaystyle\sum_k(x_k-\bar{x})(y_k-\bar{y})\right)^2}{(x_k-\bar{x})^2(y_k-\bar{y})^2}=\frac{a^2\displaystyle\sum_k(x_k-\bar{x})^2}{\displaystyle\sum_k(y_k-\bar{y})^2}=\frac{\displaystyle\sum_k(\hat{y}_k-\bar{y})^2}{\displaystyle\sum_k(y_k-\bar{y})^2} \tag{14.1.195}$$

that is to say:

$$\boxed{R^2_{X,Y}=\frac{\text{SSE}}{\text{SST}}=\frac{\displaystyle\sum_k(\hat{y}_k-\bar{y})^2}{\displaystyle\sum_k(y_k-\bar{y})^2}}\qquad(14.1.196)$$

Remark

This formulation of the correlation coefficient is extremely useful because, unlike the statistical formulation, the latter generalizes immediately to the multiple linear regression we will see a further below.

And in the framework of regression models here are some typical cases of the value of the linear correlation coefficient with the first two lines and non-linear for the third line:

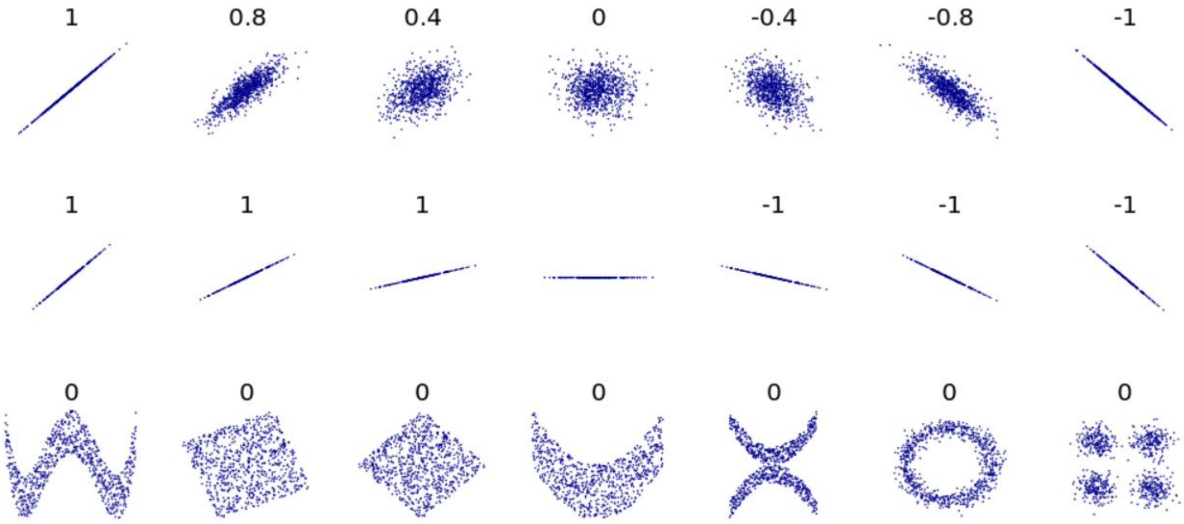

Figure 14.8: **Some values of the linear correlation coefficient (source: Wikipedia)**

Finally let us indicate that we also find very often the linear correlation coefficient as follows in softwares and literature:

$$R^2_{X,Y}=\frac{\text{SSE}}{\text{SST}}=\frac{\text{SST}-\text{SSR}}{\text{SST}}-1=1-\frac{\text{SSR}}{\text{SST}}=1-\frac{\sigma^2_{\varepsilon}}{\text{V}(y)}=1-\frac{\displaystyle\sum_k(y_k-f_k)^2}{\displaystyle\sum_k(y_k-\bar{y})^2}\qquad(14.1.197)$$

The last form highlights better that if the sum of the squares of residues SSR residues is zero, the measures are perfectly modelised by a linear relation in the range of study considered.

Remark

Some softwares communicate the "predicted R-squared" defined as:

$$R^2_{p.}=1-\frac{\text{PRESS}}{\text{SST}}\qquad(14.1.198)$$

where PRESS, the "predicted residual sum of squares", is a form of cross-validation (see further below page 6428) used in regression analysis to provide a summary measure of the fit of a model to a sample of observations that were not themselves used to estimate the model. It is calculated as the sums of squares of the prediction residuals for those observations:

$$\text{PRESS}=\sum_k (y_k-\hat{y}_{k,-k})^2 \tag{14.1.199}$$

Therefore PRESS differs from the sum of squares of the residual error in that each fitted value, $\hat{y}_k$, for PRESS is obtained from the remaining $n-1$ observations.

Given this procedure, the PRESS statistic can be calculated for a number of candidate model structures for the same dataset, with the lowest values of PRESS indicating the best structures. Models that are over-parametrised (over-fitted) would tend to give small residuals for observations included in the model-fitting but large residuals for observations that are excluded.

Modern textbooks use the average of the PRESS such that we define the "Leave-One-Out Cross-Validation score" (LOOCV) or "ordinary cross-validation" (OCV):

$$\text{LOOCV}=\frac{1}{n}\text{PRESS}=\frac{1}{n}\sum_k (y_k-\hat{y}_{k,-k})^2 \tag{14.1.200}$$

Finally, note that the ordinate value is not involved in the value of the correlation coefficient since (bilinearity property of covariance as proved in the section Statistics at page 597):

$$\text{cov}(X,Y)=\text{cov}(X,aX+b)=a\text{cov}(X,X)+b\text{cov}(X,1)=a\sigma_X^2+b\cdot 0 \tag{14.1.201}$$

14.1.10.1.4 F-test for Regression (significance test for linear regression)

Now comes a part that interests us mainly for practical scientific laboratories tests!!!

If your graduate statistical training was anything like mine, you learned ANOVA in one class and Linear Regression in another. My professors would often say things like « *ANOVA is just a special case of Regression* » but give vague answers when pressed. Let us see why!

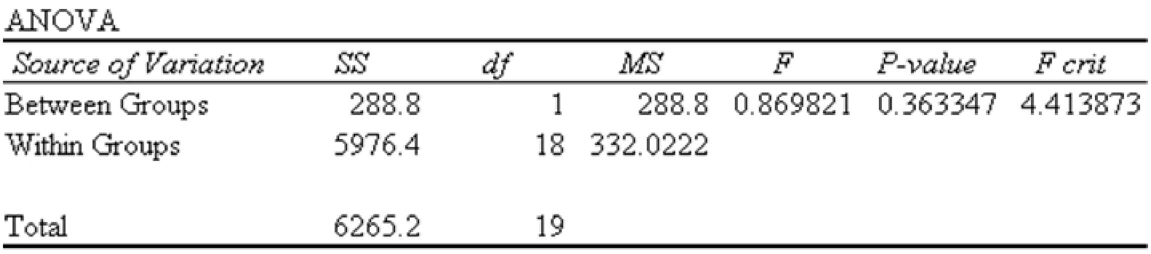
Let us recall that in the section of Statistics we proved (see page 1017) that for the one controlled factor ANOVA, the test of equality of means (through the use of the variances) was written (we just change the letter x to y to avoid confusion for the developments that will follow) is given by:

$$F_{k-1,N-k}=\frac{\mathrm{V}_A}{\mathrm{V}_R}=\frac{\dfrac{\displaystyle\sum_{j=1}^{k} n_j(\bar{y}_i-\bar{\bar{y}})^2}{k-1}}{\dfrac{\displaystyle\sum_{ij}(y_{ij}-\bar{y}_j)^2}{N-k}}=\frac{\dfrac{Q_A}{k-1}}{\dfrac{Q_R}{N-k}}=\frac{\text{MSk}}{\text{MSE}}=\frac{\text{variance between treatments}}{\text{variance within treatments}}=\frac{\text{signal}}{\text{noise}} \tag{14.1.202}$$

which is used to compare, for example, the means of the cash-flows of two supposed independent chosen months (i.e. with $k=2$) over 10 years (obviously in the case $k=2$ we could use a Student test if the conditions are of course satisfied!) supposing that for every year for the given month the values are normally distributed:

January	**February**
304	280
284	303
290	294
310	270
320	276
270	310
309	290
293	312
315	260
301	325

Therefore a simple ANOVA with one controlled factor will give according to the calculations proven in the section of Statistics (see page 1004) and using a spreadsheet software like Microsoft® Excel® 14.0.7106 the following results:



ANOVA

Source of Variation	*SS*	*df*	*MS*	*F*	*P-value*	*F crit*
Between Groups	288.8	1	288.8	0.869821	0.363347	4.413873
Within Groups	5976.4	18	332.0222			
Total	6265.2	19				

With for recall:

Source	**Sum of squares (SSE)**	χ^2 **df**	**Mean squares**	F	**Critical** F
Inter-Class	$Q_A = \sum_i n_i (\bar{x}_i - \bar{\bar{x}})^2$	$k-1$	$\text{MSk} = \dfrac{Q_A}{k-1}$	$\dfrac{\text{MSk}}{\text{MSE}}$	$P(F > F_{k-1,N-k})$
Intra-Class	$Q_R = \sum_{ij} (x_{ij} - \bar{x}_i)^2$	$N-k$	$\text{MSE} = \dfrac{Q_R}{N-k}$		
Total	$Q_T = \sum_{ij} (x_{ij} - \bar{\bar{x}})^2$	$N-1$			

Table 14.3: **One way fixed factor ANOVA table**

But you might think: Why we go back on such an example ????

Well simply because we can very well build a linear regression model of the cash-flows of these two months, which we had not mentioned in the Statistics section! Thus, when we have an ANOVA with a controlled factor, nothing prevents us from making a linear regression of the data with binary explanatory variables (and vice versa)! To do this, it is enough that we rewrite the table above in the following form (technique named "dummy coding" or "one hot encoding"):

Observation	**Cash-Flow** y_i	**January** x_{i1}	**February** x_{i2}
1	304	1	0
2	284	1	0
3	290	1	0
4	310	1	0
5	320	1	0
6	270	1	0
7	309	1	0
8	293	1	0
9	315	1	0
10	301	1	0
11	280	0	1
12	303	0	1
13	294	0	1
14	270	0	1
15	276	0	1
16	310	0	1
17	290	0	1
18	312	0	1
19	260	0	1
20	325	0	1

Obviously we not always have in reality binary $(0,1)$ explanatory values but we can always normalize the control variables to fall back on such a situation!

This necessarily can be summarized to:

n_i	Mean cash flow $\bar{y}_i$	January x_{i1}	February x_{i2}
10	299.11	1	0
10	292.00	0	1

Therefore the regression model associated with this ANOVA with 1 control factor at 2 levels can therefore be written:

$$\hat{y}_i=\hat{\beta}_0+\hat{\beta}_1x_{i1}+\hat{\beta}_2x_{i2}+\varepsilon_i=\hat{\beta}_0+\sum_{j=1}^{2}x_{ij}\hat{\beta}_j+\varepsilon_i \tag{14.1.203}$$

Remark

Notice that this last relation can also be written:

$$\hat{y}_i=\hat{\beta}_0+\hat{\beta}_1x_{i1}+\hat{\beta}_2x_{i2}+\varepsilon_i=\underbrace{\hat{\mu}}_{\hat{\beta}_0}+\underbrace{\hat{\mu}_i}_{\hat{\beta}_1x_{i1}+\hat{\beta}_2x_{i2}}+\varepsilon_i \tag{14.1.204}$$

where in linear regression with dummy variables $\hat{\mu}$ is the "intercept" and $\hat{\mu}_i$ is named the "marginal effect".

And here maybe you recognize something well known to us when we have studied all the ANOVAs!!! So as we then see, checking that the means $\hat{\mu}_i$ are all equal or not in the ANOVA such that $\mu_1=\mu_2=\ldots=\mu$ is in the case of the regression equivalent to check that $\beta_1=\beta_2=0$. So under this form, the hypotheses are then:

$$\begin{aligned}&H_0:\ \beta_1=\beta_2=\ldots=\beta_k\\&H_1:\ \text{at least there is one }\beta_i\neq 0\end{aligned} \tag{14.1.205}$$

This is what we named the "F-test of Overall Significance in Regression Analysis" (unlike T-tests that can assess only one regression coefficient at a time as we will see further below page 6395).

But, with the preceding relation and the table summarized above, we have a system of two equations with three unknowns ... which is obviously insoluble for a least squares approach. Therefore, the idea consists in sacrificing one of the explanatory variables as (generalizable to more than two variables obviously):

$$x_{i1}+x_{i2}=1 \tag{14.1.206}$$

and therefore (special choice):

$$\hat{y}_i=\hat{\beta}_0+\hat{\beta}_1x_{i1}+\hat{\beta}_2(1-x_{i1})+\varepsilon_i=\hat{\beta}_0+\hat{\beta}_2+(\hat{\beta}_1+\hat{\beta}_2)x_{i1}+\varepsilon_i=\hat{\beta}'_0+\hat{\beta}'_1x_{i1}+\varepsilon_i \tag{14.1.207}$$

and then we have indeed two equations with two unknowns:

$$\begin{aligned}\hat{y}_i&=\hat{\beta}'_0+\hat{\beta}'_1x_{i1}+\varepsilon_i\\\bar{y}_i&=\hat{\beta}'_0+\hat{\beta}'_1\bar{x}_{i1}+\varepsilon_i=\hat{\beta}'_0+\frac{1}{2}\hat{\beta}'_1+\varepsilon_i\end{aligned} \tag{14.1.208}$$

This explains the reason why statistical softwares will always give the coefficient of one of the two binary explanatory variables as zero (which obviously can be problematic in some cases and therefore it is enough to force the ordinate at the origin to be zero to have the two non-zero coefficients since then we fall back on a system of two equations with two unknowns). In the case of k binary (dichotomous) explanatory variables, there will be $k-1$ whose coefficients are non-zero (since one can always be explained by all others).

Remark

The use of ANOVA, you probably guess, is only feasible if the residues are almost normally distributed and homoscedastic... This is why statistical softwares have outputs giving such analysis when running a F-test for regression.

Finally, all this to say that the ANOVA is only a special case (with binary explanatory variables rather than continuous one and let us recall that $\mathbb{N}\in\mathbb{R}$ not the inverse!) of the linear regression.

Let us notice then that we can write:

$$\sum_{i=1}^{N}(\hat{y}_i-\bar{y})^2=\sum_{i=1}^{N}\left(\left(\sum_{j=1}^{k}x_{ij}\hat{\beta}_j+\hat{\beta}_0\right)-\bar{y}\right)^2 \tag{14.1.209}$$

and as they are either 0 or 1 (or normalized to be such as). Then there remain only the terms $x_{ij}\hat{\beta}_j$ where $x_{ij}\neq 0$ in a quantity that for each j we will denote by n_j. It comes then since we only keep the $x_{ij}=1$ (for the last equality if it is not obvious the reader can make an example on a sheet of paper with a simple numerical application!):

$$\sum_{i=1}^{N}(\hat{y}_i-\bar{y})^2=\sum_{i=1}^{N}\left(\left(\sum_{j=1}^{k}x_{ij}\hat{\beta}_j+\hat{\beta}_0\right)-\bar{y}\right)^2=\sum_{j=1}^{k}n_j\left(\hat{\beta}_j+\hat{\beta}_0-\bar{y}\right)^2 \tag{14.1.210}$$

with obviously[8] $\sum_{j=1}^{k}n_j=N$.

By the method of the ordinary least squares and the values that can take the x_{ij} we quickly see that the coefficients (parameters) of the regression will be given by (we can detail again on reader request):

$$\hat{\beta}_j+\hat{\beta}_0=\bar{y}_j \tag{14.1.211}$$

and therefore:

$$\sum_{i=1}^{N}(\hat{y}_i-\bar{y})^2=\sum_{j=1}^{k}n_j(\bar{y}_j-\bar{y})^2 \tag{14.1.212}$$

and as in our case in comparison with the one fixed factor ANOVA we have the obvious correspondences:

$$\bar{\bar{y}}\rightarrow\bar{y}=\frac{1}{N}\sum_{i=1}^{N}y_i \tag{14.1.213}$$

---

[8] In our above example $N=20$ and $n_1=n_2=10$

it follows, therefore, that there is a correspondence between the numerator of the Fisher test of ANOVA and the equivalent expression of the linear regression (and therefore with the same number of degrees of freedom) that brings us to write:

$$F_{k-1,N-k}=\frac{\dfrac{\displaystyle\sum_{j=1}^{k}n_j(\bar{y}_i-\bar{\bar{y}})^2}{k-1}}{\dfrac{\displaystyle\sum_{ij}(y_{ij}-\bar{y}_j)^2}{N-k}}=\frac{\dfrac{\displaystyle\sum_{i=1}^{n}(\hat{y}_i-\bar{y})^2}{k-1}}{\dfrac{\displaystyle\sum_{ij}(y_{ij}-\bar{y}_j)^2}{N-k}} \tag{14.1.214}$$

But it remains for us to find the equivalent also of the denominator for the regression. For this we will proceed by similarity. Let us recall that in the one fixed factor ANOVA we have proved that:

$$\begin{array}{ccccc}Q_T & = & Q_A & + & Q_R\\ \displaystyle\sum_i(y_{ij}-\bar{\bar{y}})^2 & = & \displaystyle\sum_i n_i(\bar{y}_i-\bar{\bar{y}})^2 & + & \displaystyle\sum_{ij}(y_{ij}-\bar{y}_i)^2\\ N-1 & = & k-1 & + & \displaystyle\sum_i(n_i-1)\end{array}$$

and let us recall that for the linear regression, we have proved earlier above (with the corresponding notations in usage):

$$\begin{array}{ccccc}\text{SST} & = & \text{SSE} & + & \text{SSR}\\ \displaystyle\sum_i(y_i-\bar{y})^2 & = & \displaystyle\sum_i(\hat{y}_i-\bar{y})^2 & + & \displaystyle\sum_i(y_i-\hat{y}_i)^2\end{array}$$

From what we have seen above we know that degrees of freedom of $\sum_i(\hat{y}_i-\bar{y})^2$ are $k-1$. If follows immediately that for $\sum_i(y_i-\bar{y})^2$ the degrees of freedom are $N-1$. Then we can write:

$$\begin{array}{ccccc}\text{SST} & = & \text{SSE} & + & \text{SSR}\\ \displaystyle\sum_i(y_i-\bar{y})^2 & = & \displaystyle\sum_i(\hat{y}_i-\bar{y})^2 & + & \displaystyle\sum_i(y_i-\hat{y}_i)^2\\ N-1 & = & k-1 & + & ????\end{array}$$

It then follows that the degrees of freedom of the sum of the squares residuals is then of $N-k$ such that:

$$\begin{array}{ccccc}\text{SST} & = & \text{SSE} & + & \text{SSR}\\ \displaystyle\sum_i(y_i-\bar{y})^2 & = & \displaystyle\sum_i(\hat{y}_i-\bar{y})^2 & + & \displaystyle\sum_i(y_i-\hat{y}_i)^2\\ N-1 & = & k-1 & + & N-k\end{array}$$

Sum of the squares of residues that it is customary to write (useful for later !!!):

$$\boxed{\sigma_{\varepsilon}^2=\frac{\sum\limits_i (y_i-\hat{y}_i)^2}{N-k}} \tag{14.1.215}$$

and that is given in the output of some statistical softwares (sadly!) under the misnamed "residual standard error" (instead than "residual standard deviation"):

$$\sigma_{\varepsilon}=\sqrt{\frac{\sum\limits_i (y_i-\hat{y}_i)^2}{N-k}} \tag{14.1.216}$$

As Q_T doesn't appear in the Fisher test there is no a priori reason that the equivalent which is SST for regression appears there. By elimination, the correspondence is then immediate:

$$\sum_{ij}(y_{ij}-\bar{y}_i)^2 \rightarrow \sum_i (y_i-\hat{y}_i)^2 \tag{14.1.217}$$

The Fisher test then becomes for the linear regression:

$$\boxed{F_{k-1,N-k}=\frac{\dfrac{\sum\limits_{i=1}^{n}(\hat{y}_i-\bar{y})^2}{k-1}}{\dfrac{\sum\limits_{ij}(y_i-\hat{y})^2}{N-k}}} \tag{14.1.218}$$

and is more famously known under the name "omnibus test for OLS regression" (i.e. that a significant percentage of statistical softwares give below the diagnostic table of the regression analysis!).

It follows then that as for the one-fixed factor ANOVA, with linear regression, we can also make a table of the ANOVA (see section Statistics page 1001) as we will see later with an example!

Now, let us prove a common and important form of this last relation. We have proved earlier above that the correlation coefficient could also be written in the form:

$$R^2=\frac{\text{SSE}}{\text{SST}}=\frac{\sum(\hat{y}_i-\bar{y})^2}{\sum(y_i-\bar{y})^2} \tag{14.1.219}$$

However, let us notice that:

$$\begin{aligned}F_{k-1,N-k}&=\frac{\dfrac{\sum\limits_i(\hat{y}_i-\bar{y})^2}{k-1}}{\dfrac{\sum\limits_{ij}(y_i-\hat{y})^2}{N-k}}=\frac{\sum\limits_i(\hat{y}_i-\bar{y})^2}{\sum\limits_{ij}(y_i-\hat{y})^2}\frac{\sum\limits_i(y_i-\bar{y})^2}{\sum\limits_i(y_i-\bar{y})^2}\frac{N-k}{k-1}\\&=\frac{\sum(\hat{y}_i-\bar{y})^2}{\sum(y_i-\bar{y})^2}\frac{\sum(y_i-\bar{y})^2}{\sum(y_i-\hat{y}_k)^2}\frac{N-k}{k-1}=R^2\frac{\sum(y_i-\bar{y})^2}{\sum(y_i-\hat{y}_k)^2}\frac{N-k}{k-1}\end{aligned} \tag{14.1.220}$$

And also let us recall once again that:

$$\text{SST} = \text{SSE} + \text{SSR} \tag{14.1.221}$$

Thus explicitly as we have just seen:

$$\sum_i (y_i - \bar{y})^2 = \sum_i (\hat{y}_i - \bar{y})^2 + \sum_i (y_i - \hat{y}_i)^2 \tag{14.1.222}$$

Therefore we can write:

$$\begin{aligned} F_{k-1,N-k} &= R^2 \frac{\sum (y_i - \bar{y})^2}{\sum (y_i - \hat{y}_k)^2} \frac{N-k}{k-1} = \frac{\sum (y_i - \bar{y})^2}{\sum (y_i - \bar{y})^2 - \sum (\hat{y}_i - \bar{y})^2} \frac{N-k}{k-1} \\ &= R^2 \left(\frac{1}{\dfrac{\sum (y_i - \bar{y})^2 - \sum (\hat{y}_i - \bar{y})^2}{\sum (y_i - \bar{y})^2}} \right) \frac{N-k}{k-1} = R^2 \left(\frac{1}{1 - \dfrac{\sum (\hat{y}_i - \bar{y})^2}{\sum (y_i - \bar{y})^2}} \right) \frac{N-k}{k-1} \\ &= R^2 \left(\frac{1}{1-R^2} \right) \frac{N-k}{k-1} \end{aligned} \tag{14.1.223}$$

What we usually can find in some textbooks in the following form:

$$\boxed{F_{k-1,N-k} = \frac{\dfrac{R^2}{k-1}}{\dfrac{1-R^2}{N-k}}} \tag{14.1.224}$$

We thus see that if the coefficient of determination R^2 is large (close to 1) then the value of F is large, the linear model will be considered as explaining significantly well the variable explained with respect to the explanatory variable (but this still doesn't mean that there is causality!).

Let us come back to our companion example! A simple ordinary least squares regression with a spreadsheet software like Microsoft® Excel® of the below table:

Observation	Cash-Flow y_i	January x_{i1}
1	304	1
2	284	1
3	290	1
4	310	1
5	320	1
6	270	1
7	309	1
8	293	1
9	315	1
10	301	1
11	280	0
12	303	0
13	294	0
14	270	0
15	276	0
16	310	0
17	290	0
18	312	0
19	260	0
20	325	0

gives (we make the choice not to force the ordinate at the origin and to take January as an explanatory variable with coefficient not zero otherwise we will not find the value of the calculation of the classic ANOVA seen earlier above):

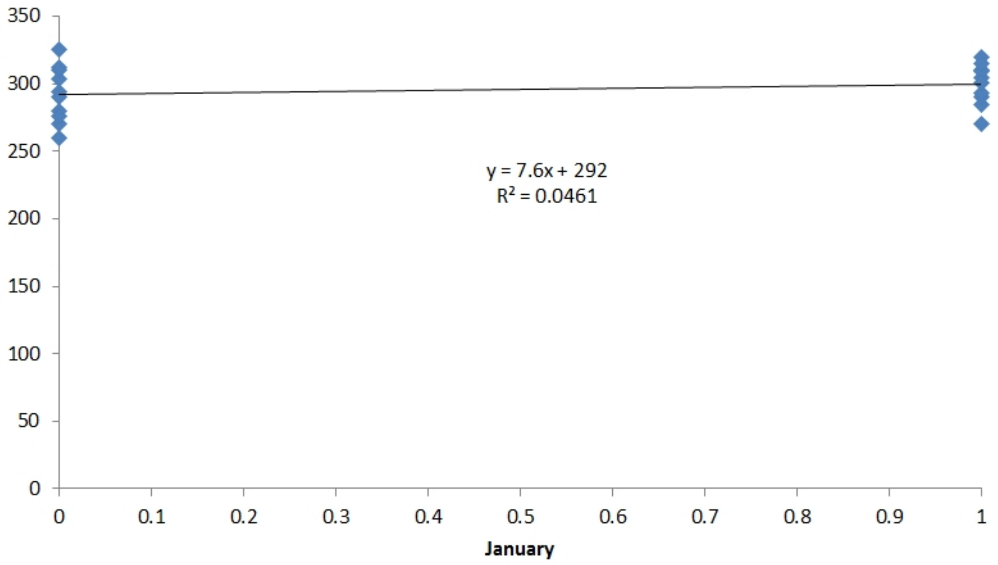


Figure 14.9: **Graphical representation of an univariate regression with the ANOVA approach in Microsoft® Excel® 14.0.7177**

that is to say:

$$\hat{y}_i = \hat{\beta}_0 + \hat{\beta}_1 x_{i1} \cong 292 + 7.6_{i,\text{january}} \tag{14.1.225}$$

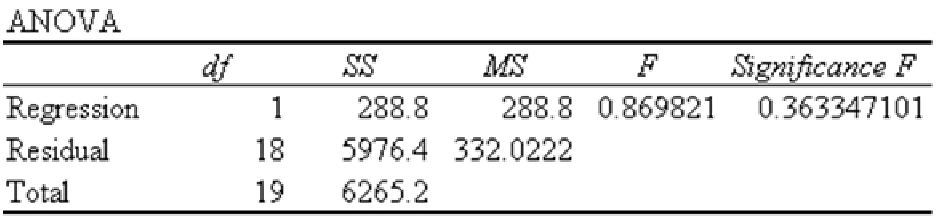
We then have:

Observation	**Cash flow y_i**	**Cash flow $\hat{y}_i$**	**SSR $(y_i-\hat{y}_i)^2$**	**SST $(y_i-\bar{y})^2$**	**SSE $(\hat{y}_i-\bar{y})^2$**
1	304	299.6	19.36	67.24	14.44
2	284	299.6	243.36	139.24	14.44
3	290	299.6	92.16	33.64	14.44
4	310	299.6	108.16	201.64	14.44
5	320	299.6	416.16	585.64	14.44
6	270	299.6	876.16	665.64	14.44
7	309	299.6	88.36	174.24	14.44
8	293	299.6	43.56	7.84	14.44
9	315	299.6	237.16	368.64	14.44
10	301	299.6	1.96	27.04	14.44
11	280	292	144	249.64	14.44
12	303	292	121	51.84	14.44
13	294	292	4	3.24	14.44
14	270	292	484	665.64	14.44
15	276	292	256	392.04	14.44
16	310	292	324	201.64	14.44
17	290	292	4	33.64	14.44
18	312	292	400	262.44	14.44
19	260	292	1024	1281.64	14.44
20	325	292	1048	852.64	14.44
		Total	**5976.4**	**6265.2**	**288.8**

with obviously:

$$k=2 \qquad N=20 \qquad N-k=18 \tag{14.1.226}$$

The calculations of all the classical ANOVA terms of the regression then give still with the same version of Microsoft® Excel® (the reader can verify by hand using the relations proved earlier above that we find the values given by this spreadsheet software):



ANOVA

	df	*SS*	*MS*	*F*	*Significance F*
Regression	1	288.8	288.8	0.869821	0.363347101
Residual	18	5976.4	332.0222		
Total	19	6265.2			

Or more explicitly:

Source	**Sum of squares (SSE)**	χ^2 **df**	**Mean squares**	F	**Critical** F
Inter-Class	$Q_A=\sum_i(\hat{y}_i-\bar{y})^2$	$k-1$	$\text{MSk}=\dfrac{Q_A}{k-1}$	$\dfrac{\text{MSk}}{\text{MSE}}$	$P(F>F_{k-1,N-k})$
Intra-Class	$Q_R=\sum_i(y_i-\hat{y}_i)^2$	$N-k$	$\text{MSE}=\dfrac{Q_R}{N-k}$		
Total	$Q_T=\sum_i(y_i-\bar{y})^2$	$N-1$			

Table 14.4: **ANOVA table for regression**

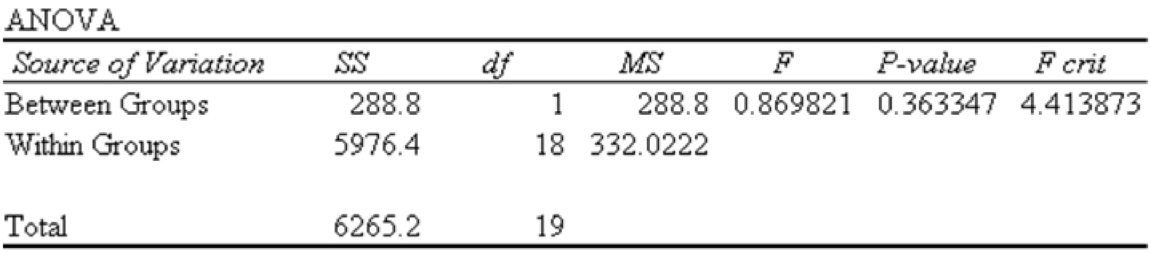
Remark

Notice that in the above ANOVA table we recognize something known to us:

$$Q_R=\sum_i(y_i-\hat{y}_i)^2=\sigma_\varepsilon^2 \tag{14.1.227}$$

That is... the SEE^2, where for recall SEE is named the "standard error of estimate" or "standard regression error" (see page 6355)! This is why in all statistical softwares you can simply rely the standard error of estimate of the regression with the intra-class mean sum of square (i.e. mean residuals errors) just by taking the square root of that latter such that: $\text{SEE}=\sqrt{\text{MSE}}$.

And running the one-fixed factor ANOVA we had already introduced a little earlier above we have for comparison:



ANOVA

Source of Variation	*SS*	*df*	*MS*	*F*	*P-value*	*F crit*
Between Groups	288.8	1	288.8	0.869821	0.363347	4.413873
Within Groups	5976.4	18	332.0222			
Total	6265.2	19				

With for recall (again!) its general table:

Source	**Sum of squares (SSE)**	χ^2 **df**	**Mean squares**	F	**Critical** F
Inter-Class	$Q_A=\sum_i n_i(\bar{x}_i-\bar{\bar{x}})^2$	$k-1$	$\text{MSk}=\dfrac{Q_A}{k-1}$	$\dfrac{\text{MSk}}{\text{MSE}}$	$P(F>F_{k-1,N-k})$
Intra-Class	$Q_R=\sum_{ij}(x_{ij}-\bar{x}_i)^2$	$N-k$	$\text{MSE}=\dfrac{Q_R}{N-k}$		
Total	$Q_T=\sum_{ij}(x_{ij}-\bar{\bar{x}})^2$	$N-1$			

Table 14.5: **One way fixed factor ANOVA table**

We see then the obvious similarity that there are with the two approaches!!! This is why some people say sometimes: « *running a regression or an ANOVA are two equivalent thinks (assumed under some given conditions)* » as in the ANOVA, the categorical variable is effect coded, which means that each category's mean is compared to the grand mean. In the regression, the categorical variable is dummy coded, which means that each category intercept is compared to the reference group intercept! Since the intercept is defined as the mean value when all other predictors $=0$, and there are no other predictors, the three intercepts are just means.

Indeed, we have:

$$\hat{\beta}_0 = \bar{y}_{\text{february}} = 292 \qquad (14.1.228)$$

and:

$$\hat{\beta}_1 + \hat{\beta}_0 = \bar{y}_{\text{january}} = 292 + 7.6 = 299.6 \qquad (14.1.229)$$

14.1.10.1.4.1 Test for Lack of Fit

The "test for lack-of-fit" compares the variation around the model with "pure" variation within replicated observations (some statistical softwares use this analysis only for the adequacy of quadratic response surface and not for simple linear models...). In particular, if there are n_i replicated observations $y_{i1},\ldots,y_{in_i}$ of the response all at the same values $\vec{x}_i$ (vector of dimension n) of the factors, then we can predict the true response at $\vec{x}_i$ either by using the predicted value $\hat{y}_i$ based on the model or by using the mean $\bar{y}_i$ of the replicated values. The test for lack-of-fit decomposes the residual error into a component due to the variation of the replications around their mean value (the "pure error"), and a component due to the variation of the mean values around the model prediction (the "lack of fit" also named the "bias error"):

$$\begin{aligned}
Q_R &= \sum_{i=1}^{n}\sum_{j=1}^{n_i}\varepsilon_{ij}^2 \\
&= \sum_{i=1}^{n}\sum_{j=1}^{n_i}\left(y_{ij}-\hat{y}_i\right)^2 = \underbrace{\sum_{i=1}^{n}\sum_{j=1}^{n_i}\left(y_{ij}-\bar{y}_{i.}\right)^2}_{\text{sum of squares due to pure error}} + \underbrace{\sum_{i=1}^{n}\sum_{i=1}^{n_i}\left(\bar{y}_{i.}-\hat{y}_{ij}\right)^2}_{\text{sum of squares due to lack of fit (bias error)}} \\
&= \sum_{i=1}^{n}\sum_{j=1}^{n_i}\left(y_{ij}-\bar{y}_{i.}\right)^2 + \sum_{i=1}^{n} n_i\left(\bar{y}_{i.}-\hat{y}_i\right)^2
\end{aligned} \qquad (14.1.230)$$

or written differently:

$$Q_R = \text{SSE} = \text{SSPE} + \text{SSLF} \qquad (14.1.231)$$

Remarks

R1. The reader should easily notice that without repeated measurements, $\text{SSPE}=0$ and hence we cannot conduct a lack-of-fit analysis!

R2. Obviously for one x_i we have multiple y_i, hence the notation y_{ij}. But the model for a given x_i gives only one and only one $\hat{y}_i$. Hence $\forall j$ and a given i, we have $\hat{y}_{ij}=\hat{y}_i$.

If the model is adequate, then both components estimate the nominal level of error; however, if the bias component of error is much larger than the pure error, then this constitutes evidence that there is significant lack of fit. The concept can be illustrated as following:

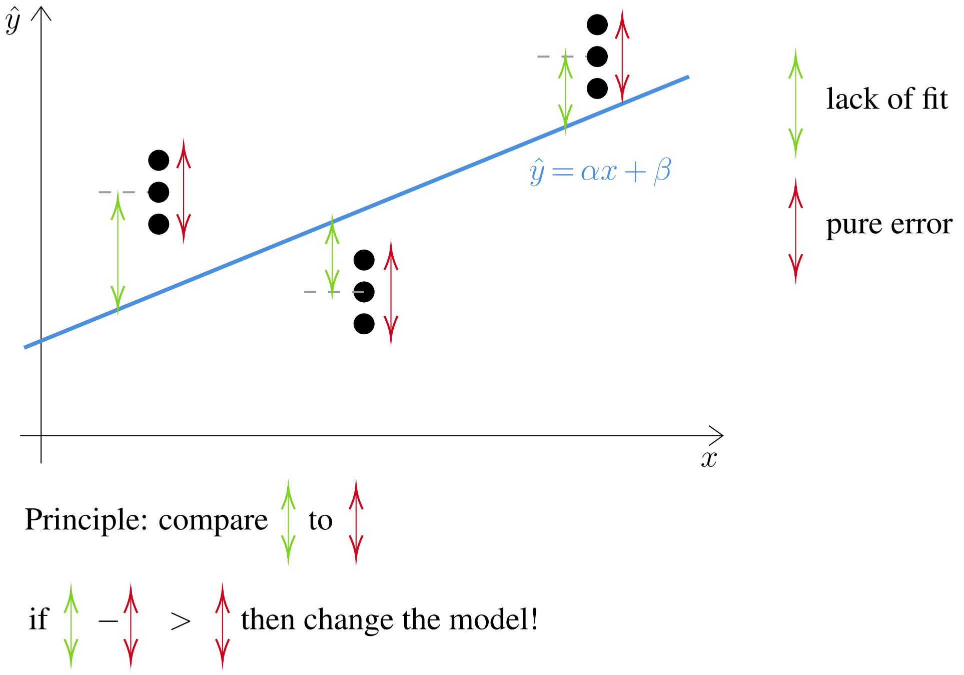


Figure 14.10: **Lack of fit and pure error**

- As before, the degrees of freedom associated with SSE (i.e. Q_R) is as we know very well given by $n(k-1) = N-k$ (keep in mind that the k comes from the fact that you estimate k parameters - the slopes plus the intercept - whenever you fit a line to a set of data).
- The degrees of freedom associated with SSLF is $n-k$, where c denotes the number of distinct x values we have.
- The degrees of freedom associated with SSPE is $nk-n = N-n$, where again n denotes the number of distinct x values we have.

Therefore the degrees of freedom breakdown as:

$$\underbrace{\text{SSE}}_{\text{df}=N-k} = \underbrace{\text{SSPE}}_{N-n} + \underbrace{\text{SSLF}}_{n-k} \tag{14.1.232}$$

It then follows that the statistic:

$$F = \frac{\text{lack-of-fit sum of squares}}{\text{degrees of freedom}} = \frac{\text{MSLF}}{\text{MSPE}} = \frac{\dfrac{\text{SSLF}}{n-k}}{\dfrac{\text{SSPE}}{N-n}} = \frac{\dfrac{\displaystyle\sum_{i=1}^{n}\sum_{j=1}^{n_i}\left(y_{ij}-\bar{y}_{i.}\right)^2}{n-k}}{\dfrac{\displaystyle\sum_{i=1}^{n} n_i\left(\bar{y}_{i.}-\hat{y}_i\right)^2}{N-n}} \tag{14.1.233}$$

has an F-distribution with the corresponding number of degrees of freedom in the numerator and the denominator, provided that the model is correct.

To understand this test keep in mind that under the null hypothesis:

- The sum of squares due to pure error, divided by the error variance σ_{ε}^2, has a chi-squared distribution with $N-n$ degrees of freedom.
- The sum of squares due to lack of fit, divided by the error variance σ_{ε}^2, has a chi-squared distribution with $n-k$ degrees of freedom.
- The two sums of squares are probabilistically independent.

If the model is wrong, then the probability distribution of the denominator is still as stated above, and the numerator and denominator are still independent. But the numerator then has a noncentral chi-squared distribution (see section Statistics page 780) and consequently the quotient as a whole has a noncentral F-distribution.

One uses this F-statistic to test the null hypothesis that there is no lack of linear fit. Since the non-central F-distribution is stochastically larger than the (central) F-distribution, one rejects the null hypothesis if the F-statistic is larger than the critical F value.

So we complete the previous analysis of variance table using the following relations:

Source	χ^2 **df**	**SS**	**Means squares**	***F***
Regression	$k-1$	$\text{SSR}=\sum\limits_{i=1}^{n} n_i(\hat{y}_i-\bar{y})^2$	$\text{MSR}=\dfrac{\text{SSR}}{k-1}$	$F=\dfrac{\text{MSR}}{\text{MSE}}$
Residual error	$N-k$	$\text{SSE}=\sum\limits_{i=1}^{n}\sum\limits_{j=1}^{n_i}(y_{ij}-\hat{y}_i)^2$	$\text{MSE}=\dfrac{\text{SSE}}{N-k}$	
Lack of Fit	$n-k$	$\text{SSLF}=\sum\limits_{i=1}^{n} n_i(\bar{y}_i-\hat{y}_i)^2$	$\text{MSLF}=\dfrac{\text{SSLF}}{n-k}$	$F=\dfrac{\text{MSLF}}{\text{MSPE}}$
Pure error	$N-n$	$\text{SSPE}=\sum\limits_{i=1}^{n}\sum\limits_{j=1}^{n_i}(y_{ij}-\bar{y}_i)^2$	$\text{MSPE}=\dfrac{\text{SSPE}}{N-k}$	
Total	$N-1$	$\text{SSTO}=\sum\limits_{i=1}^{n}\sum\limits_{j=1}^{n_i}(y_{ij}-\bar{y})^2$		

Table 14.6: **Lack-of-Fit ANOVA table**

The reader must be careful with the "Total" in the above table (last row). Indeed, the total must not take into account the row with the degrees of freedom $n-k$ and $N-n$ as their are the decomposition of the row with the $N-k$.

14.1.10.2 Univariate linear regression Gaussian Model

We will assume that for an individual k picked randomly from the population, x_k is known without error, and that y_k is a realization of a random variable that we will now denote Y_k and the theoretical least squares regression line will be written now under the general form of a "stochastic linear model":

$$Y_k = \alpha x_k + \beta + \varepsilon_k \tag{14.1.234}$$

where ε_k is assumed identically distributed and independent residue (no correlation) for each point k according to a centered Normal distribution (zero mean and standard deviation σ for all k) such as $\forall i \neq j$:

$$\boxed{\begin{aligned} \varepsilon_k &= \mathcal{N}(0,\sigma) \\ \text{cov}(\varepsilon_i,\varepsilon_j) &= 0 \end{aligned}} \tag{14.1.235}$$

So in other words[9]:

$$\begin{aligned} \text{E}(\varepsilon_k) &= 0 \\ \text{V}(\varepsilon_k) &= \sigma_\varepsilon^2 \end{aligned} \tag{14.1.236}$$

where the residue is defined by the difference between the theoretical ordinates Y_k (considered as random variable) and the measured (experimental) ordinates y_k:

$$\varepsilon_k = Y_k - y_k \tag{14.1.237}$$

and since by hypothesis $\varepsilon_k = \mathcal{N}(0,\sigma)$, it immediately comes by the stability of the Normal law (see section Statistics page 710) that:

$$Y_k = \mathcal{N}(y_k,\sigma_\varepsilon) = \mathcal{N}(\alpha x_k + \beta, \sigma_\varepsilon) \tag{14.1.238}$$

This is why this specific model is named "Gaussian linear model" .... Explicitly, we have:

$$Y_k = \frac{1}{\sigma_\varepsilon\sqrt{2\pi}} e^{\frac{1}{2}\left(\frac{\alpha x_k + \beta - \mu_k}{\sigma_\varepsilon}\right)^2} \tag{14.1.239}$$

This is why theoretical model is formally denoted:

$$y = \text{E}\left[Y|X=x\right] = f(x) \tag{14.1.240}$$

We will choose the symbol $\sim$ to say "follows the law ..." in order to avoid any notation confusion:

$$Y_k \sim \frac{1}{\sigma_\varepsilon\sqrt{2\pi}} e^{\frac{1}{2\sigma_\varepsilon^2}(\alpha x_k + \beta - \mu_k)^2} = \frac{1}{\sigma_\varepsilon\sqrt{2\pi}} e^{\frac{1}{2\sigma_\varepsilon^2}(Y_k - \mu_k)^2} \tag{14.1.241}$$

Which graphically is equivalent to have (so normally the statistical analysis of the Gaussian regression occurs only if and only if we have taken several measures of the dependent variable for fixed and identical values of the independent variables!!!!!!!!):

---

[9] The conditions $\text{cov}(\varepsilon_i,\varepsilon_j) = 0$, and $\text{E}(\varepsilon_k) = 0$ and $\text{V}(\varepsilon_k) = \sigma_\varepsilon^2$ are named the "Gauss-Markov assumptions" (see page 6405) and are at the basis of the "Gauss-Markov Linear Model" (GMLM).

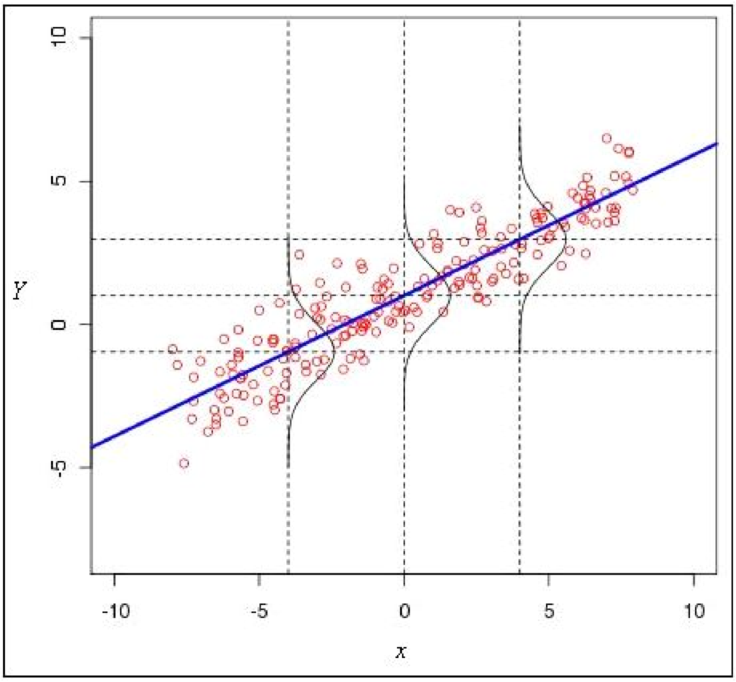

Figure 14.11: Graphical representation of the idea behind the Gaussian linear regression

Caution! Since the model is Gaussian, the variable to explain has its domain of definition which is unbounded (support of the Normal distribution). Some companies (especially auditing firms...) wish sometimes to create a simple linear model to model a probability (that for reminder is bounded in [0,1]) typically for the probability of bankruptcy/default based on various factors (explanatory variables). Therefore the measured probability must first be turn into Z values (quantiles) of the Normal distribution to have again an infinite range. This type of approach is then named "linear Z-score model".

Almost all statistical analysis software provide a pattern (figure) of residues according to the x values. Thus, these type of figures help to accept or reject the use of a linear Gaussian model:

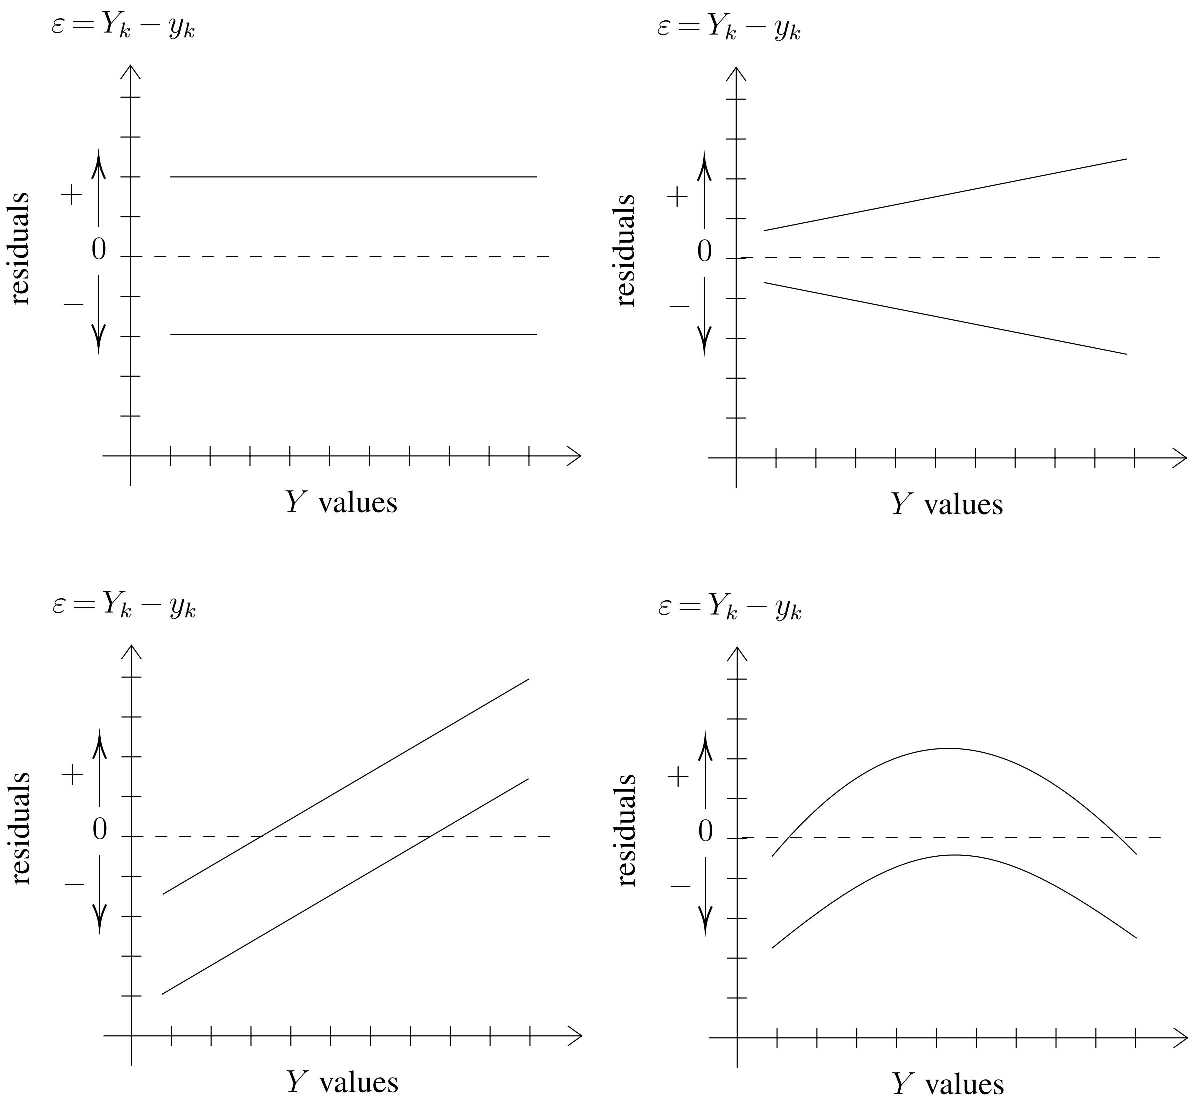

Figure 14.12: Examples of "plot" of residuals

In the above figure, the graph on the top left is what we should expect to have to be able to apply the statistical tests for the Gaussian linear model. The graph on the top right shows that the residuals variance is not constant and therefore we have a violation of the assumption of homoscedasticity (typically checked with statistical hypothesis tests like Levene, Bartlett, Fligner, Brown-Forsythe, etc.)! The graph at the bottom left shows that the variance is constant but that our model has missing endogenous variables that added could perhaps explain the shift that grows up linearly. The graph at the bottom right indicates a constant variance, but the model looks like to be more nonlinear than linear.

Previous assumptions about the moments of residues (mean, variance) are named "Gauss-Markov assumptions" and the particular hypothesis of equal variances is named as we saw it in the section Statistics "homoscedasticity" (while the fact that the variances are not equal is named for reminder "heteroskedasticity").

Remarks

R1. The majority of softwares (including Microsoft® Excel® 11.8346) propose a graph which shows the residuals in function of the ordinate values x. Obviously, it is better that the points representing the residues are not too divergent ... otherwise the homoscedasticity assumption will be not satisfied.

R2. Practitioners sometimes transform the endogenous and exogenous variables by a logarithmic or exponential function or other to try to stabilize the residuals as most as possible.

Theorem 14.2. We have through the property of the mean (see section Statistics page 571):

$$\bar{Y}=\mathrm{E}(Y_k)=\mathrm{E}(\alpha x_k+\beta+\varepsilon_k)=\mathrm{E}(\alpha x_k)+\mathrm{E}(\beta)+\mathrm{E}(\varepsilon_k)=\alpha\bar{x}+\beta \tag{14.1.242}$$

Then under the above assumptions, we will show that a and b are unbiased estimators (see section Statistics page 821) of α and β and it is possible to estimate the standard deviation from the SSR which is an important result named "Gauss-Markov theorem" (see page 6405).

Before seeing the proof let us do a recall and give some definitions of the variables that we have already handled and the new one that we will handle (if the vocabulary seems technical to the reader then it should read or reread the sections of Probabilities and Statistics):

Variable	Description
a	Slope (director coefficient) of the linear model of the least squares method (LSM). This is a punctual estimate value (deterministic).
b	Intercept of the linear model of the least squares method (LSM). This is a punctual estimate value (deterministic).
A	Random variable of the slope (director coefficient) according to the statistical Gaussian model approach and for which a is a realization. The expected mean of A being an unbiased estimator of α.
B	Random variable of the ordinate at the origin according to the statistical approach of the linear Gaussian model and for which b is a realization. The expected mean of B being an unbiased estimator of β.
α	Unbiased expected mean of the variable A representing the slope (director coefficient) within the framework of the statistical approach of the Gaussian linear model.
β	Unbiased expected mean of the variable B representing the y-intercept (ordinate at origin) in the framework of the statistical approach of linear Gaussian model.

Table 14.7: **Reminder of notations for the study of the linear regression**

Proof 14.2.1. According to the adopted model, a must now be regarded as a realization of the random variable given by (shown above as the ratio of the covariance and variance):

$$A=\frac{\sum\limits_k (x_k-\bar{x})(Y_k-\bar{Y})}{\sum\limits_k (x_k-\bar{x})^2} \tag{14.1.243}$$

and b as a realization of the random variable given by:

$$B=\bar{Y}-A\bar{x} \tag{14.1.244}$$

So we differentiate random and non-random coefficient values by passing the lowercase notation in uppercase (as it is the tradition in the field of Statistics).

Taking into account that theoretical dependent (endogenous) variable is considered as the realization of a random variable is therefore given by:

$$Y_k=\alpha x_k+\beta+\varepsilon_k \tag{14.1.245}$$

we can put A in the form:

$$\begin{aligned}
A&=\frac{\sum\limits_k (x_k-\bar{x})(Y_k-\bar{Y})}{\sum\limits_k (x_k-\bar{x})^2}=\frac{\sum\limits_k (x_k-\bar{x})(\alpha x_k+\beta+\varepsilon_k-\bar{Y})}{\sum\limits_k (x_k-\bar{x})^2}\\
&=\frac{\sum\limits_k (x_k-\bar{x})(\alpha x_k+\beta+\varepsilon_k-\mathrm{E}(Y))}{\sum\limits_k (x_k-\bar{x})^2}=\frac{\sum\limits_k (x_k-\bar{x})(\alpha x_k+\beta+\varepsilon_k-\alpha\bar{x}_k-\beta)}{\sum\limits_k (x_k-\bar{x})^2}\\
&=\frac{\sum\limits_k (x_k-\bar{x})(\alpha x_k+\varepsilon_k-\alpha\bar{x}_k)}{\sum\limits_k (x_k-\bar{x})^2}=\frac{\alpha\sum\limits_k (x_k-\bar{x})(x_k-\bar{x})+\sum\limits_k (x_k-\bar{x})\varepsilon_k}{\sum\limits_k (x_k-\bar{x})^2}\\
&=\frac{\alpha\sum\limits_k (x_k-\bar{x})^2}{\sum\limits_k (x_k-\bar{x})^2}+\frac{\sum\limits_k (x_k-\bar{x})\varepsilon_k}{\sum\limits_k (x_k-\bar{x})^2}=\alpha+\frac{\sum\limits_k (x_k-\bar{x})\varepsilon_k}{\sum\limits_k (x_k-\bar{x})^2}
\end{aligned} \tag{14.1.246}$$

Therefore:

$$\begin{aligned}
\mathrm{E}(A)&=\mathrm{E}\left(\alpha+\frac{\sum\limits_k (x_k-\bar{x})\varepsilon_k}{\sum\limits_k (x_k-\bar{x})^2}\right)=\mathrm{E}(\alpha)+\mathrm{E}\left(\frac{\sum\limits_k (x_k-\bar{x})\varepsilon_k}{\sum\limits_k (x_k-\bar{x})^2}\right)\\
&=\alpha+\frac{\sum\limits_k (x_k-\bar{x})\mathrm{E}(\varepsilon_k)}{\sum\limits_k (x_k-\bar{x})^2}=\alpha
\end{aligned} \tag{14.1.247}$$

And for B:

$$B=\bar{Y}-A\bar{x}=\mathrm{E}(Y)-A\bar{x}=\alpha\bar{x}+\beta-A\bar{x}=\beta-\bar{x}(A-\alpha) \tag{14.1.248}$$

Therefore and using also the definitions:

$$\begin{aligned}\mathrm{E}(B)&=\mathrm{E}(\beta-\bar{x}(A-\alpha))=\mathrm{E}(\beta)-\mathrm{E}(\bar{x}(A-\alpha))=\beta-\bar{x}\mathrm{E}((A-\alpha))\\&=\beta-\bar{x}\mathrm{E}(A)+\bar{x}\mathrm{E}(\alpha)=\beta-\bar{x}\alpha+\bar{x}\alpha=\beta\end{aligned} \tag{14.1.249}$$

with the same conclusion.

■ Q.E.D.

Caution! Don't confuse the "error" with the "residual". Try to remember that:

- The "error" is the difference between the observed response and the true value of the response. The error is a mathematical construct, and it is UNKNOWN.
- The "residual" is the difference between the observed response and the fitted response. The residual is KNOWN, and it is an estimate of the error for each particular value of the response variable.

Formally:

$$\begin{aligned}\text{error}:\ \varepsilon_i&=Y_i-E\left(Y_i\right)=Y_i-(\beta_0+\beta_1 x_i)\\\text{residual}:\ e_i&=Y_i-\hat{Y}_i=Y_i-\left(\hat{\beta}_0+\hat{\beta}_1 x_i\right)\end{aligned} \tag{14.1.250}$$

So the expected mean of A and B are unbiased estimators (i.e.. with minimum variance as seen in the section of Statistics) of. As they are estimators, in the literature, they are often noted $\hat{a}$,$\hat{}$ and therefore it comes the common alternative notation:

$$\hat{Y}_k=\hat{a}x_k+b \tag{14.1.251}$$

Finally, we must also calculate the variances of A and B using its properties (see section Statistics page 596) and the assumptions on the residuals, we have:

$$\begin{aligned}\mathrm{V}(A)&=\mathrm{V}\left(\alpha+\dfrac{\sum\limits_k(x_k-\bar{x})\varepsilon_k}{\sum\limits_k(x_k-\bar{x})^2}\right)=\mathrm{V}\left(\dfrac{\sum\limits_k(x_k-\bar{x})\varepsilon_k}{\sum\limits_k(x_k-\bar{x})^2}\right)\\&=\dfrac{\mathrm{V}\left(\sum\limits_k(x_k-\bar{x})\varepsilon_k\right)}{\left[\sum\limits_k(x_k-\bar{x})^2\right]^2}=\dfrac{\sum\limits_k\mathrm{V}\left((x_k-\bar{x})\varepsilon_k\right)}{\left[\sum\limits_k(x_k-\bar{x})^2\right]^2}\\&=\dfrac{\sum\limits_k(x_k-\bar{x})^2\mathrm{V}\left(\varepsilon_k\right)}{\left[\sum\limits_k(x_k-\bar{x})^2\right]^2}\end{aligned} \tag{14.1.252}$$

As by assumption we have that all the $\mathrm{V}(\varepsilon_k)$ are equal and that there is no autocorrelation (what is typically tested with the Durbin-Watson test derived at page 8015), we can write:

$$\mathrm{V}(A)=\frac{\sum_k (x_k-\bar{x})^2\mathrm{V}(\varepsilon)}{\left[\sum_k (x_k-\bar{x})^2\right]^2}=\frac{\mathrm{V}(\varepsilon)\sum_k (x_k-\bar{x})^2}{\left[\sum_k (x_k-\bar{x})^2\right]^2}=\frac{\mathrm{V}(\varepsilon)}{\sum_k (x_k-\bar{x})^2} \qquad (14.1.253)$$

And if n is large enough we will write:

$$\sigma_A^2=\mathrm{V}(A)=\frac{\sigma_\varepsilon^2}{\sum_k (x_k-\bar{x})^2}=\frac{\sigma_\varepsilon^2}{n\mathrm{V}(x)} \qquad (14.1.254)$$

Before determining the variance of B, remember that by hypothesis:

$$Y_k=\mathcal{N}(\alpha x_k+\beta,\sigma_\varepsilon) \qquad (14.1.255)$$

therefore by the property of linearity of the Normal distribution, the random variables A and B also follow a Normal distribution.

After the recall of this assumption, it follows immediately (see section Statistics page 611):

$$\mathrm{V}(Y_k)=\sigma_\varepsilon^2 \Leftrightarrow \mathrm{V}(\bar{Y})=\frac{\sigma_\varepsilon^2}{n} \qquad (14.1.256)$$

Therefore:

$$\begin{aligned}\mathrm{V}(B)&=\mathrm{V}(\bar{Y}-A\bar{x})=\mathrm{V}(\bar{Y})+\bar{x}^2\mathrm{V}(A)-2\bar{x}\mathrm{cov}(\bar{Y},A)=\mathrm{V}(\bar{Y})+\bar{x}^2\mathrm{V}(A)\\&=\frac{\sigma_\varepsilon^2}{n}+\bar{x}^2\sigma_A^2=\frac{\sigma_\varepsilon^2}{n}+\bar{x}^2\frac{\sigma_\varepsilon^2}{\sum_k (x_k-\bar{x})^2}=\frac{\sigma_\varepsilon^2\left(\sum_k (x_k-\bar{x})^2+n\bar{x}^2\right)}{n\sum_k (x_k-\bar{x})^2}\end{aligned} \qquad (14.1.257)$$

Remember the Huygens theorem (see section Statistics page 593):

$$\sum_k (x_k-\bar{x})^2=\sum_k x_k^2-n\bar{x}^2 \qquad (14.1.258)$$

in the case of equitable probabilities (Normal Law estimator of the mean as prove in the section Statistics).

Finally we have:

$$\mathrm{V}(B)=\sigma_B^2=\frac{\sigma_\varepsilon^2\left(\sum_k (x_k-\bar{x})^2+n\bar{x}^2\right)}{n\sum_k (x_k-\bar{x})^2}=\frac{\sigma_\varepsilon^2\left(\sum_k x_k^2\right)}{n\sum_k (x_k-\bar{x})^2}=\frac{\sigma_\varepsilon^2\sum_k x_k^2}{n^2\mathrm{V}(x)} \qquad (14.1.259)$$

where obviously the notation of the variance in the denominator is very unfair (because x is not a random variable in this model) but very convenient to condense the notation.

The problem now lies in determining σ_ε^2. Obviously to do this we will be forced to go through a statistical estimator.

We know we can write according to what was seen in the section Statistics regarding to estimators:

$$\hat{\sigma}_\varepsilon^2=\frac{1}{n-k}\sum(\varepsilon_i-\bar{\varepsilon})^2=\frac{1}{n-2}\sum\varepsilon_i^2=\frac{1}{n-2}\sum(Y_k-y_k)^2 \tag{14.1.260}$$

because the Normal distribution is centered for residuals and therefore $\bar{\varepsilon}=0$... and the residue is implicitly dependent of two the sum of two random variable that are A and B this is why we have a -2 at the denominator of the first fraction (we have to take away two degrees of freedom).

Let us also indicate that in practice we frequently note the last result by mixing the notations of the random and deterministic appearance (hence noting everything with lower case):

$$\hat{\sigma}_\varepsilon^2=\frac{1}{n-2}\sum(y_k'-y_k)^2=\frac{1}{n-2}\sum e_k^2=\frac{\text{SCR}}{n-2}=\text{SEE}^2 \tag{14.1.261}$$

where SEE[10] means "Standard Error of Estimate" or sometimes also named the "standard regression error" which is obtained with the English version of Microsoft® Excel® trough square of the function `STEYX( )`.

Remark

This bring us obviously to consider that standard R squared estimator uses biased estimators of σ_ε^2 and $\text{V}(Y)$, by using the divisor n (or $n-1$) for both. These estimators are biased because they ignore the degrees of freedom used to estimate the regression coefficients and mean of Y. If instead, we estimate $\text{V}(Y)$ by the usual unbiased sample variance (which uses $n-1$ as the divisor) and σ_ε^2 by its unbiased estimator which uses $n-p-1$ (where p is the number of predictors) as the divisor, we obtain the "adjusted R-squared $R^2_{\text{adj.}}$" estimator:

$$\boxed{\hat{R}^2_{\text{adj.}}=1-\frac{\text{SSE}_{\text{adj.}}}{\text{SST}}=1-\frac{\frac{1}{n-p-1}\sum_{k=1}^n(Y_k-\hat{Y}_k)^2}{\frac{1}{n-1}\sum_{k=1}^n(Y_k-\bar{Y})^2}=1-\frac{(n-1)\text{MSE}}{\text{SST}}} \tag{14.1.262}$$

From this relation, we can see that the adjusted estimator is always less than the standard one. We can also see the larger p is relative to n, the larger the adjustment. A final point: although the adjusted R squared estimator uses unbiased estimators of the residual variance and the variance of Y, it is not unbiased! This is because, as we know it, the mean of a ratio is not generally equal to the ratio of the means.

Furthermore, notice, as $\hat{R}^2=1-\text{SSE}/\text{SST}$, we have:

$$\hat{R}^2_{\text{adj.}}=1-(1-\hat{R}^2)\frac{n-1}{n-p-1} \tag{14.1.263}$$

But for any value of $p\geq 1$:

$$\frac{n-1}{n-p-1}>1 \tag{14.1.264}$$

---

[10] Sadly sometimes (like in Minitab outputs) just denoted by the letter "S"...

If we multiply both side by $(1-\hat{R}^2)$, we get:

$$(1-\hat{R}^2)\frac{n-1}{n-p-1} > (1-\hat{R}^2) \tag{14.1.265}$$

Subtracting -1:

$$(1-\hat{R}^2)\frac{n-1}{n-p-1}-1 > (1-\hat{R}^2)-1 \tag{14.1.266}$$

multiplying by -1:

$$1-(1-\hat{R}^2)\frac{n-1}{n-p-1}-1 < \hat{R}^2 \tag{14.1.267}$$

Therefore:

$$\hat{R}^2_{\text{adj.}} < \hat{R}^2 \tag{14.1.268}$$

From this relation, we can see that the adjusted estimator is always less than the standard one!

So we have to summarize the unbiased estimators variances of A and B:

$$\boxed{\hat{\sigma}_A^2=\frac{\hat{\sigma}_\varepsilon^2}{n\text{V}(x)}=\frac{\dfrac{1}{n-2}\sum e_k^2}{n\text{V}(x)} \qquad \hat{\sigma}_B^2=\frac{\hat{\sigma}_\varepsilon^2\sum\limits_k x_k^2}{n^2\text{V}(x)}=\frac{\dfrac{1}{n-2}\sum e_k^2\sum\limits_k x_k^2}{n^2\text{V}(x)}} \tag{14.1.269}$$

Relations which are therefore only valid for a linear regression with one unique explanatory variable (and under the assumptions of the Gaussian linear model). Knowing that by construction of the initial hypothesis that A and B follow a Normal distribution of respective expected mean α,β and whose variance is given just above, so we know completely the distribution that characterizes them.

What is nice knowing these variances is that we can also therefore easily estimate the variance of the dependent variable in our regression (using the properties of the variance proved in the section Statistics at page 596).

It would be interesting to make statistical inference on the mean of the parameters A and B (i.e. the slope and intercept) given their known empirical mean (i.e. average). For this, remember that we have proved in the section Statistics (see page 865) the following confidence interval:

$$\bar{X}-\frac{S}{\sqrt{n}}T_{\alpha/2}(n-1)\leq\mu\leq\bar{X}+\frac{S}{\sqrt{n}}T_{\alpha/2}(n-1) \tag{14.1.270}$$

It follows by making a parallel like engineers and physicists like to do ... that as A is an unbiased estimator of the average of the slope a and that:

$$\hat{\sigma}_A=\sqrt{\frac{\dfrac{1}{n-2}\sum e_k^2}{n\text{V}(x)}} \tag{14.1.271}$$

is in fact the standard error of the mean A, then by analogy:

$$\begin{gathered}\mu \to a\\ \bar{X} \to A\\ \frac{S}{\sqrt{n}} \to \sqrt{\frac{\dfrac{1}{n-2}\sum e_k^2}{n\mathrm{V}(x)}}\\ T_{\alpha/2}(n-1) \to T_{\alpha/2}(n-2)\end{gathered} \tag{14.1.272}$$

and then (this is a reasoning to be take with caution an it is better to use the developments that will follow later):

$$A - T_{\alpha/2}(n-2)\sqrt{\frac{\dfrac{1}{n-2}\sum e_k^2}{n\mathrm{V}(x)}} \leq a \leq A + T_{\alpha/2}(n-2)\sqrt{\frac{\dfrac{1}{n-2}\sum e_k^2}{n\mathrm{V}(x)}} \tag{14.1.273}$$

which therefore gives the confidence interval of the slope of a linear Gaussian with one unique explanatory variable (that's what gives Microsoft® Excel® 11.8346 for each coefficient). The approach is the same for the intercept.

Warning! If the explanatory variable is a random variable, then we use naively (the are more accurate and correct model that we will see later when the explanatory variable is a also a random variable):

$$A - T_{\alpha/2}(n-2)\sqrt{\frac{\dfrac{1}{n-2}\sum e_k^2}{n\hat{\mathrm{V}}(x)}} \leq a \leq A + T_{\alpha/2}(n-2)\sqrt{\frac{\dfrac{1}{n-2}\sum e_k^2}{n\hat{\mathrm{V}}(x)}} \tag{14.1.274}$$

In the case of a linear regression with several explanatory variables, therefore assimilated to the concept of "degrees of freedom DoF", the idea is the same but the calculations are longer (we don't have yet the will to do the mathematical developments for this case).

Finally, remember that we got for the empirical correlation coefficient:

$$R_{X,Y}^2 = \frac{a^2\mathrm{V}(X)}{\mathrm{V}(Y)} \tag{14.1.275}$$

We then verbatim get the famous confidence interval of the correlation coefficient:

$$\left(A - T_{\alpha/2}(n-2)\sqrt{\frac{\dfrac{1}{n-2}\sum e_k^2}{n\mathrm{V}(x)}}\right)^2 \frac{\mathrm{V}(X)}{\mathrm{V}(Y)} \leq R_{X,Y}^2 \leq \left(A + T_{\alpha/2}(n-2)\sqrt{\frac{\dfrac{1}{n-2}\sum e_k^2}{n\mathrm{V}(x)}}\right)^2 \frac{\mathrm{V}(X)}{\mathrm{V}(Y)} \tag{14.1.276}$$

The reader should know that as calculating the confidence interval for the slope or for the correlation coefficient are two equivalent things, many softwares (Tanagra, Minitab, Microsoft® Excel®, etc.) give only the value of the Student's distribution at the critical value of this latter only for the slope and... they then assume that the user of the software knows that it is the same for the correlation coefficient.

14.1.10.2.1 Pearson Correlation Coefficient Test

The calculation obtained above for the confidence interval of the correlation coefficient is a little difficult in practice. It is for this reason that many practitioners and statistical softwares implements a very simple alternative communicated only in the minimal form that is the p-value.

To see this approach, remember that we proved in the section of Statistics (see page 597) that (this time we will adopt the correct notation...):

$$\rho=\frac{\text{cov}(X,Y)}{\sqrt{\text{V}(X)\text{V}(Y)}} \tag{14.1.277}$$

And we saw just above that:

$$\rho=\frac{\text{cov}(X,Y)}{\sqrt{\text{V}(X)}}\sqrt{\text{V}(X)}\frac{1}{\sqrt{\text{V}(X)\text{V}(Y)}}=a\sqrt{\text{V}(X)}\frac{1}{\sqrt{\text{V}(X)\text{V}(Y)}}=a\frac{\sigma_X}{\sigma_Y} \tag{14.1.278}$$

Similarly, we have the Pearson correlation coefficient estimator which is (using here the various possible notations that we can find in the literature...):

$$R_{X,Y}=\sqrt{\frac{\text{SSE}}{\text{SST}}}=\frac{A\sqrt{\sum\limits_k(x_k-\bar{x}^2)}}{\sqrt{\sum\limits_k(y_k-\bar{y})^2}}=\frac{A\sqrt{\frac{1}{n-1}\sum\limits_k(x_k-\bar{x}^2)}}{\frac{1}{n-1}\sqrt{\sum\limits_k(y_k-\bar{y})^2}}=A\frac{\hat{\sigma}_X}{\hat{\sigma}_Y} \tag{14.1.279}$$

and therefore:

$$A=\frac{R_{X,Y}\hat{\sigma}_Y}{\hat{\sigma}_X} \tag{14.1.280}$$

The hypothesis test we want to do is therefore:

$$H_0:\quad \rho=0 \tag{14.1.281}$$

that is equivalent to:

$$H_0:\quad a=0 \tag{14.1.282}$$

The null hypothesis obviously being that the Pearson correlation is statistically significantly different from zero. So this is a bilateral test!

To find a simple form of the test, remember that we obtained:

$$(n-2)\hat{\sigma}_{\varepsilon}^2=\sum_k(y_k'-y_k)^2=\sum\varepsilon_k^2=\text{SSR} \tag{14.1.283}$$

and also:

$$R_{X,Y}^2=\frac{\text{SSE}}{\text{SST}}=\frac{\text{SST}-\text{SSR}}{\text{SST}}-1=1-\frac{\text{SSR}}{\text{SST}} \tag{14.1.284}$$

which brings us mixing the two to have:

$$\text{SSR}=\text{SST}(1-R_{X,Y}^2)=\sum_k (y_k-\bar{y})^2(1-R_{X,Y}^2)=(n-1)\hat{\sigma}_Y^2(1-R_{X,Y}^2) \tag{14.1.285}$$

Therefore:

$$\hat{\sigma}_\varepsilon^2=\frac{(n-1)\hat{\sigma}_Y^2(1-R_{X,Y}^2)}{n-2} \tag{14.1.286}$$

But we remember that we have also proved that if n is large enough:

$$A-T_{\alpha/2}(n-2)\sqrt{\frac{\dfrac{1}{n-2}\sum e_k^2}{n\hat{\mathbb{V}}(x)}}\leq a\leq A+T_{\alpha/2}(n-2)\sqrt{\frac{\dfrac{1}{n-2}\sum e_k^2}{n\hat{\mathbb{V}}(x)}} \tag{14.1.287}$$

But if n is small we fall back on:

$$A-T_{\alpha/2}(n-2)\sqrt{\frac{\dfrac{1}{n-2}\sum e_k^2}{(n-1)\hat{\sigma}_X}}\leq a\leq A+T_{\alpha/2}(n-2)\sqrt{\frac{\dfrac{1}{n-2}\sum e_k^2}{(n-1)\hat{\sigma}_X}} \tag{14.1.288}$$

Therefore:

$$T_{\alpha/2}(n-2)\geq\frac{A-a}{\sqrt{\dfrac{\dfrac{1}{n-2}\sum e_k^2}{(n-1)\hat{\sigma}_X}}}=\frac{A-a}{\sqrt{\dfrac{\dfrac{1}{n-2}\text{SSR}}{(n-1)\hat{\sigma}_X}}} \tag{14.1.289}$$

and with the null hypothesis $a=0$, we get:

$$\begin{aligned}T_{\alpha/2}(n-2)&\geq\frac{A}{\sqrt{\dfrac{\dfrac{1}{n-2}\text{SSR}}{(n-1)\hat{\sigma}_X}}}=\frac{R_{X,Y}\dfrac{\hat{\sigma}_Y}{\hat{\sigma}_X}}{\sqrt{\dfrac{\dfrac{\text{SSR}}{n-2}}{(n-1)\hat{\sigma}_X}}}=\frac{R_{X,Y}\hat{\sigma}_Y}{\hat{\sigma}_X\sqrt{\dfrac{\hat{\sigma}}{(n-1)\hat{\sigma}_X^2}}}=\frac{R_{X,Y}\hat{\sigma}_Y}{\hat{\sigma}_\varepsilon\sqrt{\dfrac{1}{n-1}}}\\&=\frac{R_{X,Y}\hat{\sigma}_Y}{\sqrt{\dfrac{1}{n-1}}\sqrt{\dfrac{(n-1)\hat{\sigma}_Y^2(1-R_{X,Y}^2)}{n-2}}}=\frac{R_{X,Y}}{\sqrt{\dfrac{1-R_{X,Y}^2}{n-2}}}\end{aligned} \tag{14.1.290}$$

Be careful with the use of this test often and logically named "Student's T-test for univariate regression slope" or "T-test for coefficient slope", depending if the Pearson correlation coefficient is negative or positive and don't forget that it is bilateral!

✍**Examples:**

E1. We have calculated for a series of data a positive Pearson correlation coefficient R of value 0.298 and the explanatory variable has 7 values. So we have with the English version Microsoft® Excel® 11.8346 the p-value that is given by (we find exactly the same value as with Minitab 15.1.1):

```
=2*(1-T.DIST(0.298/SQRT((1-0.298^2)/(7-2));7-2;1))
=2*(1-0.741869)=0.51626
```

In this case we sadly can't reject the null hypothesis as the Pearson correlation coefficient is equal to zero at a threshold of 5%.

E2. We have calculated for a data set a positive Pearson correlation coefficient R of -0.084 and the explanatory variable contains 19 values. So we have with the English version of Microsoft® Excel® 11.8346 the p-value that is equal to (we find exactly the same value as with Minitab 15.1.1):

```
=2* T.DIST((-0.084)/SQRT((1-(-0.084)^2)/(19-2));19-2;1)
=2*(1-0.366)=0.74186
```

In this case we also sadly can't reject the null hypothesis as what the Pearson correlation coefficient is equal to zero at a threshold of 5%.

This small trap makes that finally we take the absolute value of the Pearson correlation coefficient and we therefore use the always the same calculation method.

14.1.10.2.2 Confidence interval of predicted values

We wish for each measured value of the dependent variable, know the confidence interval. In other words, we would like to know the statistical variance estimator of Y (we do not write the subscripts anymore to save time):

$$\text{V}(Y)=\text{V}(Ax+B)=\text{V}(Ax)+\text{V}(B)+2\text{cov}(A,B) \tag{14.1.291}$$

Unfortunately, we will go into the wall because the covariance is difficult to calculate (A and B are not independent as shown by the expressions we got previously).

By cons, being a good observer, we see that if we use the result seen above:

$$B=\bar{Y}-A\bar{x} \tag{14.1.292}$$

Then:

$$\text{V}(Y)=\text{V}(Ax+B)=\text{V}(Ax+(\bar{Y}-A\bar{x}))=\text{V}(\bar{Y}+A(x-\bar{x})) \tag{14.1.293}$$

The problem being circumvented, we now have using the properties of variance:

$$\begin{aligned}\text{V}(Y)&=\text{V}(\bar{Y}+A(x-\bar{x}))=\text{V}(\bar{Y})+\text{V}(A(x-\bar{x}))+2\underbrace{\text{cov}(\bar{Y},A(x-\bar{x}))}_{=0}\\&=\text{V}(\bar{Y})+\text{V}(A(x-\bar{x}))=\text{V}(\bar{Y})+(x-\bar{x})^2\text{V}(A)=\frac{\sigma^2}{n}+(x-\bar{x})^2\frac{\sigma^2}{\sum\limits_k(x_k-\bar{x})^2}\end{aligned} \tag{14.1.294}$$

Therefore:

$$\text{V}(Y)=\sigma^2\left(\frac{1}{n}+\frac{(x-\bar{x})^2}{\sum\limits_k(x_k-\bar{x})^2}\right) \tag{14.1.295}$$

Then we have finally:

$$Y=\mathcal{N}\left(Ax+B,\sigma\sqrt{\frac{1}{n}+\frac{(x-\bar{x})^2}{\sum\limits_k(x_k-\bar{x})^2}}\right) \tag{14.1.296}$$

Now let us recall (see section Statistics page 595) that:

$$Z=\frac{X-\mu}{\sigma} \tag{14.1.297}$$

and as Y is distributed according to a Normal distribution for whose the unbiased estimator of the mean and standard deviation are given by the prior-previous relation it comes immediately:

$$Z=\frac{Y-(Ax+B)}{\sigma\sqrt{\dfrac{1}{n}+\dfrac{(x-\bar{x})^2}{\sum\limits_k(x_k-\bar{x})^2}}} \tag{14.1.298}$$

In practice you must also check that this ratio follows a Normal distribution in order to make the confidence intervals and statistical tests that follow.

Let us recall now that we have proved in the section Statistics (see page 783) that:

$$T(k)=T_k=\frac{Z}{\sqrt{U/k}} \tag{14.1.299}$$

follows a Student law of degrees of freedom k and the variable U follows a chi-square law of degree of freedom k.

Now let us come back to the expression of the Z obtained above and remember that:

$$\hat{\sigma}^2=\frac{1}{n-2}\sum\varepsilon_i^2 \tag{14.1.300}$$

Therefore:

$$\hat{\sigma}=\sqrt{\frac{\sum\varepsilon_i^2}{n-2}} \tag{14.1.301}$$

But as we have the assumption:

$$\varepsilon_i=\mathcal{N}(0,\sigma) \tag{14.1.302}$$

Therefore:

$$\frac{\varepsilon_i}{\sigma}=\mathcal{N}(0,1) \tag{14.1.303}$$

and obviously:

$$\sum\frac{\varepsilon_i^2}{\sigma^2}=\sum\left(\frac{\varepsilon_i}{\sigma}\right)^2 \tag{14.1.304}$$

corresponds to a sum of squares of reduced centered Normal laws. And therefore according to what we have proved in section Statistics (see page 863) it follows that:

$$\sum\left(\frac{\varepsilon_i}{\sigma}\right)^2=\chi^2(n-2)=\chi^2_{n-2} \tag{14.1.305}$$

Therefore:

$$\begin{aligned}T(n-2)=T_{n-2}&=\frac{Z}{\sqrt{U/k}}=\frac{Z}{\sqrt{\dfrac{\sum\left(\frac{\varepsilon_i}{\sigma}\right)^2}{n-2}}}=\frac{Z}{\sqrt{\dfrac{1}{\sigma^2}\sum\dfrac{\varepsilon_i^2}{n-2}}}\\&=\frac{\sigma Z}{\sqrt{\sum\dfrac{\varepsilon_i^2}{n-2}}}=\frac{\sigma Z}{\hat{\sigma}}\end{aligned} \tag{14.1.306}$$

That is to say:

$$T(n-2)=\frac{\sigma Z}{\hat{\sigma}}=\frac{\sigma\dfrac{Y-(Ax+B)}{\sigma\sqrt{\dfrac{1}{n}+\dfrac{(x-\bar{x})^2}{\sum\limits_k(x_k-\bar{x})^2}}}}{\hat{\sigma}}=\frac{Y-(Ax+B)}{\hat{\sigma}\sqrt{\dfrac{1}{n}+\dfrac{(x-\bar{x})^2}{\sum\limits_k(x_k-\bar{x})^2}}} \tag{14.1.307}$$

This is one reason why many statisticians note directly and without detours:

$$Z=\frac{Y-(Ax+B)}{\sigma\sqrt{\dfrac{1}{n}+\dfrac{(x-\bar{x})^2}{\sum\limits_k (x_k-\bar{x})^2}}}\Rightarrow T(n-2)=\frac{Y-(Ax+B)}{\hat{\sigma}\sqrt{\dfrac{1}{n}+\dfrac{(x-\bar{x})^2}{\sum\limits_k (x_k-\bar{x})^2}}} \tag{14.1.308}$$

Which is not necessarily obvious at first glance. This is why, following the request of a reader, we have detailed a little bit the mechanism behind this involvement.

This done, we have finally:

$$T(n-2)=\frac{Y-(Ax+B)}{\hat{\sigma}\sqrt{\dfrac{1}{n}+\dfrac{(x-\bar{x})^2}{\sum\limits_k (x_k-\bar{x})^2}}} \tag{14.1.309}$$

and we deduce from this immediately a bilateral confidence interval of a given threshold level α for a fixed x whose expression is:

$$\boxed{Y=Ax+B\pm T_{\alpha/2}(n-2)\hat{\sigma}\sqrt{\dfrac{1}{n}+\dfrac{(x-\bar{x})^2}{\sum\limits_k (x_k-\bar{x})^2}}} \tag{14.1.310}$$

Remark

The same kind of development can be done for the slope and the intercept. This is why software like Microsoft® Excel®, SPSS, Minitab, Statistica, etc. give the value of the Student T-distribution as well as the confidence interval for a given threshold level α. But for this to be meaningful, you must never forget that all the assumptions of the model must be met.

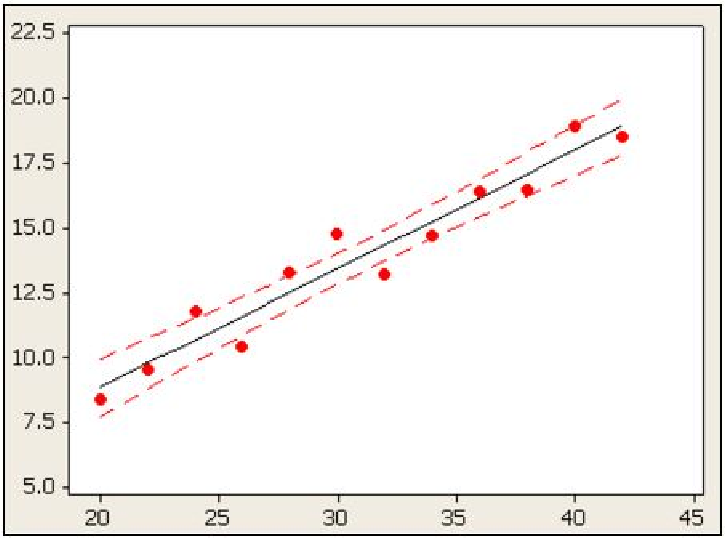

Figure 14.13: Print screen of a confidence interval obtained with Minitab 15

The reader will may have noticed that:

- It is very boring to obtain without software or without coding the plot of the confidence interval for the ordinary least squares since we have to calculate it for each point...
- The confidence interval is curved which is sometimes considered as common sense, at least in the temporal version of the regression: furthest is the forecast less accurate it will be

The true value of Y is given by:

$$y = a + bx + \varepsilon \tag{14.1.311}$$

with the variance:

$$\mathrm{V}(y) = \mathrm{V}(\varepsilon) = \sigma^2 \tag{14.1.312}$$

which is independent of the estimator Y. Therefore, the difference between Y and y (therefore between estimator and real value) has for variance:

$$\mathrm{V}(Y-y) = \mathrm{V}(Y) - \mathrm{V}(y) = \sigma^2 \left(1 + \frac{1}{n} + \frac{(x-\bar{x})^2}{\sum\limits_k (x_k - \bar{x})^2}\right) \tag{14.1.313}$$

Therefore it is customary to consider that the "prediction interval" (not to be confused with the confidence interval of the estimator) is taken as:

$$\boxed{Y = Ax + B \pm T_{\alpha/2}(n-2)\hat{\sigma}\sqrt{1 + \frac{1}{n} + \frac{(x-\bar{x})^2}{\sum\limits_k (x_k - \bar{x})^2}}} \tag{14.1.314}$$

Remark

The same kind of development can be done for the slope and the intercept. This is why software like Microsoft® Excel®, IBM SPSS, Minitab, Statistica, etc. give the value of the Student T-distribution as well as the confidence interval for a given threshold level α. But for this to be meaningful, you must never forget that all the assumptions of the model must be met.

This gives us the following type of chart with a software such as Minitab 15:

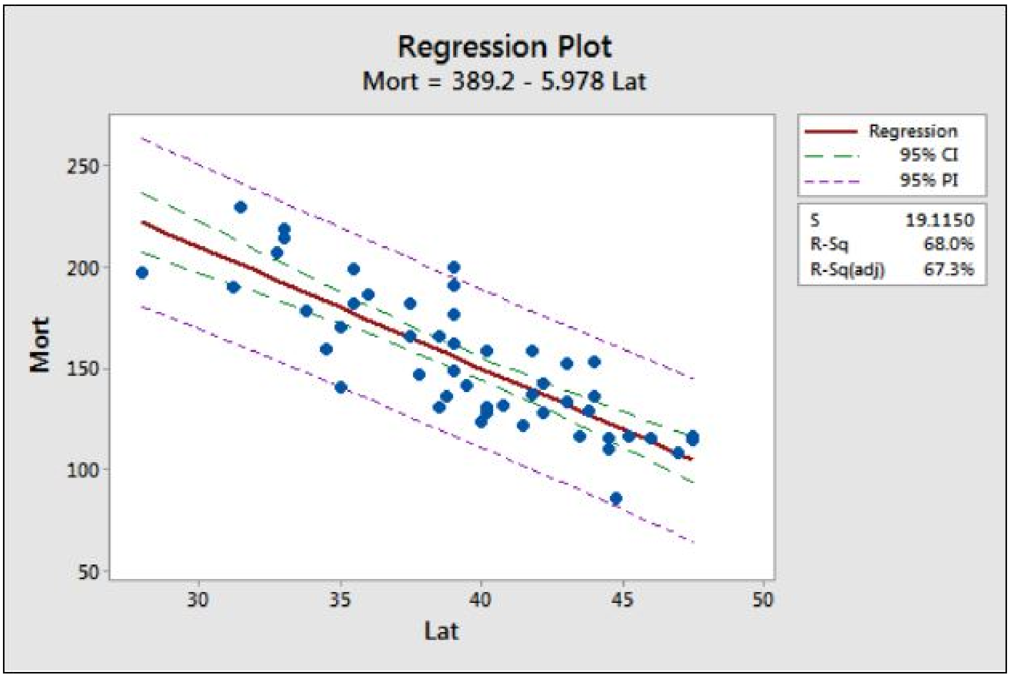

Figure 14.14: Print screen of a prediction interval (PI) in green obtained with Minitab 15

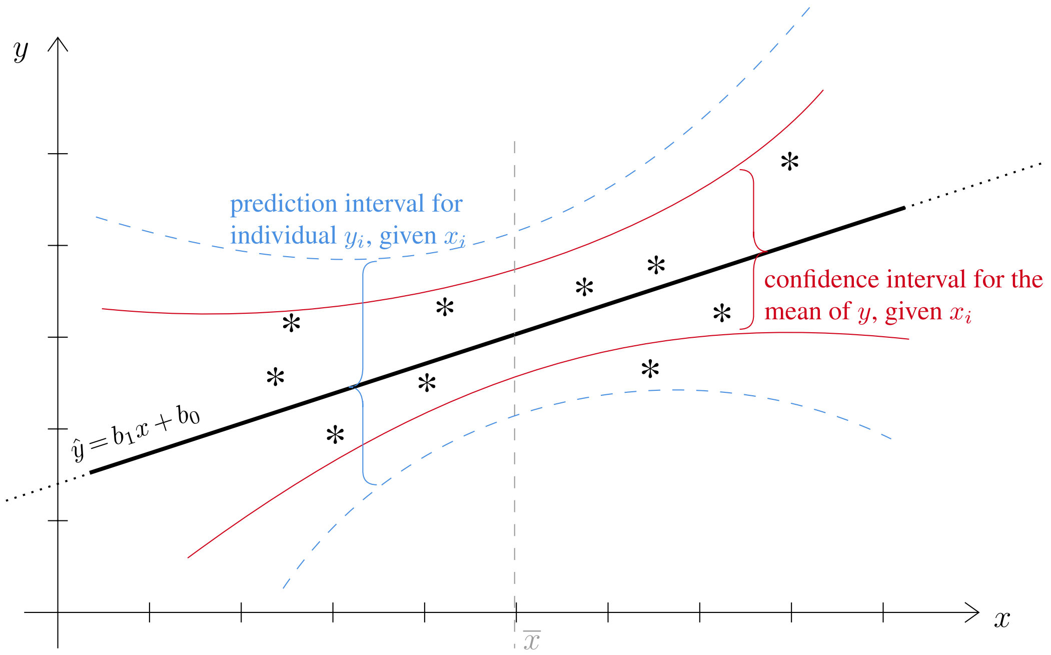
Where we can see the prediction interval (PI) in green and the confidence interval (CI) in red and its is obvious to see by the property of the variance that CI<PI.



y
x
$\overline{x}$
$\hat{y}=b_1x+b_0$
prediction interval for individual y_i, given x_i
confidence interval for the mean of y, given x_i

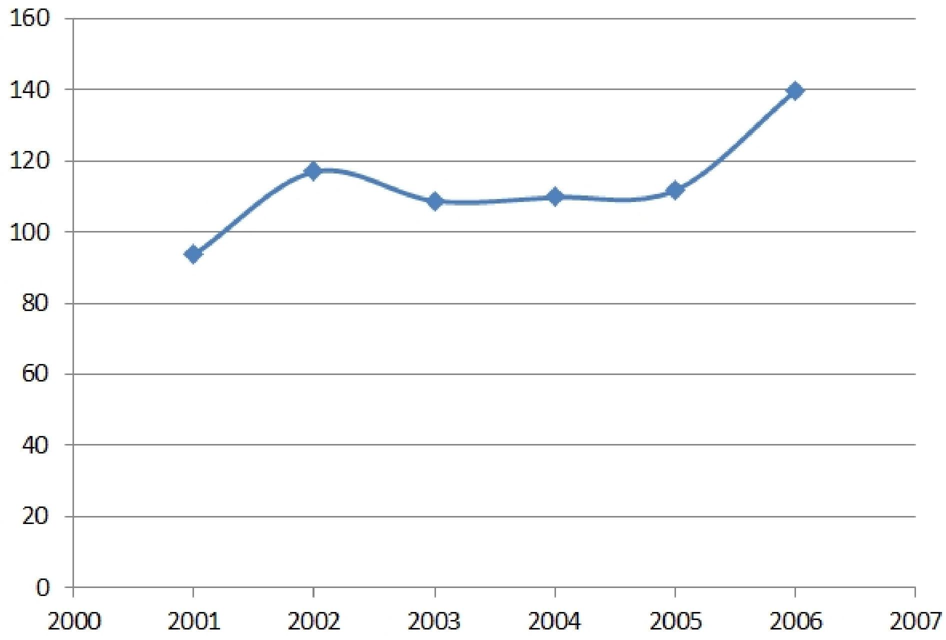
Figure 14.15: Confidence vs Prediction interval

These two intervals are often confused. To understand these, it's important to realize that a regression model fits a relationship between the input variables and the mean value of the outcome variable - this is the red line in the below chart. The confidence interval indicates a range of certainty around the mean value of the outcome variable - usually 95% - and is illustrated by the green lines above. The prediction interval indicates a range of certainty around any value of the outcome variable and is illustrated by the purple lines above. Another way of looking at this is to imagine taking a vertical slice of the below chart. This would translate - under the most common models - to a bell curve for the value of the outcome variable at that specific value of the input variable. The red point indicates the most likely center of the bell curve, the green lines represents the 95% likelihood range for that center and the purple lines represents the likelihood for the 95% range (i.e. width) of all these bell curves.

So what must be well understand by the reader so far, is that if we are dealing with univariate linear regression or any other type of regression and want to plot the following data that corresponds to a sample for each x-value:

	A	B
1	**Year**	**Value**
2	2001	90.00
3	2001	98.00
4	2001	98.00
5	2001	90.00
6	2001	92.00
7	2002	129.00
8	2002	112.00
9	2002	109.00
10	2002	119.00
11	2002	116.00
12	2003	110.00
13	2003	114.00
14	2003	110.00
15	2003	105.00
16	2003	105.00
17	2004	106.00
18	2004	115.00
19	2004	113.00
20	2004	107.00
21	2004	108.00
22	2005	126.00
23	2005	106.00
24	2005	111.00
25	2005	109.00
26	2005	107.00
27	2006	133.00
28	2006	143.00
29	2006	144.00
30	2006	135.00
31	2006	144.00

Therefore using a spreadsheet software to make a plot of that the average of each year as following (most common case see in Fortune 500 companies by top managers and also by auditing companies like Klynveld Peat Marwick Goerdeler/KPMG and Ernst & Young/EY):



using a smooth chart is everything but scientific. Indeed:

1. No spreadsheet software is able to summary the data list above automatically in quick an efficient way (with Microsoft® Excel® even Pivot Charts cannot do smooth scatter charts of such a list of data...).
2. Smooth scatter plot in spreadsheet softwares use splines interpolation and these are not statistical models that can be used for samples! So reading such charts in a spreadsheet software introduce a huge deterministic bias in the mind of the board committee or any customer/supplier.
3. As the averages come from samples there is an implicit confidence interval THAT HAS TO BE SHOWN to the board committee or customer/supplier. Do not show a confidence interval on sample data is a high-school level error that is not acceptable when done by a senior manager or business analyst or even a consultant of a big 5 auditing companies.

So following the detailed steps given in our `R` companion book we get something truly scientific and robust that is:

14.1.10.3 Linear univariate regression forced through the origin (RTO)

One very common requested case in laboratories (and generally in other departments) of corporations, is to force the linear regression through the origin. This technique is named "regression through origin" and abbreviated RTO.

We will see now (in the univariate case) that the approach is only a simplified variant of the method of the ordinary least squares.

We use as before:

$$\text{SSR} = \sum_{k=1}^{n} (y_k - y'_k)^2 \tag{14.1.315}$$

where n is the number of points. But this time, let us write:

$$y'_k = a x_k \tag{14.1.316}$$

then:

$$\text{SSR} = \sum_{k=1}^{n} (y_k - a x_k)^2 = \Phi(a) \tag{14.1.317}$$

This relation make appears the sum of squared deviations as a function of the parameter a. When this function is minimal (extremal), the derivatives with respect to its parameters are cancelled:

$$\frac{\partial \Phi}{\partial a}(a) = -2x_k \sum_{k=1}^{n} (y_k - a x_k) = 0 \tag{14.1.318}$$

After simplification:

$$a \sum_{k=1}^{n} x_k^2 = \sum_{k=1}^{n} x_k y_k \tag{14.1.319}$$

Finally:

$$a = \frac{\displaystyle\sum_{k=1}^{n} x_k y_k}{\displaystyle\sum_{k=1}^{n} x_k^2} \tag{14.1.320}$$

You can also easily check with any spreadsheet software (Microsoft® Excel® for example) that the calculations corresponds well.

However the reader must know now that the RTO subject is surprisingly controversial among statisticians. Indeed, forcing the regression line through the origin is generally inconsistent with the best fit.

Caution! The text below is mainly a reproduction with some adaptations of the following article [163]. Thanks to the donations we were able to buy the rights (225 US$...) to John Wiley & Sons, Inc. to reproduce it in this textbook. But in no manner the reader is authorized to reproduce the same text without the agreement of John Wiley & Sons, Inc. !!!

The proper method for evaluating RTO has long been disputed. To appreciate the controversy, note the familiar identity:

$$(y_k-\bar{y})=(y_k-\hat{y}_k)+(\hat{y}_k-\bar{y}) \tag{14.1.321}$$

Squaring both sides and summing across all observation gives:

$$\sum(y_k-\bar{y})^2=\sum(y_k-\hat{y}_k)^2+\sum(\hat{y}_k-\bar{y})^2+2\sum(y_k-\hat{y}_k)(\hat{y}_k-\bar{y}) \tag{14.1.322}$$

However, as we have proved earlier above, the cross-product term must be equal to zero in the case of OLS. The remaining terms therefore constitute the usual analysis of variance decomposition:

$$\sum(y_k-\bar{y})^2=\sum(y_k-\hat{y}_k)^2+\sum(\hat{y}_k-\bar{y})^2 \tag{14.1.323}$$

And we know that the coefficient of determination for OLS is then defined by:

$$R^2=\frac{\sum(\hat{y}_k-\bar{y})^2}{\sum(y_k-\bar{y})^2}=1-\frac{\sum(y_k-\hat{y}_k)^2}{\sum(y_k-\bar{y})^2} \tag{14.1.324}$$

Some authors claim that because this diagnostic measure is based on an identity, it should not depend on the inclusion or exclusion of a constant term in the regression. From that perspective, the previous relation is equally valid for RTO and OLS.

However, when there is no constant in the regression, $\sum(y_k-\hat{y}_k)(\hat{y}_k-\bar{y})$ will generally take a non-zero value, so the variance decomposition:

$$\sum(y_k-\bar{y})^2=\sum(y_k-\hat{y})^2+\sum(\hat{y}_k-\bar{y})^2 \tag{14.1.325}$$

is not a valid basis for analysis of variance in RTO. And if the RTO model provides a sufficiently poor fit, the data may exhibit more variation around the regression line than around y, in which case:

$$\sum(y_k-\hat{y})^2>\sum(y_k-\bar{y})^2 \tag{14.1.326}$$

Heedlessly applying:

$$R^2=1-\frac{\sum(y_k-\hat{y})^2}{\sum(y_k-\bar{y})^2} \tag{14.1.327}$$

would then result in an implausibly negative (and thus non-interpretable) coefficient of determination as well as a negative F ratio. Moreover, it is often argued that defining SST as the sum of squared deviations from the mean is inappropriate when the regression line is forced through the origin but does not necessarily pass through $(\bar{x},\bar{y})$, when so viewed, the starting relation:

$$(y_k-\bar{y})=(y_k-\hat{y})+(\hat{y}_k-\bar{y}) \tag{14.1.328}$$

is replaced by identity:

$$(y_k-0)=(y_k-\hat{y}_k)+(\hat{y}_k-0) \tag{14.1.329}$$

Squaring and summing yields:

$$\sum y_k^2=\sum(y_k-\hat{y}_k)^2+\sum\hat{y}_k^2+2\sum\hat{y}_k(y_k-\hat{y}_k) \tag{14.1.330}$$

but the final (cross-product) term in this equation equals zero under RTO, because:

$$\begin{aligned}\sum\hat{y}_k(y_k-\hat{y}_k)&=\sum\hat{\beta}x_k(y_k-\hat{\beta}x_k)=\hat{\beta}\left(\sum x_ky_k-\hat{\beta}\sum x_k^2\right)\\&=\hat{\beta}\left[\sum x_ky_k-\left(\frac{\sum x_ky_k}{\sum x_k^2}\right)\sum x_k^2\right]=0\end{aligned} \tag{14.1.331}$$

Thus, the variance OLS decomposition:

$$\sum(y_k-\bar{y})^2=\sum(y_k-\hat{y}_k)^2+\sum(\hat{y}_k-\bar{y})^2 \tag{14.1.332}$$

is replaced by:

$$\sum y_k^2=\sum(y_k-\hat{y}_k)^2+\sum\hat{y}_k^2 \tag{14.1.333}$$

Applying this latter relation one rather than the classical OLS one to RTO, one finds that SSE is unchanged, but $\text{SST}=\sum y_k^2$ and $\text{SSR}=\sum\hat{y}_k^2$. Redefining SST and SSR in this manner results in:

$$R^2=\frac{\sum\hat{y}_k^2}{\sum y_k^2} \tag{14.1.334}$$

ie, also a strictly non-negative coefficient of determination that equals or exceeds the classical R^2 measurement. Of course, these definitions also affect the adjusted R^2 and F statistics.

Note that, without a constant, the degrees of freedom for SST, SSR and SSE are n, k and $n\breve{\ }k$, respectively, where n is the sample size and k is the number of independent variables. Thus:

$$\text{SE}=\sqrt{\frac{\text{SSE}}{n-k}} \tag{14.1.335}$$

regardless of how SST is defined.

The controversy over SST is not merely academic: practitioners (and students) running RTO got various outputs depending on which computer packages they use a few dozens of years ago (since they almost all give the same result based on the adapted definition of the correlation coefficient).

14.1.10.4 Deming regression (orthogonal regression)

As we have already mentioned it, the "orthogonal linear regression model" or "Deming regression" is used as complement to the paired T-test to check the stability of the measuring instruments in laboratories. This is a case where the explanatory and dependent variables are tainted with uncertainty (we speak then of "stochastic regressors" at the opposite classical case where we have "nonstochastic regressors"). In other words, this regression is used when working in a situation where it is desired to compare two linearly increasing or decreasing variables and where each is tainted with measurement errors including error values (of the two variables!) are independent.

Remarks

R1. Chemists do this analysis sometimes in a qualitative form using the "Bland-Altman plots".

R2. Deming regression is a special case of "Total Least Squares regression" (TLSR) that minimize the total geometric distance between data points and the best-fit line rather than just the vertical distance as in Ordinary Least Squares regression (OLSR).

We will see now the derivation of the maximum likelihood estimates related to the Deming regression model. It is based on the book *Models in regression and related topics* (chapter three), from 1969 by Peter Sprent, but with more detailed calculations included (big thanks to Anders Jensen for the LaTeX code of the proof!) .

14.1.10.4.1 Deming orthogonal regression log-likelihood derivation

The mathematical model $\eta=\alpha+\beta\xi$ describes a linear relationship between two variables ξ and η. Observations x and y of two variables are usually described by a regression of y on x where x is assumed to be observed without error (or, equivalently using the conditional distribution of y given x). In linear regression with observations subject to additive random variation on both x and y and observed values for individuals $(x_i,y_i), i=1,\ldots,n$, a model may be written:

$$x_i=\xi_i+e_{xi}\quad y_i=\eta_i+e_{yi}=\alpha+\beta\xi_i+e_{yi} \tag{14.1.336}$$

where e_{xi} and e_{y_i} denotes the random part of the model. This is known as a functional relationship because the ξ_i's are assumed to be fixed parameters, as opposed to a structural relationship where some distribution for the ξ_i's is assumed. In the following it is assumed that the e_{xi}s are independent and identically distributed with:

$$e_{yi}\sim\mathcal{N}(0,\sigma^2) \tag{14.1.337}$$

and that the e_{yi}s are independent and identically distributed with:

$$e_{yi}\sim\mathcal{N}(0,\lambda\sigma^2) \tag{14.1.338}$$

for some $\lambda>0$. Furthermore e_{xi} is assumed to be independent of e_{yi}.

The aim of this document is to derive the maximum likelihood estimates for α,β,ξ_i and σ^2 in the functional model stated above.

The likelihood function:

$$f_{x_1,x_2,\ldots,x_n,y_1,y_2,\ldots,y_n}(\alpha,\beta,\xi_1,\xi_2,\ldots,\xi_n,\sigma^2) \tag{14.1.339}$$

denoted f is:

$$f=\prod_{i=1}^{n}\left(2\pi\sigma^2\right)^{-\frac{1}{2}}\exp\left(-\frac{(x_i-\xi_i)^2}{2\sigma^2}\right)\left(2\pi\lambda\sigma^2\right)^{-\frac{1}{2}}\exp\left(-\frac{(y_i-\alpha-\beta\xi_i)^2}{2\lambda\sigma^2}\right) \tag{14.1.340}$$

and the log-likelihood, denoted $\mathcal{L}$, is:

$$\begin{aligned}\mathcal{L}&=\sum_{i=1}^{n}-\frac{1}{2}\log\left(2\pi\sigma^2\right)-\frac{(x_i-\xi_i)^2}{2\sigma^2}-\frac{1}{2}\log\left(2\pi\lambda\sigma^2\right)-\frac{(y_i-\alpha-\beta\xi_i)^2}{2\lambda\sigma^2}\\&=-\frac{n}{2}\log\left(4\pi^2\right)-\frac{n}{2}\log\left(\lambda\sigma^4\right)-\frac{\displaystyle\sum_{i=1}^{n}(x_i-\xi_i)^2}{2\sigma^2}-\frac{\displaystyle\sum_{i=1}^{n}(y_i-\alpha-\beta\xi_i)^2}{2\lambda\sigma^2}\end{aligned} \tag{14.1.341}$$

It follows that the likelihood function is not bounded from above when σ^2 goes to 0, so in the following it is assumed that $\sigma^2>0$.

Let us solve for ξ_i now! The differentiation of $\mathcal{L}$ with respect to ξ_i gives:

$$\begin{aligned}\frac{\partial\mathcal{L}}{\partial\xi_i}&=\frac{\partial}{\partial\xi_i}\left(-\frac{\displaystyle\sum_{i=1}^{n}(x_i-\xi_i)^2}{2\sigma^2}-\frac{\displaystyle\sum_{i=1}^{n}(y_i-\alpha-\beta\xi_i)^2}{2\lambda\sigma^2}\right)\\&=\frac{(x_i-\xi_i)}{\sigma^2}+\frac{\beta(y_i-\alpha-\beta\xi_i)}{\lambda\sigma^2}\end{aligned} \tag{14.1.342}$$

Setting $\frac{\partial\mathcal{L}}{\partial\xi_i}$ equal to zero yields:

$$\frac{\partial\mathcal{L}}{\partial\xi_i}=0\Rightarrow\quad\xi_i=\frac{\lambda\sigma^2x_i+\beta\sigma^2y_i-\beta\alpha\sigma^2}{\lambda\sigma^2+\beta^2\sigma^2}=\frac{\lambda x_i+\beta(y_i-\alpha)}{\lambda+\beta^2} \tag{14.1.343}$$

So to estimate ξ_i, estimates for β and α are needed. Therefore focus is turned to the derivation of $\hat{\alpha}$.

Let us now solve for α. The differentiation of $\mathcal{L}$ with respect to α gives:

$$\frac{\partial\mathcal{L}}{\partial\alpha}=\frac{\partial}{\partial\alpha}\left(-\frac{\displaystyle\sum_{i=1}^{n}(y_i-\alpha-\beta\xi_i)^2}{2\lambda\sigma^2}\right)=\frac{\displaystyle\sum_{i=1}^{n}(y_i-\alpha-\beta\xi_i)}{\lambda\sigma^2} \tag{14.1.344}$$

and putting $\frac{\partial\mathcal{L}}{\partial\alpha}$ equal to zero yields to:

$$\frac{\partial L}{\partial\alpha}=0\Rightarrow\quad\alpha=\frac{1}{n}\sum_{i=1}^{n}(y_i-\beta\xi_i) \tag{14.1.345}$$

Now one can use:

$$\xi_i = \frac{\lambda x_i + \beta(y_i - \alpha)}{\lambda + \beta^2} \tag{14.1.346}$$

to dispense with ξ_i:

$$\begin{aligned}
\alpha &= \frac{1}{n}\sum_{i=1}^{n}(y_i - \beta\xi_i)\\
&= \frac{1}{n}\sum_{i=1}^{n}\left(y_i - \beta\frac{\lambda x_i + \beta(y_i - \alpha)}{\lambda + \beta^2}\right)\\
&= \frac{1}{n}\sum_{i=1}^{n}\left(y_i - \beta\frac{\lambda x_i + \beta y_i}{\lambda + \beta^2} + \frac{\beta^2\alpha}{\lambda + \beta^2}\right)\\
&\Updownarrow\\
\alpha\left(1 - \frac{\beta^2}{\lambda + \beta^2}\right) &= \frac{1}{n}\sum_{i=1}^{n}\left(y_i - \beta\frac{\lambda x_i + \beta y_i}{\lambda + \beta^2}\right)\\
&= \frac{1}{n}\sum_{i=1}^{n}\left(y_i\left(1 - \frac{\beta^2}{\lambda + \beta^2}\right) - x_i\frac{\beta\lambda}{\lambda + \beta^2}\right)\\
&\Updownarrow\\
\alpha &= \frac{1}{n}\sum_{i=1}^{n}\left(y_i - x_i\frac{\beta\lambda}{\lambda + \beta^2}\frac{\lambda + \beta^2}{\lambda}\right)\\
&= \frac{1}{n}\sum_{i=1}^{n}(y_i - x_i\beta)\\
&= \overline{y} - \overline{x}\beta
\end{aligned} \tag{14.1.347}$$

Hence the estimate for α becomes:

$$\hat{\alpha} = \overline{y} - \overline{x}\hat{\beta} \tag{14.1.348}$$

Solving for β by differentiating $\mathcal{L}$ with respect to β gives:

$$\frac{\partial\mathcal{L}}{\partial\beta} = \frac{\partial}{\partial\beta}\left(-\frac{\displaystyle\sum_{i=1}^{n}(y_i - \alpha - \beta\xi_i)^2}{2\lambda\sigma^2}\right) = \frac{\displaystyle\sum_{i=1}^{n}(y_i - \alpha - \beta\xi_i)\xi_i}{\lambda\sigma^2} \tag{14.1.349}$$

Setting $\frac{\partial\mathcal{L}}{\partial\beta}$ equal to zero yields:

$$\frac{\partial\mathcal{L}}{\partial\beta}=0\Leftrightarrow\sum_{i=1}^{n}(y_i-\alpha-\beta\xi_i)\xi_i=0 \tag{14.1.350}$$

and using again:

$$\xi_i=\frac{\lambda x_i+\beta(y_i-\alpha)}{\lambda+\beta^2} \tag{14.1.351}$$

we get:

$$\begin{aligned}0&=\sum_{i=1}^{n}(y_i-\alpha-\beta\xi_i)\xi_i\\&=\sum_{i=1}^{n}\left(y_i-\alpha-\beta\frac{\lambda x_i+\beta(y_i-\alpha)}{\lambda+\beta^2}\right)\frac{\lambda x_i+\beta(y_i-\alpha)}{\lambda+\beta^2}\end{aligned} \tag{14.1.352}$$

This implies that:

$$\begin{aligned}0&=\sum_{i=1}^{n}\Big((y_i-\alpha)(\lambda+\beta^2)-\beta\lambda x_i-\beta^2(y_i-\alpha)\Big)\Big(\lambda x_i+\beta(y_i-\alpha)\Big)\\&=\sum_{i=1}^{n}\lambda^2x_i(y_i-\alpha)+\beta^2\lambda x_i(y_i-\alpha)-\beta\lambda^2x_i^2-\beta^2\lambda x_i(y_i-\alpha)+\\&\sum_{i=1}^{n}\beta\lambda(y_i-\alpha)^2+\beta^3\lambda(y_i-\alpha)^2-\beta^2\lambda x_i(y_i-\alpha)-\beta^3(y_i-\alpha)^2\\&=-\beta^2\lambda\left(\sum_{i=1}^{n}x_iy_i\right)-\beta\lambda^2\left(\sum_{i=1}^{n}x_i^2\right)+\lambda^2\left(\sum_{i=1}^{n}x_iy_i\right)\\&+\beta^2\lambda\alpha\left(\sum_{i=1}^{n}x_i\right)+\beta\lambda\left(\sum_{i=1}^{n}(y_i-\alpha)^2\right)-\lambda^2\alpha\left(\sum_{i=1}^{n}x_i\right)\end{aligned} \tag{14.1.353}$$

Dividing with λ and using the fact that:

$$\alpha=\overline{y}-\overline{x}\beta \tag{14.1.354}$$

it is seen that:

$$
\begin{aligned}
0 &= -\beta^2\Big(\sum_{i=1}^{n} x_i y_i\Big) - \beta\lambda\Big(\sum_{i=1}^{n} x_i^2\Big) + \lambda\Big(\sum_{i=1}^{n} x_i y_i\Big) + \beta^2(\overline{y}-\overline{x}\beta)\Big(\sum_{i=1}^{n} x_i\Big) \\
&+ \beta\Big(\sum_{i=1}^{n} (y_i - (\overline{y}-\overline{x}\beta))^2\Big) - \lambda(\overline{y}-\overline{x}\beta)\Big(\sum_{i=1}^{n} x_i\Big) \\
&= -\beta^2\Big(\sum_{i=1}^{n} x_i y_i\Big) - \beta\lambda\Big(\sum_{i=1}^{n} x_i^2\Big) + \lambda\Big(\sum_{i=1}^{n} x_i y_i\Big) + \beta^2\overline{y}\Big(\sum_{i=1}^{n} x_i\Big) \\
&- \beta^3\overline{x}\beta\Big(\sum_{i=1}^{n} x_i\Big) + \beta\Big(\sum_{i=1}^{n} y_i^2\Big) + \beta\Big(\sum_{i=1}^{n} (\overline{y}-\overline{x}\beta)^2\Big) \\
&- 2\beta\Big(\sum_{i=1}^{n} y_i(\overline{y}-\overline{x}\beta)\Big) - \lambda\overline{y}\Big(\sum_{i=1}^{n} x_i\Big) + \lambda\overline{x}\beta\Big(\sum_{i=1}^{n} x_i\Big)
\end{aligned}
\tag{14.1.355}
$$

Splitting up the sums even more gives:

$$
\begin{aligned}
0 = &-\beta^2\Big(\sum_{i=1}^{n} x_i y_i\Big) - \beta\lambda\Big(\sum_{i=1}^{n} x_i^2\Big) + \lambda\Big(\sum_{i=1}^{n} x_i y_i\Big) + \beta^2\overline{y}\Big(\sum_{i=1}^{n} x_i\Big) - \beta^3\overline{x}\beta\Big(\sum_{i=1}^{n} x_i\Big) \\
&+ \beta\Big(\sum_{i=1}^{n} y_i^2\Big) + \beta\Big(\sum_{i=1}^{n} \overline{y}^2\Big) + \beta\Big(\sum_{i=1}^{n} (\overline{x}.\beta)^2\Big) - 2\beta\Big(\sum_{i=1}^{n} \overline{yx}\beta\Big) - 2\beta\Big(\sum_{i=1}^{n} y_i\overline{y}\Big) \\
&+ 2\beta\Big(\sum_{i=1}^{n} y_i\overline{x}\beta\Big) - \lambda\overline{y}\Big(\sum_{i=1}^{n} x_i\Big) + \lambda\overline{x}\beta\Big(\sum_{i=1}^{n} x_i\Big)
\end{aligned}
\tag{14.1.356}
$$

Finally the terms are sorted and collected according to powers of β:

$$
\begin{aligned}
0 = &\beta^3\left(\sum_{i=1}^{n} \overline{x}^2 - \overline{x}\sum_{i=1}^{n} x_i\right) \\
&+ \beta^2\left(\overline{y}\sum_{i=1}^{n} x_i - \sum_{i=1}^{n} x_i y_i - 2\sum_{i=1}^{n} \overline{yx} + 2\sum_{i=1}^{n} y_i\overline{x}\right) \\
&+ \beta\left(\sum_{i=1}^{n} y_i^2 - \lambda\sum_{i=1}^{n} x_i^2 + \sum_{i=1}^{n} \overline{y}^2 - 2\sum_{i=1}^{n} y_i\overline{y} + \lambda\overline{x}\sum_{i=1}^{n} x_i\right) \\
&+ \lambda\left(\sum_{i=1}^{n} x_i y_i - \overline{y}\sum_{i=1}^{n} x_i\right)
\end{aligned}
\tag{14.1.357}
$$

Since:

- $\sum_{i=1}^{n}\overline{x}^2-\overline{x}\sum_{i=1}^{n}x_i=0$
- $\overline{y}\sum_{i=1}^{n}x_i-\sum_{i=1}^{n}x_iy_i-2\sum_{i=1}^{n}\overline{yx}+2\sum_{i=1}^{n}y_i\overline{x}=-\text{SPD}_{xy}$
- $\sum_{i=1}^{n}y_i^2-\lambda\sum_{i=1}^{n}x_i^2+\sum_{i=1}^{n}\overline{y}^2-2\sum_{i=1}^{n}y_i\overline{y}+\lambda\overline{x}\sum_{i=1}^{n}x_i=\text{SSD}_y-\lambda\text{SSD}_x$
- $\sum_{i=1}^{n}x_iy_i-\overline{y}\sum_{i=1}^{n}x_i=\text{SPD}_{xy}$

it is clear that the derivation of β comes down to solve:

$$-\beta^2\text{SPD}_{xy}+\beta(\text{SSD}_y-\lambda\text{SSD}_x)+\lambda\text{SPD}_{xy}=0 \tag{14.1.358}$$

For $\text{SPD}_{xy}\neq 0$ this implies that:

$$\begin{aligned}\beta&=\frac{-(\text{SSD}_y-\lambda\text{SSD}_x)\pm\sqrt{(\text{SSD}_y-\lambda\text{SSD}_x)^2-4(-\text{SPD}_{xy})\lambda\text{SPD}_{xy}}}{-2\text{SPD}_{xy}}\\&=\frac{\text{SSD}_y-\lambda\text{SSD}_x\pm\sqrt{(\text{SSD}_y-\lambda\text{SSD}_x)^2+4\lambda\text{SPD}_{xy}^2}}{2\text{SPD}_{xy}}\end{aligned} \tag{14.1.359}$$

Since:

$$\text{SSD}_y-\lambda\text{SSD}_x\leq\sqrt{(\text{SSD}_y-\lambda\text{SSD}_x)^2+4\lambda\text{SPD}_{xy}^2} \tag{14.1.360}$$

there is always a positive and a negative solution to (**??**). The desired solution should always have the same sign as SPD_{xy}, hence the solution with the positive numerator is selected. Therefore:

$$\hat{\beta}=\frac{\text{SSD}_y-\lambda\text{SSD}_x+\sqrt{(\text{SSD}_y-\lambda\text{SSD}_x)^2+4\lambda\text{SPD}_{xy}^2}}{2\text{SPD}_{xy}} \tag{14.1.361}$$

Let us solve for ξ_i - again... With estimates for β and α it is now possible to estimate ξ_i using:

$$\xi_i=\frac{\lambda x_i+\beta(y_i-\alpha)}{\lambda+\beta^2} \tag{14.1.362}$$

we get:

$$\hat{\xi}_i=\frac{\lambda x_i+\hat{\beta}(y_i-\hat{\alpha})}{\lambda+\hat{\beta}^2} \tag{14.1.363}$$

Let us now solve for σ^2 by differentiating $\mathcal{L}$ with respect to σ^2 gives:

$$\begin{aligned}\frac{\partial\mathcal{L}}{\partial\sigma^2}&=\frac{\partial}{\partial\sigma^2}\left(-\frac{n}{2}\log(\lambda\sigma^4)-\frac{\sum\limits_{i=1}^{n}(x_i-\xi_i)^2}{2\sigma^2}-\frac{\sum\limits_{i=1}^{n}(y_i-\alpha-\beta\xi_i)^2}{2\lambda\sigma^2}\right)\\&=\frac{-n\sigma^2}{\sigma^4}+\frac{\sum\limits_{i=1}^{n}(x_i-\xi_i)^2}{2\sigma^4}+\frac{\sum\limits_{i=1}^{n}(y_i-\alpha-\beta\xi_i)^2}{2\lambda\sigma^4}\\&=\frac{-2\lambda n\sigma^2+\lambda\sum\limits_{i=1}^{n}(x_i-\xi_i)^2+\sum\limits_{i=1}^{n}(y_i-\alpha-\beta\xi_i)^2}{2\lambda\sigma^4}\end{aligned}\tag{14.1.364}$$

and setting $\frac{\partial\mathcal{L}}{\partial\sigma^2}$ equal to zero yields:

$$\begin{gathered}\frac{\partial\mathcal{L}}{\partial\sigma^2}=0\Rightarrow-2\lambda n\sigma^2+\lambda\sum_{i=1}^{n}(x_i-\xi_i)^2+\sum_{i=1}^{n}(y_i-\alpha-\beta\xi_i)^2=0\\\Rightarrow\sigma^2=\frac{\lambda\sum\limits_{i=1}^{n}(x_i-\xi_i)^2+\sum\limits_{i=1}^{n}(y_i-\alpha-\beta\xi_i)^2}{2\lambda n}\end{gathered}\tag{14.1.365}$$

To get a central estimate of σ^2 one must divide by $n-2$ instead of $2n$ since there are $n+2$ parameters to be estimated, namely $\xi_1,\xi_2,\ldots,\xi_n,\alpha$ and β. Hence the degrees of freedom are $2n-(n+2)=n-2$. Therefore:

$$\hat{\sigma}^2=\frac{\lambda\sum\limits_{i=1}^{n}(x_i-\hat{\xi}_i)^2+\sum\limits_{i=1}^{n}(y_i-\hat{\alpha}-\hat{\beta}\hat{\xi}_i)^2}{2\lambda(n-2)}\tag{14.1.366}$$

Finally summing up:

$$\boxed{\begin{aligned}&\hat{\alpha}=\overline{y}-\overline{x}\hat{\beta}\\&\hat{\beta}=\frac{\text{SSD}_y-\lambda\text{SSD}_x+\sqrt{(\text{SSD}_y-\lambda\text{SSD}_x)^2+4\lambda\text{SPD}_{xy}^2}}{2\text{SPD}_{xy}}\\&\hat{\sigma}=\sqrt{\frac{\lambda\sum\limits_{i=1}^{n}(x_i-\hat{\xi}_i)^2+\sum\limits_{i=1}^{n}(y_i-\hat{\alpha}-\hat{\beta}\hat{\xi}_i)^2}{2\lambda(n-2)}}\\&\hat{\xi}_i=\frac{\lambda x_i+\hat{\beta}(y_i-\hat{\alpha})}{\lambda+\hat{\beta}^2}\end{aligned}}\tag{14.1.367}$$

These results are implemented in Minitab 16.1.2 and also in the `Deming()` function in the MethComp package of `R` as the ready can see it in the corresponding companion books.

14.1.11 Multiple linear regression Gaussian Model

Of course, in some situations, linear regression is too simple or just not suitable. The most typical case that will concern us now in what follows are the situations where we have several explanatory variables (multivariate case!).

The idea of multiple linear regression is relatively simple. We want to determine the dependent variable y from $p-1$ independent variables (i.e. in the absence of "colinearity"!) - and therefore of p parameters to determine - connected by a linear relation of the general form:

$$y=\beta_0+\beta_1 x+\ldots+\beta_{p-1}x_{p-1}+\varepsilon \tag{14.1.368}$$

In a sample of n individuals we measure $y_i, x_{i,1},\ldots,x_{i,p-1}$ for $i=1\ldots n$:

Observation	y_i	$x_{i,1}$	$\ldots$	$x_{i,p-1}$
1	y_1	$x_{1,1}$	$\ldots$	$x_{1,p-1}$
2	y_2	$x_{2,1}$	$\ldots$	$x_{2,p-1}$
$\vdots$	$\vdots$	$\vdots$	$\ldots$	$\ldots$
n	y_n	$x_{n,1}$	$\ldots$	$x_{n,p-1}$

Remark

The terms "multivariate" and "multivariable" are often used interchangeably in the statistical literature. However, these terms actually represent two very distinct types of analyses! A "multivariable model" can be thought of as a model in which multiple variables are found on the right side of the model equation (one outcome, multiple predictors). "Multivariate", by contrast, refers to the modelling of data that have multiple output variables for multiple variables on the right side of the model equation (multiple outcomes, modeled jointly). Unfortunately "multivariable regression" is often mistakenly named "multivariate regression", or vice versa.

In facts, to estimate the parameters $\beta_0,\ldots,\beta_{p-1}$ (estimated values which we denote by $\hat{\beta}_0,\ldots,\hat{\beta}_{p-1}$ to respect traditions) the approach is very simple because it is just a generalization of the method of least squares we saw earlier for the simple univariate linear regression.

So in the end we rewrite the relation of Sum of Squared Residuals seen above by modifying a little bit because we now have the multi-linear stuff:

$$\text{SSR}=\sum_{i=1}^{k}(y_i-y_i')^2 \tag{14.1.369}$$

with the estimated theoretical model:

$$y_i'=\hat{\beta}_0+\hat{\beta}_1 x_{i,1}+\ldots+\hat{\beta}_{p-1}x_{i,p-1} \tag{14.1.370}$$

So we have to minimize:

$$\text{SSR}=\sum_{i=1}^{k}(y_i-(\hat{\beta}_0+\hat{\beta}_1 x_{i,1}+\ldots+\hat{\beta}_{p-1}x_{i,p-1}))^2 \tag{14.1.371}$$

The above parentheses can be rewritten in the form (using what we learned in the sections of Vector Calculus and Linear Algebra):

$$\begin{pmatrix} y_1 \\ \vdots \\ y_n \end{pmatrix} = \begin{bmatrix} 1 & x_{1,1} & \dots & x_{1,p-1} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_{n,1} & \dots & x_{n,p-1} \end{bmatrix} \begin{pmatrix} \hat{\beta}_0 \\ \vdots \\ \hat{\beta}_{p-1} \end{pmatrix} + \begin{pmatrix} \varepsilon_0 \\ \vdots \\ \varepsilon_n \end{pmatrix} \tag{14.1.372}$$

Whose condensed form is:

$$\vec{y} = X\vec{\hat{\beta}} + \vec{\varepsilon} \tag{14.1.373}$$

where X is named the "designed matrix", also known as "regressor matrix" or "model matrix" or "data matrix".

We then have the vector of residues that can be written:

$$\vec{\varepsilon} = \vec{y} - \vec{y}' = \vec{y} - X\vec{\hat{\beta}} \tag{14.1.374}$$

As we know, the least squares method is to find the vector $\vec{\hat{\beta}}$ that minimizes:

$$||\vec{\varepsilon}||^2 = \vec{\varepsilon} \circ \vec{\varepsilon} = \vec{\varepsilon}^T \circ \vec{\varepsilon} \tag{14.1.375}$$

Therefore explicitly:

$$||\vec{\varepsilon}||^2 = \vec{\varepsilon}^T \circ \vec{\varepsilon} = (\vec{y} - X\vec{\hat{\beta}})^T \circ (\vec{y} - X\vec{\hat{\beta}}) = \vec{y}^T\vec{y} - \vec{y}^T(X\vec{\hat{\beta}}) - (X\vec{\hat{\beta}})^T\vec{y} + (X\vec{\hat{\beta}})^T(X\vec{\hat{\beta}}) \tag{14.1.376}$$

Notice that we have:

$$(X\vec{\hat{\beta}})^T(X\vec{\hat{\beta}}) = (X\vec{\hat{\beta}})(X\vec{\hat{\beta}})^T \tag{14.1.377}$$

and:

$$\vec{y}^T(X\vec{\hat{\beta}}) = (X\vec{\hat{\beta}})^T\vec{y} \tag{14.1.378}$$

as each of the elements of the multiplication is a simple vector!

Therefore we have (caution! do not forget that some multiplications in the relation that will follow are dot products!!!) the quadratic multivariate function of coefficients of vectors:

$$||\vec{\varepsilon}||^2 = \vec{\varepsilon} \circ \vec{\varepsilon} = (\vec{y} - X\vec{\hat{\beta}}) \circ (\vec{y} - X\vec{\hat{\beta}}) = \vec{y} \circ \vec{y} - 2(X\vec{\hat{\beta}}) \circ \vec{y} + (X\vec{\hat{\beta}}) \circ (X\vec{\hat{\beta}}) = F \tag{14.1.379}$$

Let us derivate this latter "object function F" at the order of vector $\hat{\beta}$ (it is as internal derivative component by component). What we will write:

$$\begin{aligned} \frac{\partial F}{\partial \vec{\hat{\beta}}} &= \frac{\partial}{\partial \vec{\hat{\beta}}} \left(\vec{y} \circ \vec{y} - 2(X\vec{\hat{\beta}}) \circ \vec{y} + (X\vec{\hat{\beta}}) \circ (X\vec{\hat{\beta}}) \right) \\ &= \frac{\partial}{\partial \vec{\hat{\beta}}} \left(-2(X\vec{\hat{\beta}}) \circ \vec{y} + (X\vec{\hat{\beta}}) \circ (X\vec{\hat{\beta}}) \right) \\ &= -2(X\vec{u}) \circ \vec{y} + \frac{\partial}{\partial \vec{\hat{\beta}}} \left((X\vec{\hat{\beta}}) \circ (X\vec{\hat{\beta}}) \right) \\ &= -2(X\vec{u}) \circ \vec{y} + \frac{\partial (X\vec{\hat{\beta}})}{\partial \vec{\hat{\beta}}} \circ (X\vec{\hat{\beta}}) + (X\vec{\hat{\beta}}) \circ \frac{\partial (X\vec{\hat{\beta}})}{\partial \vec{\hat{\beta}}} \\ &= -2(X\vec{u}) \circ \vec{y} + (X\vec{u}) \circ (X\vec{\hat{\beta}}) + (X\vec{\hat{\beta}}) \circ (X\vec{u}) \\ &= -2(X\vec{u}) \circ \vec{y} + 2(X\vec{u}) \circ (X\vec{\hat{\beta}}) \end{aligned} \tag{14.1.380}$$

Now let us rewrite this form a vector notation to a pure matrix notation:

$$\frac{\partial F}{\partial \vec{\hat{\beta}}} = -2(X\vec{u})^T\vec{y} + 2(X\vec{u})^T(X\vec{\hat{\beta}}) \tag{14.1.381}$$

We seek the $\vec{\hat{\beta}}$ that cancel this derivative. Therefore we must solve the following equation:

$$-2(X\vec{u})^T\vec{y} + 2(X\vec{u})^T(X\vec{\hat{\beta}}) = 0 \tag{14.1.382}$$

Therefore:

$$(X\vec{u})^T(X\vec{\hat{\beta}}) = (X\vec{u})^T\vec{y} \tag{14.1.383}$$

Remember before we continue that:

$$(X\vec{u})^T = \vec{u}^T X^T \tag{14.1.384}$$

Therefore the prior-previous relation can be written:

$$(\vec{u}^T X^T)(X\vec{\hat{\beta}}) = (\vec{u}^T X^T)\vec{y} \tag{14.1.385}$$

As Linear Algebra is associative, let us write without the parenthesis:

$$\vec{u}^T X^T X\vec{\hat{\beta}} = \vec{u}^T X^T\vec{y} \tag{14.1.386}$$

We can obviously not simplify right and left by $\vec{u}^T X^T$ as it is not a squared matrix, this term is then by obligation not reversible. The only one thing we can do is identify the elements such that:

$$\vec{u}^T(X^T X\vec{\hat{\beta}}) = \vec{u}^T(X^T\vec{y}) \tag{14.1.387}$$

this implies obviously:

$$X^T X\vec{\hat{\beta}} = X^T\vec{y} \tag{14.1.388}$$

We find then that if the squared matrix $X^T X$ is reversible then:

$$\boxed{\vec{\hat{\beta}} = \left(X^T X\right)^{-1} X^T\vec{y}} \tag{14.1.389}$$

The matrix $X^T X$ that we will see again in the field of multiple linear regression and in the field of design of experiments (see section Industrial Engineering page 8780) is named "information matrix" or "dispersion matrix" for a reason that will be very obvious later.

The expression $(X^T X)^{-1}X^T$ is named the "left pseudo-inverse", or simply "pseudoinverse", and even sometimes "Moore-Penrose pseudoinverse" of X and is denoted X^- in some textbooks.

Remark

We say that the regression is "balanced and orthogonal" when the information matrix is diagonal. We say that the regression is "orthogonal" when the sub-matrix of the information matrix excluding the first row and first columns is orthogonal. We say that the regression is just "balanced" when all the values of the first row and of the first column excepted the one at the intersection are equal to zero.

To show that this seem correct a priori, let us fall back on the results we get of the simple univariate regression:

$$y=\hat{\beta}_0+\hat{\beta}_1 x_1 \tag{14.1.390}$$

Then supposing 2 observations, we have therefore:

$$\begin{aligned}\vec{\hat{\beta}}&=\left(X^TX\right)^{-1}X^T\vec{y}\\&=\left(\begin{bmatrix}1 & x_{1,1}\\1 & x_{2,1}\end{bmatrix}^T\begin{bmatrix}1 & x_{1,1}\\1 & x_{2,1}\end{bmatrix}\right)^{-1}\begin{bmatrix}1 & x_{1,1}\\1 & x_{2,1}\end{bmatrix}^T\begin{pmatrix}y_1\\y_2\end{pmatrix}\\&=\left(\begin{bmatrix}1 & 1\\x_{1,1} & x_{2,1}\end{bmatrix}^T\begin{bmatrix}1 & x_{1,1}\\1 & x_{2,1}\end{bmatrix}\right)^{-1}\begin{bmatrix}1 & 1\\x_{1,1} & x_{2,1}\end{bmatrix}^T\begin{pmatrix}y_1\\y_2\end{pmatrix}\\&=\left(\begin{bmatrix}1\cdot 1+1\cdot 1 & x_{1,1}+x_{2,1}\\x_{1,1}+x_{2,1} & x_{1,1}^2+x_{2,1}^2\end{bmatrix}\right)^{-1}\begin{pmatrix}y_1+y_2\\x_{1,1}y_1+x_{2,1}y_2\end{pmatrix}\\&=\left(\begin{bmatrix}n & \sum x_i\\\sum x_i & \sum x_i^2\end{bmatrix}\right)^{-1}\begin{pmatrix}\sum y_i\\\sum x_iy_i\end{pmatrix}\end{aligned} \tag{14.1.391}$$

Using the relation proved in the section of Linear Algebra (see page 1980) to calculate in generality the inverse of a matrix $A(a_{ij})$ in $A^{-1}(b_{ij})$:

$$b_{ij}=\frac{1}{\det(A)}(-1)^{i+j}\det(A_{ji}) \tag{14.1.392}$$

We have in our special case:

$$\boxed{\det(X^TX)=a_{11}a_{22}-a_{12}a_{21}=n\sum x_i^2-\sum x_i\sum x_i=n\sum x_i^2-\left(\sum x_i\right)^2} \tag{14.1.393}$$

Therefore we have:

$$\begin{aligned}(X^TX)^{-1}&=\frac{1}{n\sum x_i^2-\left(\sum x_i\right)^2}(-1)^{i+j}\det(X^TX_{ji})\\&=\frac{1}{n\sum x_i^2-\left(\sum x_i\right)^2}\begin{bmatrix}\det(X^TX_{11}) & -\det(X^TX_{21})\\-\det(X^TX_{12}) & \det(X^TX_{22})\end{bmatrix}\end{aligned} \tag{14.1.394}$$

and since we have a square matrix of dimension 2 only, the calculation of the four determinants is reduced to selecting the components of X^TX (see section Linear Algebra page 1966):

$$(X^TX)^{-1}=\frac{1}{n\sum x_i^2-\left(\sum x_i\right)^2}\begin{bmatrix}\sum x_i^2 & -\sum x_i\\-\sum x_i & n\end{bmatrix} \tag{14.1.395}$$

Therefore:

$$
\begin{aligned}
\vec{\hat{\beta}} &= \left(\begin{bmatrix} n & \sum x_i \\ \sum x_i & \sum x_i^2 \end{bmatrix}\right)^{-1} \begin{pmatrix} \sum y_i \\ \sum x_i y_i \end{pmatrix} \\
&= \frac{1}{n\sum x_i^2 - \left(\sum x_i\right)^2} \begin{bmatrix} \sum x_i^2 & -\sum x_i \\ -\sum x_i & n \end{bmatrix} \begin{pmatrix} \sum y_i \\ \sum x_i y_i \end{pmatrix} \\
&= \frac{1}{n\sum x_i^2 - \left(\sum x_i\right)^2} \begin{bmatrix} \sum x_i^2 \sum y_i - \sum x_i \sum x_i y_i \\ -\sum x_i \sum y_i + n \sum x_i y_i \end{bmatrix} \\
&= \begin{bmatrix} \dfrac{\sum x_i^2 \sum y_i - \sum x_i \sum x_i y_i}{n\sum x_i^2 - \left(\sum x_i\right)^2} \\ \dfrac{-\sum x_i \sum y_i + n \sum x_i y_i}{n\sum x_i^2 - \left(\sum x_i\right)^2} \end{bmatrix} = \begin{bmatrix} \beta_0 \\ \beta_1 \end{bmatrix} = \begin{bmatrix} b \\ a \end{bmatrix}
\end{aligned}
\tag{14.1.396}
$$

So to a change in notations for the indices and experimental measurements, we fall back on the results that we obtained during our study of the simple linear univariate regression that was (for refresh...):

$$
a = \frac{n\sum_{k=1}^{n} x_k y_k - \sum_{k=1}^{n} x_k \sum_{k=1}^{n} y_k}{n\sum_{k=1}^{n} x_k^2 - \left(\sum_{k=1}^{n} x_k\right)^2} \qquad b = \frac{\sum_{k=1}^{n} x_k^2 \sum_{k=1}^{n} y_k - \sum_{k=1}^{n} x_k \sum_{k=1}^{n} x_k y_k}{n\sum_{k=1}^{n} x_k^2 - \left(\sum_{k=1}^{n} x_k\right)^2}
\tag{14.1.397}
$$

Now, we need a quality indicator regarding our multi-linear regression. Remember that in the context of our study of the univariate linear regression, we proved that the linear correlation coefficient can be written as (see page 6333):

$$
R_{X,Y}^2 = \frac{\text{SSE}}{\text{SST}} = \frac{\sum_k (\hat{y}_k - \bar{y})^2}{\sum_k (y_k - \bar{y})^2}
\tag{14.1.398}
$$

and in fact it also applies directly to the multiple linear regression, since it does not presuppose the number of explanatory variables!!

But it is the tradition to rewrite that latter in matrix form. So at it is beautiful, let us do the work.

First we start with:

$$
\text{SSE} = \sum_k (\hat{y}_k - \bar{y})^2 = (\vec{\hat{Y}} - \vec{\bar{Y}})^T (\vec{\hat{Y}} - \vec{\bar{Y}}) = (X\vec{\hat{\beta}} - \vec{\bar{Y}})^T (X\vec{\hat{\beta}} - \vec{\bar{Y}}) = \vec{\hat{\beta}}^T (X^T X)\vec{\hat{\beta}} - \vec{\bar{Y}}^T \vec{\bar{Y}} - 2\vec{\hat{\beta}} X^T \vec{\bar{Y}}
\tag{14.1.399}
$$

and finally:

$$
\text{SST} = \sum_k (y_k - \bar{y})^2 = (\vec{Y} - \vec{\bar{Y}})^T (\vec{Y} - \vec{\bar{Y}}) = \vec{Y}^T \vec{Y} + \vec{\bar{Y}}^T \vec{\bar{Y}} - 2\vec{Y}^T \vec{\bar{Y}}
\tag{14.1.400}
$$

Hence:

$$R^2=\frac{\text{SSE}}{\text{SST}}=\frac{\vec{\hat{\beta}}^T(X^TX)\vec{\hat{\beta}}-\vec{\bar{Y}}^T\vec{\bar{Y}}-2\vec{\hat{\beta}}X^T\vec{\bar{Y}}}{\vec{Y}^T\vec{Y}+\vec{\bar{Y}}^T\vec{\bar{Y}}-2\vec{Y}^T\vec{\bar{Y}}} \qquad (14.1.401)$$

Remark

The reader interested in the practical application of these results may, just as for simple univariate regression, refer to the server exercises on the companion website - Numerical Methods section - where there are practical examples with Microsoft® Excel®.

Obviously with multiple linear regression, we can now, with a small trick, do linear regression ... of polynomials (we will see later how to apply directly the ordinary least squares method on a polynomial) too! Indeed, consider a polynomial of the form:

$$y=ax^3+bx^2+cx+d \qquad (14.1.402)$$

That we can consider, when rewritten, as:

$$y=az+bw+cx+d \qquad (14.1.403)$$

So in spreadsheet softwares like Microsoft® Excel®, just use the Regression Analysis Tool with the input variable x column, a second column that we will have taken care to create with inside the square of x (i.e. x^2) and which will be considered as the explanatory variable w and a third column we have also taken care to create as the cube of x (i.e. x^3) and which will be considered as the explanatory variable z.

More formally, this is like solving the following system:

$$\begin{bmatrix} y_1\\ y_2\\ y_3\\ \vdots\\ y_n \end{bmatrix}=\begin{bmatrix} 1 & x_1 & x_1^2 & \ldots & x_1^m\\ 1 & x_2 & x_2^2 & \ldots & x_2^m\\ 1 & x_3 & x_3^2 & \ldots & x_3^m\\ \vdots & \vdots & \vdots & \ddots & \vdots\\ 1 & x_n & x_n^2 & \ldots & x_n^m \end{bmatrix}\begin{bmatrix} \beta_0\\ \beta_1\\ \beta_2\\ \vdots\\ \beta_m \end{bmatrix}+\begin{bmatrix} \varepsilon_1\\ \varepsilon_2\\ \varepsilon_3\\ \vdots\\ \varepsilon_n \end{bmatrix} \qquad (14.1.404)$$

We can also directly obtain the polynomials coefficients using functions already presented earlier above with Microsoft® Excel® (but you will not have all the relevant results of the Analysis Tool). For example for a polynomial of second degree:

```
a:  =INDEX(LINEST(y,x^{1,2}),1)
b:  =INDEX(LINEST(y,x^{1,2}),1,2)
c:  =INDEX(LINEST(y,x^{1,2}),1,3)
```

and for a third-degree polynomial:

```
a:  =INDEX(LINEST(y,x^{1,2,3}),1)
b:  =INDEX(LINEST(y,x^{1,2,3}),1,2)
c:  =INDEX(LINEST(y,x^{1,2,3}),1,3)
d:  =INDEX(LINEST(y,x^{1,2,3}),1,4)
```

The same kind of method also works for Fourier series (see section Sequences and Series page 1727):

$$y=a_0+\sum_{i=1}^{m} a_i\cos(i\omega x)+b_i\sin(i\omega x) \tag{14.1.405}$$

More formally, this is like solving the following system:

$$\begin{bmatrix} y_1\\ y_2\\ y_3\\ \vdots\\ y_n \end{bmatrix}=\begin{bmatrix} 1 & \cos(\omega x_1) & \sin(\omega x_1) & \ldots & \sin(m\omega x_1)\\ 1 & \cos(\omega x_2) & \sin(\omega x_2) & \ldots & \sin(m\omega x_2)\\ 1 & \cos(\omega x_3) & \sin(\omega x_3) & \ldots & \sin(m\omega x_3)\\ \vdots & \vdots & \vdots & \ddots & \vdots\\ 1 & \cos(\omega x_n) & \sin(\omega x_n) & \ldots & \sin(m\omega x_n) \end{bmatrix}\begin{bmatrix} \beta_0\\ \beta_1\\ \beta_2\\ \vdots\\ \beta_m \end{bmatrix}+\begin{bmatrix} \varepsilon_1\\ \varepsilon_2\\ \varepsilon_3\\ \vdots\\ \varepsilon_n \end{bmatrix} \tag{14.1.406}$$

This is this trick that allows us to understand why and how the linear correlation coefficient also applies to polynomials and Fourier series in most spreadsheets softwares and statistical softwares. However we can have a more direct approach that does not require this transformation but which therefore is a little longer.

Now let us go back to the Gaussian linear model with a concept a little more rigorous and adapted to the multi-linear case and in particular to highlight the distinction between estimators of the slope of the regression and exact values:

$$Y_i\sim\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{1}{2\sigma^2}\left(\left(\hat{\beta}_0+\hat{\beta}_1x_{i,1}+\ldots+\hat{\beta}_{p-1}x_{i,p-1}\right)-\mu_i\right)^2}=\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{1}{2\sigma^2}(y_i-\mu_i)^2} \tag{14.1.407}$$

But under this notation convention we have:

$$Y_i\sim\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{1}{2\sigma^2}(y_i-(\beta_0+\beta_1x_{i,1}+\ldots+\beta_{p-1}x_{i,p-1}))^2} \tag{14.1.408}$$

and written in vector form:

$$Y_i\sim\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{1}{2\sigma^2}\left(y_i-\vec{x}^T\vec{\beta}\right)^2} \tag{14.1.409}$$

Now, we use the technique of maximum likelihood (see section Statistics page 818) and we seek the coefficients that maximizes therefore:

$$L\left(\vec{\beta},\sigma\right)=\prod_{i=1}^{n}L(y_i,\vec{\beta},\sigma)=\left(\frac{1}{\sigma\sqrt{2\pi}}\right)^n e^{-\frac{1}{2\sigma^2}\sum_{i=1}^{n}\left(y_i-\vec{x}_i^T\vec{\beta}\right)^2} \tag{14.1.410}$$

That we can write in matrix form:

$$L\left(\vec{\beta},\sigma\right)=\left(\frac{1}{\sigma\sqrt{2\pi}}\right)^n e^{-\frac{1}{2\sigma^2}\sum_{i=1}^{n}\left(y_i-\vec{x}_i^T\vec{\beta}\right)^2}=\left(\frac{1}{\sigma\sqrt{2\pi}}\right)^n e^{-\frac{1}{2\sigma^2}\left(\vec{y}-X\vec{\beta}\right)^T\left(\vec{y}-X\vec{\beta}\right)} \tag{14.1.411}$$

Taking as in the section of Statistics the log-likelihood to facilitate future calculations and using the property of the transposed matrices proved in section of Linear Algebra, we get:

$$\begin{aligned}\ln\left(L\left(\vec{\beta},\sigma\right)\right)&=\ln\left(\left(\frac{1}{\sigma\sqrt{2\pi}}\right)^n e^{-\frac{1}{2\sigma^2}\left(\vec{y}-X\vec{\beta}\right)^T\left(\vec{y}-X\vec{\beta}\right)}\right)\\&=n\ln\left(\frac{1}{\sigma\sqrt{2\pi}}\right)+\ln\left(e^{-\frac{1}{2\sigma^2}\left(\vec{y}-X\vec{\beta}\right)^T\left(\vec{y}-X\vec{\beta}\right)}\right)\\&=n\ln\left(\frac{1}{\sigma\sqrt{2\pi}}\right)-\frac{1}{2\sigma^2}\left(\vec{y}-X\vec{\beta}\right)^T\left(\vec{y}-X\vec{\beta}\right)\\&=-\frac{n}{2}\ln(2\pi)-\frac{n}{2}\ln(\sigma^2)-\frac{1}{2\sigma^2}\left(\vec{y}-X\vec{\beta}\right)^T\left(\vec{y}-X\vec{\beta}\right)\\&=-\frac{n}{2}\ln(2\pi)-\frac{n}{2}\ln(\sigma^2)-\frac{1}{2\sigma^2}\left(\vec{y}^T\vec{y}-2\vec{\beta}^TX^T\vec{y}+\vec{\beta}^TX^TX\vec{\beta}\right)\\&=-\frac{n}{2}\ln(2\pi)-\frac{n}{2}\ln(\sigma^2)-\frac{1}{2\sigma^2}\text{RSS}\end{aligned}\tag{14.1.412}$$

Now let us look to the expression of $\vec{\beta}$ that maximizes the log-likelihood. It comes then:

$$\begin{aligned}\frac{\partial\ln\left[L(\vec{\beta},\sigma)\right]}{\partial\vec{\beta}}&=\frac{1}{2\sigma^2}\left[\frac{\partial\left(\vec{y}^T\vec{y}-2\vec{\beta}^TX^T\vec{y}+\vec{\beta}^TX^TX\vec{\beta}\right)}{\partial\vec{\beta}}\right]\\&=\frac{1}{2\sigma^2}\left[\frac{\partial\left(-2\vec{\beta}^TX^T\vec{y}+\vec{\beta}^TX^TX\vec{\beta}\right)}{\partial\vec{\beta}}\right]=\frac{1}{2\sigma^2}\left[-2\frac{\partial\vec{\beta}^T}{\partial\vec{\beta}}X^T\vec{y}+\frac{\partial}{\partial\vec{\beta}}\left(\vec{\beta}^TX^T\vec{\beta}\right)\right]\\&=\frac{1}{2\sigma^2}\left[-2\left(\frac{\partial\vec{\beta}}{\partial\vec{\beta}}\right)^TX^T\vec{y}+\frac{\partial\vec{\beta}^T}{\partial\vec{\beta}}X^TX\vec{\beta}+\vec{\beta}^TX^TX\frac{\partial\vec{\beta}}{\partial\vec{\beta}}\right]\\&=\frac{1}{2\sigma^2}\left[-2[1\dots1]X^T\vec{y}+[1\dots1]X^TX\vec{\beta}+\vec{\beta}^TX^TX\begin{pmatrix}1\\\vdots\\1\end{pmatrix}\right]\end{aligned}\tag{14.1.413}$$

Let us use the property of the transposed matrix proved in the section of Linear Algebra (see page 1951):

$$A^TB^TCD=D^TC^TBA\tag{14.1.414}$$

Therefore we have:

$$\begin{aligned}\frac{\partial\ln\left[L(\vec{\beta},\sigma)\right]}{\partial\vec{\beta}}&=\frac{1}{2\sigma^2}\left[-2[1\dots1]X^T\vec{y}+2\vec{\beta}^TX^TX\begin{pmatrix}1\\\vdots\\1\end{pmatrix}\right]\\&=\frac{1}{2\sigma^2}\left[-2[1\dots1]X^T\vec{y}+2[1\dots1]X^TX\vec{\beta}\right]\end{aligned}\tag{14.1.415}$$

For reasons which will appear evident a little further below we chose the second equivalence. Therefore, we have (and remembering that seeking for an optimum is equivalent to have partial derivative equal to zero):

$$\frac{\partial\ln\left[L(\vec{\beta},\sigma)\right]}{\partial\vec{\beta}}=\frac{[1\dots1]}{\sigma^2}\left[-X^T\vec{y}+X^TX\vec{\beta}\right]\tag{14.1.416}$$

Therefore:

$$-X^T\vec{y}+X^TX\vec{\beta}=0 \qquad (14.1.417)$$

That is to say, after rearrangement:

$$\vec{\beta}=(X^TX)^{-1}X^T\vec{y} \qquad (14.1.418)$$

That is to say exactly the same expressions that we got just a little earlier above with the least squares method in the multi-linear case and that was for reminder:

$$\hat{\vec{\beta}}=(X^TX)^{-1}X^T\vec{y} \qquad (14.1.419)$$

This shows that the statistical of the linear model by the maximum likelihood can fall back into the multi-linear case (and thus also the univariate case) on the results of the least squares method. This has something almost divine ...

Finally, let us indicate that we find here the almost famous "hat matrix" or "influence matrix" H that connects alone all information between the real and explained theoretical values (and depending only on X!) and therefore verbatim the error of the theoretical model:

$$\boxed{\hat{\vec{Y}}=X\hat{\vec{\beta}}=X(X^TX)^{-1}X^T\vec{y}=H\vec{y}} \qquad (14.1.420)$$

We have then something interesting to observe:

$$\hat{Y}_i=H_i\vec{y}_i=\sum_{j=1}^{n}H_{ij}y_i \qquad (14.1.421)$$

By definition, the influence of the observation i in the regression and named the "leverage" (or "leverage score") is defined by:

$$\boxed{H_i=||H_{i.}||^2=\sum_{j=1}^{n}H_{ij}^2} \qquad (14.1.422)$$

H_i is therefore the influence of y_i on its own fitted value! It is a qualitative method (available in many statistical softwares) to judge the influence of points that could be considered as outliers. The idea is to compare the values of leverage between them.

Let us now give the famous explicit expression of the leverage of the simple linear regression.

We start be remembering that by definition:

$$H=X(X^TX)^{-1}X^T \qquad (14.1.423)$$

and we have proved earlier above that in the simple linear regression that we have:

$$X=\begin{bmatrix}1 & x_1\\ 1 & x_2\\ \vdots & \vdots\\ 1 & x_n\end{bmatrix}\Rightarrow X^TX=\begin{bmatrix}n & \displaystyle\sum_{i=1}^{n}x_i\\ \displaystyle\sum_{i=1}^{n}x_i & \sum_{i=1}^{n}x_i^2\end{bmatrix} \qquad (14.1.424)$$

and also:

$$(X^TX)^{-1}=\frac{1}{n\sum\limits_{i=1}^{n}x_i^2-\left(\sum\limits_{i=1}^{n}x_i\right)^2}\begin{bmatrix}\sum\limits_{i=1}^{n}x_i^2 & -\sum\limits_{i=1}^{n}x_i\\ -\sum\limits_{i=1}^{n}x_i & n\end{bmatrix}\tag{14.1.425}$$

Let us put by definition (to make notations more light...):

$$SXX=\sum_{i=1}^{n}x_i^2-\frac{1}{n}\left(\sum_{i=1}^{n}x_i\right)^2\tag{14.1.426}$$

Hence we may rewrite:

$$(X^TX)^1=\frac{1}{SXX}\begin{bmatrix}\frac{1}{n}\sum\limits_{i=1}^{n}x_i^2 & \bar{x}\\ -\bar{x} & 1\end{bmatrix}=\frac{1}{SXX}\begin{bmatrix}\frac{1}{n}\sum\limits_{i=1}^{n}x_i^2-x_1\bar{x} & -\bar{x}+x_1\\ \frac{1}{n}\sum\limits_{i=1}^{n}x_i^2-x_2\bar{x} & -\bar{x}+x_2\\ \vdots & \vdots\\ \frac{1}{n}\sum\limits_{i=1}^{n}x_i^2-x_n\bar{x} & -\bar{x}+x_n\end{bmatrix}\tag{14.1.427}$$

Hence:

$$\begin{aligned}H_{ii}&=\frac{1}{SXX}\left[1\cdot\left(\frac{1}{n}\sum_{j=1}^{n}x_j^2-x_i\bar{x}\right)+x.(-\bar{x}+x_i)\right]\\&=\frac{1}{SXX}\left[\frac{1}{n}\sum_{j=1}^{n}x_j^2-(\bar{x})^2+(\bar{x})^2-2x_i\bar{x}+x_i^2\right]=\frac{1}{SXX}\left[\frac{1}{n}\sum_{j=1}^{n}x_j^2-(\bar{x})^2+(x_i-\bar{x})^2\right]\\&=\frac{1}{nSXX}\left[\sum_{j=1}^{n}x_j^2-\frac{1}{n}\left(\sum_{j=1}^{n}x_j\right)^2\right]+\frac{(x_i-\bar{x})^2}{SXX}\\&=\frac{1}{n}+\frac{(x_i-\bar{x})^2}{SXX}\end{aligned}\tag{14.1.428}$$

Finally:

$$\boxed{H_{ii}=\frac{1}{n}+\frac{(x_i-\bar{x})^2}{\sum\limits_{k=1}^{n}(x_k-\bar{x})^2}}\tag{14.1.429}$$

This relation has a nice interpretation in the SLR model: if the distance from x_i to $\bar{x}$ is large relative to the other x's then H_{ii} will be close to 1.

Leverages have nice mathematical properties, for example, they satisfy:

$$0\leq H_{ii}\leq 1\tag{14.1.430}$$

and their sum is:

$$\sum_{i=1}^{n} H_{ii} = \sum_{i=1}^{n}\left[\frac{1}{n}+\frac{(x_i-\bar{x})^2}{\sum\limits_{k=1}^{n}(x_k-\bar{x})^2}\right] = \frac{n}{n}+\frac{\sum\limits_{i}(x_i-\bar{x})^2}{\sum\limits_{k}(x_k-\bar{x})^2} = 2 \tag{14.1.431}$$

A rule of thumb is to consider leverage values to be large if they are more than double their average size (which is $2/n$ according to the previous relations). So leverages larger than $4/n$ are suspect. Another rule of thumb is to say that values bigger than 0.5 indicate high leverage, while values between 0.3 and 0.5 indicate moderate leverage.

14.1.11.1 Fisher Matrix

We have proved just earlier that:

$$\ln\left(L\left(\vec{\beta},\sigma\right)\right) = -\frac{n}{2}\ln(2\pi)-\frac{n}{2}\ln(\sigma^2)-\frac{1}{2\sigma^2}\left(\vec{y}-X_i\vec{\beta}\right)^T\left(\vec{y}-X_i\vec{\beta}\right) \tag{14.1.432}$$

And we have afterwards also prove that (changing the notation just a bit):

$$\frac{\partial\ln\left(L\left(\vec{\beta},\sigma\right)\right)}{\partial\vec{\beta}} = -\frac{1}{2\sigma^2}(2X^TX\vec{\beta}-2X^T\vec{y}) = \frac{1}{\sigma^2}(X^T\vec{y}-X^TX\vec{\beta}) = 0 \tag{14.1.433}$$

And we also get immediately:

$$\frac{\partial\ln\left(L\left(\vec{\beta},\sigma\right)\right)}{\partial\sigma^2} = -\frac{n}{2\sigma^2}+\frac{1}{2\sigma^4}(\vec{y}-X\vec{\beta})^T(\vec{y}-X\vec{\beta}) = 0 \tag{14.1.434}$$

From the both relation above we immediately deduce (note that $\hat{\sigma}^2$ is biased!):

$$\hat{\vec{\beta}} = (X^TX)^{-1}\vec{y} \qquad \text{and} \qquad \hat{\sigma}^2 = \frac{1}{n}\left(\vec{y}-X\hat{\vec{\beta}}\right)^T\left(\vec{y}-X\hat{\vec{\beta}}\right) \tag{14.1.435}$$

To compute $\mathcal{I}(\vec{\theta})$, notice that we have immediately:

$$\begin{aligned}
\frac{\partial^2\ln\left(L\left(\vec{\beta},\sigma\right)\right)}{\partial\vec{\beta}\partial\vec{\beta}} &= -\frac{1}{\sigma^2}X^TX \\
\frac{\partial^2\ln\left(L\left(\vec{\beta},\sigma\right)\right)}{\partial\sigma^2\partial\sigma^2} &= \frac{n}{2\sigma^4}-\frac{(\vec{y}-X\vec{\beta})^T(\vec{y}-X\vec{\beta})}{\sigma^6} \\
\frac{\partial^2\ln\left(L\left(\vec{\beta},\sigma\right)\right)}{\partial\sigma^2\partial\vec{\beta}} &= \frac{\partial^2\ln\left(L\left(\vec{\beta},\sigma\right)\right)}{\partial\vec{\beta}\partial\sigma^2} = -\frac{1}{\sigma^4}(X^T\vec{y}-X^TX\vec{\beta}) = -\frac{1}{\sigma^4}X^T(\vec{y}-X\vec{\beta})
\end{aligned} \tag{14.1.436}$$

Since:

$$\begin{aligned}
&\mathrm{E}\left(\frac{\partial^2 \ln\left(L\left(\vec{\beta},\sigma\right)\right)}{\partial\vec{\beta}\partial\vec{\beta}}\right)=\mathrm{E}\left(-\frac{1}{\sigma^2}X^TX\right)=-\frac{1}{\sigma^2}X^TX\\
&\mathrm{E}\left(\frac{\partial^2 \ln\left(L\left(\vec{\beta},\sigma\right)\right)}{\partial\sigma^2\partial\sigma^2}\right)=\frac{n}{2\sigma^4}-\frac{\mathrm{E}\left((\vec{y}-X\vec{\beta})^T(\vec{y}-X\vec{\beta})\right)}{\sigma^6}=\frac{n}{2\sigma^4}-\frac{n\sigma^2}{\sigma^6}=-\frac{n}{2\sigma^4}\\
&\mathrm{E}\left(\frac{\partial^2 \ln\left(L\left(\vec{\beta},\sigma\right)\right)}{\partial\sigma^2\partial\vec{\beta}}\right)=-\frac{1}{\sigma^4}X^T\mathrm{E}\left((\vec{y}-X\vec{\beta})\right)=0
\end{aligned} \tag{14.1.437}$$

Then the expected mean of the Hessian is (see section Statistics page 839):

$$-\mathrm{E}\left(H(\vec{\theta})\right)=\mathrm{E}\left(\frac{\partial^2\mathcal{L}(\vec{\theta})}{\partial\theta_i\partial\theta_j}\right)=\begin{bmatrix}-\dfrac{1}{\sigma^2}X^TX & 0\\ 0 & -\dfrac{n}{2\sigma^4}\end{bmatrix} \tag{14.1.438}$$

Without forgetting that (see section Statistics page 839):

$$\mathcal{I}(\vec{\theta})=-\mathrm{E}\left(H(\vec{\theta})\right)=\begin{bmatrix}\dfrac{1}{\sigma^2}X^TX & 0\\ 0 & \dfrac{n}{2\sigma^4}\end{bmatrix} \tag{14.1.439}$$

And finally:

$$\Sigma(\vec{\theta})\cong-\mathrm{E}(H^{-1})=\begin{bmatrix}\sigma^2(X^TX)^{-1} & 0\\ 0 & \dfrac{2\sigma^4}{n}\end{bmatrix} \tag{14.1.440}$$

It may seems to the reader in a first view that it is a 2×2 matrix. But this is forget that the term in the upper left corner is itself a $p\times p$ (where p is the number of predictors and we put $+1$ because of the intercept). Hence the matrix dimension is $(p+1)\times(p+1)$.

14.1.11.2 R^2 decomposition in multiple regression

Let us see now how to decompose R^2 into components that capture the percentage of variation explained by predictor in a multiple linear regression!

Consider n predictors and K observations in the sample:

$$y_k,x_{1k},\ldots,x_{nk}\qquad \text{for } k=1,\ldots,K \tag{14.1.441}$$

where all variables have been standardized to have mean zero and variance one. That is, we have centered and rescaled the observations such that for $i=1,\ldots,n$:

$$\begin{gathered}
\sum_{k=1}^K y_k=0=\sum_{k=1}^K x_{ik}\\
\frac{1}{K-1}\sum_{k=1}^K y_k^2=1=\frac{1}{K-1}\sum_{k=1}^K x_{ik}^2
\end{gathered} \tag{14.1.442}$$

Standardizing all variables in this manner is without loss of generality since R^2 is manifestly invariant to centering and rescaling of variables. Our multiple linear model is then given by:

$$y_k = \beta_1 x_{1k} + \ldots + \beta_n x_{nk} + \varepsilon_k, \qquad \text{for} \qquad k = 1, \ldots, K \tag{14.1.443}$$

since standardization ensures that the intercept in the regression above is identically zero.

We estimate the slope coefficient and obtain the fitted values:

$$\hat{y}_k = \hat{\beta}_1 x_{1k} + \ldots + \hat{\beta}_n x_{nk} \tag{14.1.444}$$

where $\hat{\beta}_i$ are the estimated slope coefficients for predictors $i = 1, \ldots, n$. Let $\text{cov}(\cdot, \cdot)$ denote the sample covariance operator, defined for centered vectors x and y by:

$$\text{cov}(x,y) = \frac{1}{K-1}\sum_{k=1}^{K} x_k y_k \tag{14.1.445}$$

Then by definition and construction:

$$R^2 = \frac{\sum\limits_{k=1}^{K} \hat{y}_k^2}{\sum\limits_{k=1}^{K} y_k^2} = \frac{\sum\limits_{k=1}^{K} \hat{y}_k^2}{1\cdot(K-1)} = \frac{1}{K-1}\sum_{k=1}^{K} \hat{y}_k^2 = \text{cov}(\hat{y},\hat{y}) = \text{cov}\left(\sum_{i=1}^{n} \hat{\beta}_i x_i, \hat{y}\right) = \sum_{i=1}^{n} \hat{\beta}_i \text{cov}\left(x_i, \hat{y}\right) \tag{14.1.446}$$

That is, we have the decomposition:

$$\boxed{R^2 = \hat{\beta}_1 \text{cov}\left(x_1, \hat{y}\right) + \ldots + \hat{\beta}_n \text{cov}\left(x_n, \hat{y}\right)} \tag{14.1.447}$$

We can therefore define the percentage of variation explained by the predictor i, denoted R_i^2, by:

$$R_i^2 = \hat{\beta}_i \text{cov}\left(x_i, \hat{y}\right) \tag{14.1.448}$$

14.1.11.3 Influential points

An "outlier" as we already know is a data point which is very far, somehow, from the rest of a group of the data. They are often worrisome, but not always a problem. When we are doing regression modelling, in fact, we don't really care about whether some data point is far from a group of data, but whether it breaks a pattern the rest of the data seems to follow and this is what we name an "influential point". We will look here some empirical ways of quantifying how much influence particular data points have on the model.

The points marked in red and blue in the figure below are clearly not like the main cloud of the data points, even though their x and y coordinates are quite typical of the data as a whole: the x coordinates of those points aren't related to the y coordinates in the right way, they break a pattern. On the other hand, the point marked in green, while its coordinates are very weird on both axes, does not break that pattern - it was positioned to fall right on the regression line.

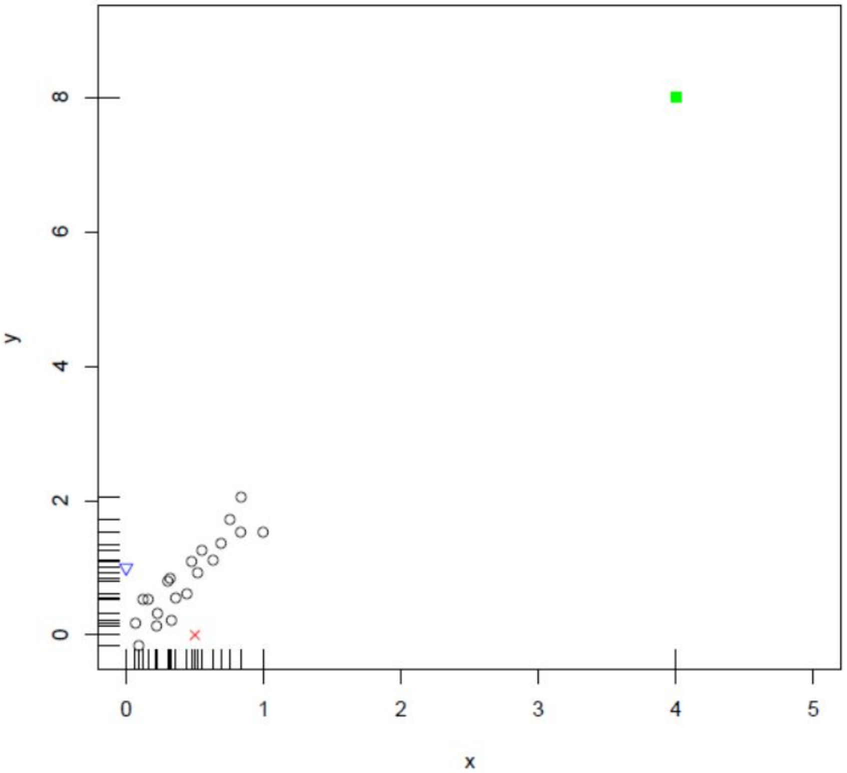

Figure 14.16: **Outliers (red) vs Influential (blue) points**

Be very very very careful with influential points!!! Even if they follow the global pattern, they may quite significantly (and surprisingly) modify the regression equation and the importance of the different coefficients of that same equation (see further below for an example)!

We have seen just earlier the "leverage". But let us introduce other influential indicators that are very common in the 120th century (holocene calendar) and beginning of 121st century in many statistical softwares and textbooks!

The "semistudentized residuals" are defined as:

$$\boxed{e_i^*=\frac{e_i}{\hat{\sigma}_e}=\frac{Y_i-\hat{y}_i}{\sqrt{\dfrac{1}{N-k}\displaystyle\sum_{i=1}^{N}(Y_i-\hat{y}_i)^2}}} \tag{14.1.449}$$

But... Let us recall that we have proved just earlier that:

$$\vec{\hat{Y}}=H\vec{y} \tag{14.1.450}$$

Hence:

$$\vec{e}=\vec{y}-\vec{\hat{Y}}=\vec{y}-H\vec{y}=(\mathbb{1}-H)\vec{y} \tag{14.1.451}$$

Let us rewrite this in term of noise:

$$\vec{e}=(\mathbb{1}-H)\vec{\varepsilon} \tag{14.1.452}$$

Since $\text{E}(\vec{\varepsilon})=\vec{0}$ and $\text{V}(\vec{\varepsilon})=\sigma_{\varepsilon}^2\vec{\mathbb{1}}$, we have:

$$\text{E}(\vec{e})=\text{E}\left[(\mathbb{1}-H)\vec{\varepsilon}\right]=\vec{0} \tag{14.1.453}$$

and:

$$\text{V}(\vec{e})=\text{V}\left[(\mathbb{1}-H)\vec{\varepsilon}\right]=(\mathbb{1}-H)\sigma_{\varepsilon}^2 \tag{14.1.454}$$

What does this imply for the residual at the ith data point? First, and obviously, it has expectation of 0:

$$\text{E}(\varepsilon_i)=0 \tag{14.1.455}$$

and it has variance which depends on i through the hat matrix:

$$\text{V}(e_i)=\sigma_{\varepsilon}^2(\mathbb{1}-H)_{ii}=\sigma_{\varepsilon}^2(1-H_{ii}) \tag{14.1.456}$$

In other words, the bigger the leverage of i, the smaller the variance of the residual is. This is yet another sense in which points with high leverage are points which the model tries very hard to fit.

Previously, when we looked at the residuals, we expected them to all be of roughly the same magnitude. This rests on the leverages H_{ii} being all about the same! If there are substantial variations in leverage across the data points, it's better to scale the residuals by their expected size.

The usual way to do this is through the "standardized residuals" or "internally studentized residuals" or just simply "studentized residuals":

$$\boxed{r_i=\frac{e_i}{\hat{\sigma}_{\varepsilon}\sqrt{1-H_{ii}}}=\frac{Y_i-\hat{y}_i}{\sqrt{\dfrac{1}{N-k}\displaystyle\sum_{i=1}^{N}(Y_i-\hat{y}_i)^2}\sqrt{1-\displaystyle\sum_{j=1}^{N}(X(X^TX)^{-1}X^T)_{ij}}}} \tag{14.1.457}$$

Why "studentized"? Because we're dividing by an estimate of the standard error, just like in Student's T-test for differences in means.

However the single e_i and $\hat{\sigma}_{\varepsilon}$ are non independent, so r_i can't have a T distribution.

Remark

Indeed, let us recall that in the section Statistics we have seen that given Z a random variable of Normal law centered and reduced $\mathcal{N}(0,1)$ and U a variable independent of Z and distributed according to the law of χ^2 at k degrees of freedom. By definition, the variable:

$$T=\frac{Z}{\sqrt{U/k}} \tag{14.1.458}$$

follows a Student law of k degrees of freedom.

The procedure is then to delete the ith observation, fit the regression function to the remaining $n-1$ observations, and get new $\hat{y}$'s which can be denoted by $\hat{y}_{i(i)}$. The difference:

$$d_i = Y_i - \hat{y}_{i(i)} \tag{14.1.459}$$

is named "deleted residual".

Then we define the "studentized deleted residuals" or "externally studentized residuals":

$$\boxed{t_i = \frac{d_i}{\hat{\sigma}_{\varepsilon(i)}\sqrt{1-H_{ii}}} = \frac{Y_i - \hat{y}_{i(i)}}{\sqrt{\dfrac{1}{N-k-1}\sum_{i=1}^{N}(Y_i-\hat{y}_{i(i)})^2}\sqrt{1-\sum_{j=1}^{n}(X(X^TX)^{-1}X^T)_{ij}}}} \tag{14.1.460}$$

Then if the errors are independent and normally distributed with expected value 0 and variance σ_ε^2, then the probability distribution of the i externally studentized residual is a Student's T-distribution with $N-k-1$ degrees of freedom:

$$T(N-k-1) = \frac{d_i}{\hat{\sigma}_{\varepsilon(i)}\sqrt{1-H_{ii}}} \tag{14.1.461}$$

Remark

In some statistical softwares we can find a influential indicator named DFITS (or also sometimes DFFITS) that is the acronym of "DiFference In fiTS" and defined by:

$$\text{DFIT} = \frac{Y_i - \hat{y}_{i(i)}}{\hat{\sigma}_{\varepsilon(i)}\sqrt{H_{ii}}} \tag{14.1.462}$$

DFITS is very similar to the externally studentized residual, and is in obviously equal to the latter times $\sqrt{H_{ii}/(1-H_{ii})}$.

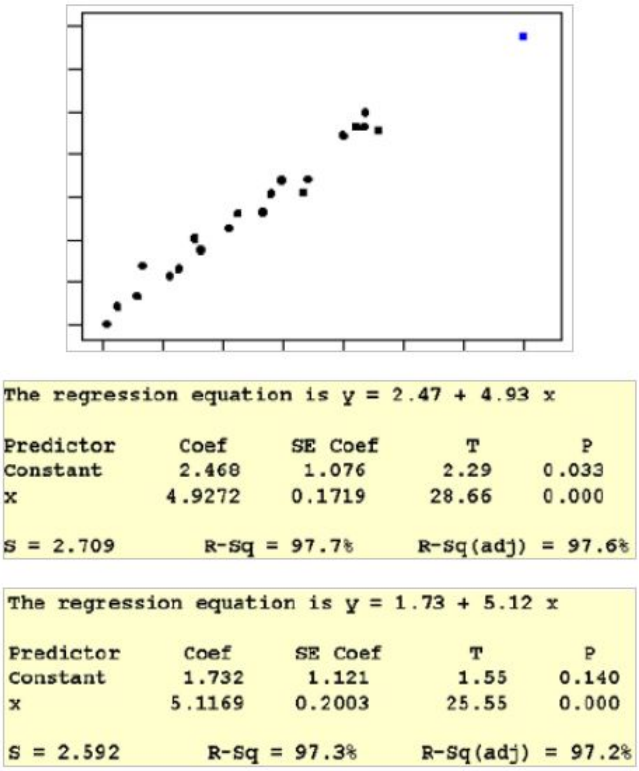
Probably one of the most famous influential indicator is the "Cook's distance". Omitting point i will generally change all of the fitted values, not just the fitted value at that point. Hence the idea to measure the total change and to define this distance as the sum of all the changes in the regression model when observation i is removed from it:

$$\|\vec{\hat{y}} - \vec{\hat{y}}^{(-i)}\|^2 = \sum_{j=1}^{n}(\hat{y}_j - \hat{y}_{j(i)})^2 \tag{14.1.463}$$

To make that relation more comparable across data sets, it's conventional to divide it by p, since there are really only p independent coordinates here, each of which might contribute something on the order of $\hat{\sigma}_\varepsilon$:

$$\boxed{D_i = \frac{\displaystyle\sum_{j=1}^{n}(\hat{y}_j - \hat{y}_{j(i)})^2}{p\hat{\sigma}_\varepsilon}} \tag{14.1.464}$$

There are different opinions regarding what cutoff values to use for spotting highly influential points. A simple operational guideline of $D_i > 1$ has been suggested. Others have indicated that $D_i > 4/n$ where N is the number of observations, might be used.



```
The regression equation is y = 2.47 + 4.93 x

Predictor        Coef    SE Coef        T        P
Constant        2.468      1.076     2.29    0.033
x              4.9272     0.1719    28.66    0.000

S = 2.709          R-Sq = 97.7%      R-Sq(adj) = 97.6%
```

```
The regression equation is y = 1.73 + 5.12 x

Predictor        Coef    SE Coef        T        P
Constant        1.732      1.121     1.55    0.140
x              5.1169     0.2003    25.55    0.000

S = 2.592          R-Sq = 97.3%      R-Sq(adj) = 97.2%
```

Figure 14.17: **Importance of an influential point on regression equation**

14.1.11.4 Significance of regression coefficients (variable importance)

When you study variable importance, you should always first remember to standardize all your predictors (thus, centered and scaled by the sample standard deviations).

Now let us deal first with the Gaussian multivariate regression case! Let us recall that (see page 6401):

$$\hat{\beta}_i = \mathcal{N}\left(\beta_i, \text{V}(\hat{\beta}_i)\right) = \mathcal{N}\left(\beta_i, \sigma_\varepsilon^2 (X_c^T X_c)_{ii}^{-1}\right) \qquad (14.1.465)$$

Thus:

$$\frac{\hat{\beta}_i - \beta_i}{\sqrt{\text{V}(\hat{\beta}_i)}} = \frac{\hat{\beta}_i - \beta_i}{\text{SE}(\hat{\beta}_i)} = \frac{\hat{\beta}_i - \beta_i}{\sigma_\varepsilon \sqrt{(X_c^T X_c)_{ii}^{-1}}} = \mathcal{N}(0,1) \qquad (14.1.466)$$

under the null $H_0 : \beta_i = 0$ we would actually have a simple Z test:

$$\frac{\hat{\beta}_i}{\text{SE}(\hat{\beta})} = \frac{\hat{\beta}_i}{\sigma_\varepsilon \sqrt{(X_c^T X_c)_{ii}^{-1}}} = \mathcal{N}(0,1) \qquad (14.1.467)$$

This relation is again a kind of "Wald statistics" and the related hypothesis also belong to the family of a Wald tests (not the first we meet in this textbook). Also often denoted:

$$W=\frac{\left(\hat{\beta}-\beta_0\right)}{\widehat{\text{se}}(\hat{\beta})}=\mathcal{N}(0,1) \tag{14.1.468}$$

or:

$$W^2=\frac{\left(\hat{\beta}-\beta_0\right)^2}{\widehat{\mathrm{V}}(\hat{\beta})}=\chi_1^2 \tag{14.1.469}$$

Now let us introduce a necessary intermediate result. Remember that for the bivariate regression, we have proved that:

$$(n-2)\hat{\sigma}_\varepsilon^2=\sum_k (y_k'-y_k)^2=\sum \varepsilon_k^2=\text{SSR} \tag{14.1.470}$$

Let us divide by the supposed true value of σ_ε:

$$(n-2)\frac{\hat{\sigma}_\varepsilon^2}{\sigma_\varepsilon^2}=\sum_k \frac{(y_k'-y_k)^2}{\sigma_\varepsilon^2}=\frac{\text{SSR}}{\sigma_\varepsilon^2} \tag{14.1.471}$$

We recognize here a sum of square of Normal distribution that led us to write:

$$\frac{(n-2)\hat{\sigma}_\varepsilon^2}{\sigma_\varepsilon^2}=\sum_k \frac{(y_k'-y_k)^2}{\sigma_\varepsilon^2}=\frac{\text{SSR}}{\sigma_\varepsilon^2}=\chi^2(n-2) \tag{14.1.472}$$

That we will guess can be generalized to the multivariate case by:

$$\frac{(n-k)\hat{\sigma}_\varepsilon^2}{\sigma_\varepsilon^2}=\chi^2(n-k) \tag{14.1.473}$$

Let us rearrange and take the square root:

$$\frac{\hat{\sigma}_\varepsilon}{\sigma_\varepsilon}=\sqrt{\frac{\chi^2(n-k)}{n-k}} \tag{14.1.474}$$

Let us divide:

$$\frac{\hat{\beta}_i}{\sigma_\varepsilon\sqrt{(X_c^TX_c)_{ii}^{-1}}}=\mathcal{N}(0,1) \tag{14.1.475}$$

by this previous result. Then:

$$\frac{\hat{\beta}_i}{\hat{\sigma}_\varepsilon\sqrt{(X_c^TX_c)_{ii}^{-1}}}=\frac{\mathcal{N}(0,1)}{\sqrt{\dfrac{\chi^2(n-k)}{n-k}}} \tag{14.1.476}$$

We recognize here well the term on the right. It's the definition itself the Student distribution (see Statistics section page 783). Then we can write:

$$\boxed{\frac{\hat{\beta}_i}{\hat{\sigma}_\varepsilon\sqrt{(X_c^TX_c)_{ii}^{-1}}}=T(n-k)} \tag{14.1.477}$$

That latter relation is also sometimes denoted:

$$\frac{\hat{\beta}_i}{\text{SE}(\hat{\beta}_i)}=T(n-k) \tag{14.1.478}$$

It explains why, in regression analysis and in variable importance, greater the Student $T(n-k)$ value is (in absolute value) the more the coefficient is significant ($H_1:\ \beta_i\neq 0$) and the more the corresponding predictor is important (hence the expression "variable importance")!

In logistic (and Poisson) regression that we will see later, the variance of the residuals is related to the mean! Indeed, if $Y\sim\mathcal{B}(n,p)$, the mean is $\text{E}(Y)=np$ and the variance is $\text{V}(Y)=np(1-p)=\text{E}(Y)(1-p)$ so the variance and the mean are related.

In statistics, the "dispersion parameter" ϕ indicates if we have more or less than the expected variance. If $\phi=1$ this means we observe the expected amount of variance, whereas $\phi<1$ means that we have less than the expected variance (named "underdispersion") and $\phi>1$ means that we have extra variance beyond the expected variance (named "overdispersion"). The dispersion parameter in logistic and Poisson regression is fixed at 1 which means that we can use the Z-score (that's why statistical softwares give the Z-score for the coefficients of such regression models!). In other regression types such as Normal linear regression, we have to estimate the residual variance and thus this is why, a T-value is used for calculating the p-values (that's why statistical softwares give the T-score for the coefficients of such regression models!).

- Linear Regression:

  The use of T-tests in linear regression comes from the distribution of Normally distributed error terms: $y_i=X_i^T\beta+\varepsilon_i$ where $\varepsilon_i\sim\mathcal{N}(0,1)$ are independent and identically distributed. It follows then as seen above that $\frac{\hat{\beta}_j-\beta_{j0}}{\widehat{\text{se}}\left(\hat{\beta}_j\right)}\sim T(n-k)$.

  Note that the default in most regression software packages test the hypothesis that $\hat{\beta}_j=0$, i.e. setting β_{j0} equal to zero.

- Logistic Regression:

  Logistic regression assumes errors follow the logistic distribution. Consequently, the term $\frac{\hat{\beta}_j-\beta_{j0}}{\widehat{\text{se}}\left(\hat{\beta}_j\right)}$ does not follow a T-distribution. Instead, we can use the Wald test, which relies on asymptotic normality as is implied by the Central limit Theorem.

Note, though, that even if the T-test and Wald test are asymptotically equivalent (i.e. as the sample size, $n\rightarrow+\infty$, they will reject the same cases); certainly some people - if a bit loosely - name a test based on a T-statistic a "Wald test", whether the statistic is compared with the asymptotic Normal distribution or the small sample result (T-distribution)...

14.1.11.5 Variance Inflation Factor (multicollinearity detection)

In statistics, the "variance inflation factor" (VIF) quantifies the severity of multicollinearity in an ordinary least squares regression analysis. It provides an index that measures how much the variance (the square of the estimate's standard deviation) of an estimated regression coefficient is increased because of collinearity.

To start, the reader must know that during our study of Principal Component Analyses (see section Statistics page 1213) we have proved in a trivial way that the variance-covariance matrix is given by:

$$\text{cov}_{jj'}=\frac{1}{n}X_c^TX_c \tag{14.1.479}$$

with for recall (for a regression model with p terms, and hence $p-1$ variables):

$$X=\begin{bmatrix}1 & X_{11} & \ldots & X_{1(p-1)}\\ 1 & X_{21} & \ldots & X_{2(p-1)}\\ \vdots & \vdots & \vdots & \vdots\\ 1 & X_{n1} & \ldots & X_{n(p-1)}\end{bmatrix}\Rightarrow X_c=\begin{bmatrix}0 & X_{c,11} & \ldots & X_{c,1(p-1)}\\ 0 & X_{c,21} & \ldots & X_{c,2(p-1)}\\ \vdots & \vdots & \vdots & \vdots\\ 0 & X_{c,n1} & \ldots & X_{c,n(p-1)}\end{bmatrix} \tag{14.1.480}$$

Therefore for example (and for recall again) for the special case of a 2×2 design matrix:

$$X_c^TX_c=\begin{bmatrix}0 & X_{c,11}+X_{c,21}\\ X_{c,11}+X_{c,21} & X_{c,11}^2+X_{c,21}^2\end{bmatrix}=\begin{bmatrix}0 & 0\\ 0 & X_{c,11}^2+X_{c,21}^2\end{bmatrix} \tag{14.1.481}$$

Hence:

$$\text{cov}_{jj'}=\frac{1}{n}X_c^TX_c=\begin{bmatrix}0 & 0\\ 0 & \dfrac{X_{c,11}^2+X_{c,21}^2}{n}\end{bmatrix}=\begin{bmatrix}0 & 0\\ 0 & \overline{X_{c,1}^2}\end{bmatrix} \tag{14.1.482}$$

And for a 3×3 matrix:

$$\text{cov}_{jj'}=\begin{bmatrix}0 & 0 & 0\\ 0 & \overline{X_{c,1}^2} & \overline{X_{c,1}X_{c,2}}\\ 0 & \overline{X_{c,1}X_{c,2}} & \overline{X_{c,2}^2}\end{bmatrix} \tag{14.1.483}$$

And as the matrix of correlations is given by (see section Statistics page 621):

$$R_{jj'}=\frac{\text{cov}_{jj'}}{\sigma_j\sigma_{j'}} \tag{14.1.484}$$

Then we get:

$$R_{jj'}=\frac{1}{n}\frac{1}{\sigma_j\sigma_{j'}}X_c^TX_c \tag{14.1.485}$$

The ideal would also be to be able to put the inverse of the standard deviations in a matrix form in order to have a totally matrix expression. After some trial and error we quickly find that we can write the correlation matrix in the form:

$$R_{jj'}=\frac{1}{n}S^{-1}(X_c^TX_c)S^{-1}=R \tag{14.1.486}$$

where S^{-1} is the usual notation to say that it is the diagonal matrix containing the inverse of the σ_j, or explicitly (so that it is clear to the reader!):

$$S^{-1}=\begin{bmatrix} \dfrac{1}{\sigma_1} & 0 & \ldots & 0 \\ 0 & \dfrac{1}{\sigma_2} & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \ldots & \ldots & \dfrac{1}{\sigma_n} \end{bmatrix} \tag{14.1.487}$$

So for now, we have two relations (out of three ... waiting for the proof of the third one) that will be very useful to us (attention the components of the vectors of the explanatory variables are always centered henceforth what implies a forced linear regression by the origin!):

$$\begin{gathered} R=\frac{1}{n}S^{-1}(X_c^TX_c)S^{-1} \\ \hat{\vec{\beta}}=(X_c^TX_c)^{-1}X_c^T\vec{y} \end{gathered} \tag{14.1.488}$$

Remark

Because $X_c^TX_c$ has the first row and column only with zeros (due to recall by the constant of the model) that generates issues when inverting the matrix (i.e. $(X_c^TX_c)^{-1}$), we then eliminate this column and row. To highlight this choice, a few textbooks write instead:

$$\left(X_{(-1)c}^TX_{(-1)c}\right)^{-1} \tag{14.1.489}$$

where the (-1) is here to indicate that the first row and first column were removed. For what will follow we did not make this choice of notation, so keep in mind now that when you see X_c, it is the "design matrix" but without the first column, or said differently: $X_c^TX_c$ without the first column and without the first row.

Now let's start from (don't forget that starting from now $\vec{\beta}$ does not contain β_0 anymore!!!):

$$\hat{\vec{\beta}}=(X_c^TX_c)^{-1}X_c^T\vec{y} \tag{14.1.490}$$

and let us rewrite this in a somewhat more explicit form:

$$\begin{aligned} \hat{\vec{\beta}}&=(X_c^TX_c)^{-1}X_c^T(X_c\vec{\beta}+\vec{\varepsilon})=(X_c^TX_c)^{-1}X_c^TX_c\vec{\beta}+(X_c^TX_c)^{-1}X_c^T\vec{\varepsilon} \\ &=\vec{\beta}+(X_c^TX_c)^{-1}X_c^T\vec{\varepsilon} \end{aligned} \tag{14.1.491}$$

Therefore:

$$\hat{\vec{\beta}}-\vec{\beta}=(X_c^TX_c)^{-1}X_c^T\vec{\varepsilon} \tag{14.1.492}$$

We understand now better why $(X_c^TX_c)^{-1}$ is often named "dispersion matrix" as we have already mentioned earlier above.

Let us now take the matrix of the covariance-variances matrix of the coefficients (measurement of multicollinearity):

$$\text{cov}\left(\hat{\vec{\beta}}\right)=\text{E}\left[\left(\hat{\vec{\beta}}-\vec{\beta}\right)\left(\hat{\vec{\beta}}-\vec{\beta}\right)^T\right]=\text{E}\left[\left((X_c^TX_c^{-1})X_c^T\vec{\varepsilon}\right)\left((X_c^TX_c)^{-1}X_c^T\vec{\varepsilon}\right)^T\right] \tag{14.1.493}$$

Using the following property of the transposed matrices proved in the section Linear Algebra (see page 1951):

$$(AB)^T = B^T A^T \tag{14.1.494}$$

we then have using this property a first time:

$$\begin{aligned}\text{cov}\left(\hat{\vec{\beta}}\right) &= \text{E}\left[((X_c^T X_c)^{-1} X_c^T \vec{\varepsilon})\left(\underbrace{(X_c^T X_c)^{-1}}_{:=A}\underbrace{X_c^T \vec{\varepsilon}}_{:=B}\right)^T\right]\\ &= \text{E}\left[((X_c^T X_c)^{-1} X_c^T \vec{\varepsilon})\left((X_c^T \vec{\varepsilon})^T\left((X_c^T X_c)^{-1}\right)^T\right)\right]\end{aligned} \tag{14.1.495}$$

and using it a second time:

$$\begin{aligned}\text{cov}\left(\hat{\vec{\beta}}\right) &= \text{E}\left[((X_c^T X_c)^{-1} X_c^T \vec{\varepsilon})\left((\underbrace{X_c^T}_{:=A}\underbrace{\vec{\varepsilon}}_{:=B})^T\left((X_c^T X_c)^{-1}\right)^T\right)\right]\\ &= \text{E}\left[((X_c^T X_c)^{-1} X_c^T \vec{\varepsilon})\left(\vec{\varepsilon}^T X_c \left((X_c^T X_c)^{-1}\right)^T\right)\right]\end{aligned} \tag{14.1.496}$$

Using now the following property proven in the section Linear Algebra (see page 1951):

$$(A^{-1})^T = (A^T)^{-1} \tag{14.1.497}$$

We then have:

$$\text{cov}\left(\hat{\vec{\beta}}\right) = \text{E}\left[((X_c^T X_c)^{-1} X_c^T \vec{\varepsilon})\left(\vec{\varepsilon}^T X_c \left((X_c^T X_c)^T\right)^{-1}\right)\right] \tag{14.1.498}$$

and reusing:

$$(AB)^T = B^T A^T \tag{14.1.499}$$

it comes:

$$\begin{aligned}\text{cov}\left(\hat{\vec{\beta}}\right) &= \text{E}\left[((X_c^T X_c)^{-1} X_c^T \vec{\varepsilon})\left(\vec{\varepsilon}^T X_c \left((\underbrace{X_c^T}_{:=A}\underbrace{X_c}_{:=B})^T\right)^{-1}\right)\right]\\ &= \text{E}\left[((X_c^T X_c)^{-1} X_c^T \vec{\varepsilon})\left(\vec{\varepsilon}^T X_c \left(X_c^T X_c\right)^{-1}\right)\right]\end{aligned} \tag{14.1.500}$$

Using the associativity property of the matrix product, we will write:

$$\begin{aligned}\text{cov}\left(\hat{\vec{\beta}}\right) &= \text{E}\left[((X_c^T X_c)^{-1} X_c^T \vec{\varepsilon})\left(\vec{\varepsilon}^T X_c \left(X_c^T X_c\right)^{-1}\right)\right]\\ &= \text{E}\left[(X_c^T X_c)^{-1} X_c^T (\vec{\varepsilon}\vec{\varepsilon}^T) X_c (X_c^T X_c)^{-1}\right]\end{aligned} \tag{14.1.501}$$

And by taking out the elements which are not random variables of the expected mean, it comes:

$$\begin{aligned}\text{cov}\left(\hat{\vec{\beta}}\right) &= (X_c^T X_c)^{-1} X_c^T \text{E}(\vec{\varepsilon}\vec{\varepsilon}^T) X_c (X_c^T X_c)^{-1}\\ &= (X_c^T X_c)^{-1} X_c^T \sigma_\varepsilon^2 X_c (X_c^T X_c)^{-1}\\ &= \sigma_\varepsilon^2 \underbrace{(X_c^T X_c)^{-1}(X_c^T X_c)}_{=1}(X_c^T X_c)^{-1}\\ &= \sigma_\varepsilon^2 (X_c^T X_c)^{-1}\end{aligned} \tag{14.1.502}$$

It is sadly often traditional (in spite of the confusion) to write this last result in the following form which we will see (and use) in the section of Industrial Engineering during our study of the Box-Behnken experimental designs:

$$\boxed{\mathrm{V}\left(\hat{\vec{\beta}}\right)=\sigma_{\varepsilon}^{2}(X_c^T X_c)^{-1}} \tag{14.1.503}$$

Remark

At this point, notice something important! As by assumption for the Gaussian multivariate linear regression we have $Y=\mathcal{N}(X\vec{\beta},\sigma_{\varepsilon}^{2}\mathbb{1}_k)$ as a consequence, we then have using the result above:

$$\boxed{\hat{\vec{\beta}}=\mathcal{N}\left(\vec{\beta},\sigma_{\varepsilon}^{2}(X_c^T X_c)^{-1}\right)} \tag{14.1.504}$$

This relation will be important for us later in our study of variable importance in the case of regression models and statistical significant test for the coefficient of the regression!

This last matrix $\mathrm{V}\left(\hat{\vec{\beta}}\right)$ contains in the diagonal the general expression in the general case of multi-linear regression the "standard error of the regression coefficients" (relation that uses among other the spreadsheet software Microsoft® Excel® in the case of the multi-linear regression for the column "Standard error" of the coefficients ... except that it takes the square root to have the standard deviation and not the variance!). If the linear regression is not forced at the origin, it will be necessary to use obviously:

$$\mathrm{V}\left(\hat{\vec{\beta}}\right)=\sigma_{\varepsilon}^{2}(X_T X)^{-1} \tag{14.1.505}$$

with for recall:

$$\sigma_{\varepsilon}^{2}=\frac{1}{n-k}\sum(Y_i-y_i)^2 \tag{14.1.506}$$

where k is for recall the number of coefficients of the multiple linear model.

We have now three important relations[11]:

$$\begin{aligned}R&=\frac{1}{n}S^{-1}(X_c^T X_c)S^{-1}\\ \hat{\vec{\beta}}&=(X_c^T X_c)^{-1}X_c^T\vec{y}\\ \mathrm{V}\left(\hat{\vec{\beta}}\right)&=\sigma_{\varepsilon}^{2}(X_c^T X_c)^{-1}\end{aligned} \tag{14.1.507}$$

Let us take up the first relation and manipulate it a little bit:

$$X_c^T X_c=nSRS \tag{14.1.508}$$

It comes then:

$$(X_c^T X_c)^{-1}=\frac{1}{n}(SRS)^{-1} \tag{14.1.509}$$

---

[11] There is a fourth one in reality that is also important...! The bias-variance tradeoff of the ordinary least squares regression as derived in details at page 6799.

Then we have:

$$(X_c^T X_c)^{-1}=\frac{1}{n}S^{-1}R^{-1}S^{-1} \tag{14.1.510}$$

By substituting the right-hand term for equality in the third of the equalities, we then have:

$$\text{V}\left(\hat{\vec{\beta}}\right)=\sigma_\varepsilon^2(X_c^T X_c)^{-1}=\sigma_\varepsilon^2\frac{1}{n}S^{-1}R^{-1}S^{-1}=\frac{\sigma_\varepsilon^2}{n}S^{-1}R^{-1}S^{-1} \tag{14.1.511}$$

If we denote by $\text{V}\left(\hat{\vec{\beta}}\right)_j$ the j-th diagonal element of the covariance-variance matrix of the $\hat{\vec{\beta}}$ and VIF_j, the "Variance Inflation Factor (VIF)", the j-th diagonal element of the matrix R^{-1} then it trivially follows that:

$$\text{V}\left(\hat{\vec{\beta}}\right)_j=\frac{\sigma_\varepsilon^2}{n}\frac{\text{VIF}_j}{\sigma_j\sigma_j}=\frac{\sigma_\varepsilon^2}{n}\frac{\text{VIF}_j}{\text{V}_j}=\frac{\sigma_\varepsilon^2}{n}\frac{\text{VIF}_j}{\text{V}(X_{c,j})} \tag{14.1.512}$$

The "scaled Variance Inflation Factor" is sometimes used instead and defined by:

$$\text{V}\left(\hat{\vec{\beta}}\right)_j=\frac{\sigma_\varepsilon^2}{n}\frac{\text{VIF}_j}{\sigma_j\sigma_j}=\frac{\sigma_\varepsilon^2}{n}\text{VIF}_{js} \tag{14.1.513}$$

Remark

Remember that if the variances are all equal to the unit ($\text{V}_i=1$) then the covariance matrix is equal to the correlation matrix, i.e. $R=\Sigma$. Hence if we work with the VIF_{js}, all the information is then also contained in the inverse of the covariance matrix, i.e. $\Sigma^{-1}=\Theta$ named the "precision matrix".

However, we must find the explicit formulation of the VIF_j. For this, let us recall that R is a positive definite symmetric matrix (see section Linear Algebra page 1957). Let us, for example, calculate the inverse of such a matrix of dimension 2×2 explicitly by using the relation proved in the section Linear Algebra (see page 1980) that is for recall:

$$b_{ij}=\frac{1}{\det(A)}(-1)^{i+j}\det(A_{ji}) \tag{14.1.514}$$

In the special case that interests us, we have then:

$$R^{-1}=\begin{bmatrix}R_{11} & R_{12}\\ R_{21} & R_{22}\end{bmatrix}^{-1}=\frac{1}{R_{11}R_{22}-R_{12}R_{21}}\begin{bmatrix}R_{11} & -R_{12}\\ -R_{21} & R_{22}\end{bmatrix} \tag{14.1.515}$$

and since the correlation matrix is symmetric and unit diagonal, we have:

$$R^{-1}=\frac{1}{1-R_{21}^2}\begin{bmatrix}1 & -R_{21}\\ -R_{21} & 1\end{bmatrix}=\frac{1}{1-R_{12}^2}\begin{bmatrix}1 & -R_{12}\\ -R_{12} & 1\end{bmatrix} \tag{14.1.516}$$

It comes then that if we focus on the elements of the diagonal:

$$R^{-1}=\begin{bmatrix}\dfrac{1}{1-R_{21}^2} & \ldots\\ \ldots & \dfrac{1}{1-R_{21}^2}\end{bmatrix}=\begin{bmatrix}\dfrac{1}{1-R_{12}^2} & \ldots\\ \ldots & \dfrac{1}{1-R_{12}^2}\end{bmatrix} \tag{14.1.517}$$

Repeating the job with a 3×3 matrix, we have:

$$\begin{aligned}R^{-1} &= \begin{bmatrix} R_{11} & R_{12} & R_{13} \\ R_{21} & R_{22} & R_{23} \\ R_{31} & R_{32} & R_{33} \end{bmatrix}^{-1} = \begin{bmatrix} 1 & R_{12} & R_{13} \\ R_{21} & 1 & R_{23} \\ R_{31} & R_{32} & 1 \end{bmatrix}^{-1} \\ &= \frac{1}{1-R_{12}^2-R_{13}^2-R_{23}^2+2R_{12}R_{13}R_{23}} \begin{bmatrix} 1-R_{23}^2 & R_{13}R_{23}-R_{12} & R_{12}R_{23}-R_{13} \\ R_{13}R_{23}-R_{21} & 1-R_{13}^2 & R_{12}R_{13}-R_{23} \\ R_{12}R_{23}-R_{31} & R_{12}R_{13}-R_{32} & 1-R_{12}^2 \end{bmatrix}\end{aligned} \tag{14.1.518}$$

Let us focus on the first diagonal component and rearrange it a bit to get something similar to the 2×2 case:

$$\begin{aligned}R_{1,1}^{-1} &= \frac{1-R_{23}^2}{1-R_{12}^2-R_{13}^2-R_{23}^2+2R_{12}R_{13}R_{23}} = \frac{1-R_{23}^2}{(1-R_{23}^2)-R_{12}^2-R_{13}^2+2R_{12}R_{13}R_{23}} \\ &= \frac{1}{1-\dfrac{R_{12}^2+R_{13}^2-2R_{12}R_{13}R_{23}}{1-R_{23}^2}}\end{aligned} \tag{14.1.519}$$

Now we put:

$$R_{1,23}^2 = \frac{R_{12}^2+R_{13}^2-2R_{12}R_{13}R_{23}}{1-R_{23}^2} \tag{14.1.520}$$

So that:

$$R_{1,1}^{-1} = \frac{1}{1-\dfrac{R_{12}^2+R_{13}^2-2R_{12}R_{13}R_{23}}{1-R_{23}^2}} = \frac{1}{1-R_{1,23}^2} \tag{14.1.521}$$

Where we define:

$$\boxed{R_{1,23} = \sqrt{\frac{R_{12}^2+R_{13}^2-2R_{12}R_{13}R_{23}}{1-R_{23}^2}}} \tag{14.1.522}$$

as the "multiple correlation coefficient" (for three variables...). This is by definition the way we calculate the correlation between x_1 and the other explanatory variables:

$$x_1 = \alpha_0 + \alpha_1 x_2 + \alpha_2 x_3 + \varepsilon \tag{14.1.523}$$

And the reader can check that regardless of the size of the matrix, the VIF_j can always be put in the form:

$$\boxed{\text{VIF}_j = S^{-1}R^{-1}S^{-1} = \frac{1}{1-R_j^2}} \tag{14.1.524}$$

In the case of 2×2 correlation matrix there is therefore only one coefficient VIF_j for the simple and good reason that the associated linear regression has only two coefficients ...

Remark

Some textbooks give the following relation for the general case:

$$\text{VIF}_j=\frac{1}{1-R_j^n} \tag{14.1.525}$$

But this is false as far as I know!

Most statistical softwares simply use the following relation:

$$\text{V}\left(\hat{\vec{\beta}}\right)=\frac{\sigma_\varepsilon^2}{n}\frac{\text{VIF}_j}{\text{V}(x_{c,j})} \tag{14.1.526}$$

So we understand (how the name suggests...) why the variance inflation factor (VIF) quantifies how much the variance of the coefficients is inflated when multicollinearity exists.

Therefore:

$$\text{VIF}_j=\frac{n\text{V}\left(\hat{\vec{\beta}}\right)\text{V}(X_{c,j})}{\sigma_\varepsilon^2} \tag{14.1.527}$$

It is important here to notice that the VIF (multicolinearity) is proportional to the variance of the beta coefficients estimation. Hence as we have proved earlier (see page 6395) that the significance of regression coefficients is inversely proportional to the square of the variance of the beta coefficients estimation, multicollinearity implies therefore small p-values and thus leading to some variables becoming significant even though they are actually not significant.

Either in the case where the data are such that the regression is not forced at the origin:

$$\begin{aligned}\text{VIF}_j&=\frac{n\text{V}\left(\hat{\vec{\beta}}\right)\text{V}(X_j)}{\sigma_\varepsilon^2}=\frac{n\sigma_\varepsilon^2(X^TX)^{-1}\dfrac{1}{n}\displaystyle\sum_i(x_{ij}-\bar{x}_j)^2}{\dfrac{1}{n-k}\displaystyle\sum_i(Y_i-y_i)^2}\\&=\frac{\dfrac{1}{n-k}\displaystyle\sum_i(Y_i-y_i)^2(X^TX)^{-1}\sum_i(x_{ij}-\bar{x}_j)^2}{\dfrac{1}{n-k}\displaystyle\sum_i(Y_i-y_i)^2}\\&=(X^TX)^{-1}\sum_i(x_{ij}-\bar{x}_j)^2\end{aligned} \tag{14.1.528}$$

Therefore the version I prefer to use and to teach (especially for customers and students having only a spreadsheet software at their disposition is):

$$\boxed{\text{VIF}_j=\frac{1}{1-R_j^2}=n(X^TX)^{-1}\sqrt{\sum_i(x_{ij}-\bar{x}_j)^2}} \tag{14.1.529}$$

and as all terms are known to us in practice, the calculation of the VIF_j doesn't make us problems anymore!

A rule of thumb is that if $\text{VIF}_j > 10$ then multicollinearity is high (solving backwards this translates into an R_j^2 value of 0.90). Obviously a VIF of 1 means that there is no correlation among the kth predictor and the remaining predictor variables, and hence the variance of β_k is not inflated at all. VIFs exceeding 4 should warrant further investigation.

Remark

Some softwares instead calculates the tolerance which is just the reciprocal of the VIF. The choice of which to use is a matter of personal preference.

The square root of the variance inflation factor finally indicates how much larger the standard error is, compared with what it would be if that variable were uncorrelated with the other predictor variables in the model.

✍**Example:**

If the variance inflation factor of a predictor variable is equal to 5.27 ($\sqrt{5.27}=2.3$), this means that the standard error for the coefficient of that predictor variable is 2.3 times as large as it would be if that predictor variable was uncorrelated with the other predictor variables.

Regardless of your criterion for what constitutes a high VIF, there are situations in which a high VIF is not a problem and can be safely ignored. For example, if you specify a regression model with both x and x^2, there is a good chance that those two variables will be highly correlated.

14.1.11.5.1 Gauss-Markov theorem

After all this we finally have the tools and results necessary to prove the Gauss-Markov theorem in an easy way!

In statistics, the "Gauss–Markov theorem" (or simply Gauss theorem for some authors) states that the ordinary least squares (OLS) estimator has the lowest sampling variance within the class of linear unbiased estimators, if the errors in the linear regression model are uncorrelated, have equal variances and expectation value of zero. The errors do not need to be Normally distributed, nor do they need to be independent and identically distributed (only uncorrelated with mean zero and homoscedastic with finite variance).

It's not a very important proof for the engineer but statisticians like a lot such properties!

First we need a definition!

Definition (#559): Given a parameter vector $\vec{\omega}$ in q dimensions, and a vector $\vec{y}$ from which to estimate it, we say that the estimator $\vec{\omega}^*$ is the best unbiased estimator of $\vec{\omega}$, or "Best Linear Unbiased Estimator" (BLUE) of $\vec{\omega}$, if:

1. $\vec{\omega}^*$ is a linear estimator of $\vec{\omega}$, in other words there is a matrix A such that $\vec{\omega}^* = A\vec{y}$;
2. $\vec{\omega}^*$ is unbiased, in other words, $\text{E}(\vec{\omega}^*)=\vec{\omega}$

3. Whatever the unbiased linear estimator $\tilde{\vec{\omega}}$ of $\vec{\omega}$, the variance of this estimator is greater than or equal to that of $\vec{\omega}^*$.

Theorem 14.3. Given n observations $\vec{x}^1,\vec{x}^2,\ldots,\vec{x}^n\in\mathbb{R}^p$ and their labels $y^1,y^2,\ldots,y^n\in\mathbb{R}$. Under the assumption that, for all $i, y^i=\beta_0+\sum_{j=1}^p\beta_j x_j^i+\varepsilon^i$ and that the ε^i are normally distributed and centered at 0, then the estimator of $\vec{\beta}$ by the least squares method is its unique BLUE!

Proof 14.3.1. First as we know:

$$\vec{\beta}^*=\left(X^TX\right)^{-1}X^T\vec{y} \tag{14.1.530}$$

and $\vec{\beta}^*$ is therefore linear. It's expected mean is:

$$\mathrm{E}\left(\vec{\beta}^*\right)=\mathrm{E}\left(\left(X^TX\right)^{-1}X^T(X\vec{\beta}+\varepsilon)\right) \tag{14.1.531}$$

As $X,\vec{y}$ and $\vec{\beta}$ are not random, and that ε has a 0 expected mean, we get:

$$\mathrm{E}\left(\vec{\beta}^*\right)=\mathrm{E}\left(\left(X^TX\right)^{-1}X^T\vec{\beta}\right)=\vec{\beta} \tag{14.1.532}$$

Therefore, $\vec{\beta}^*$ is unbiased.

Its variance is equal to (see page 6400):

$$\mathrm{V}\left(\vec{\beta}^*\right)=\left(X^TX\right)^{-1}\sigma_\varepsilon^2 \tag{14.1.533}$$

Finally, suppose now that $\tilde{\vec{\beta}}=A\vec{y}$ is another linear unbiased estimator of $\vec{\beta}$. By definition, therefore $\mathrm{E}(\tilde{\vec{\beta}})=\vec{\beta}$. By replacing $\vec{y}$ by it value, we get $\mathrm{E}\left(A(X\vec{\beta}+\varepsilon)\right)=\vec{\beta}$ and therefore $AX\vec{\beta}=\vec{\beta}$. As this is true for every $\vec{\beta}$, we conclude that $AX=I$ (this result will be useful for later below).

Let us put $D=A-\left(X^TX\right)^{-1}X^T$, such that $\tilde{\vec{\beta}}-\vec{\beta}^*=D\vec{y}$. The variance of $\tilde{\vec{\beta}}$ is equal to:

$$\mathrm{V}(\tilde{\vec{\beta}})=\mathrm{V}(A\vec{y})=\mathrm{V}(A\varepsilon)=A^2\sigma_\varepsilon^2=AA^T\sigma_\varepsilon^2 \tag{14.1.534}$$

We can then express AA^T as follows:

$$\begin{aligned}AA^T&=\left(D+\left(X^TX\right)^{-1}X^T\right)\left(D+\left(X^TX\right)^{-1}X^T\right)^T\\&=\left(D+\left(X^TX\right)^{-1}X^T\right)\left(D^T+X\left(X^TX\right)^{-1}\right)\\&=DD^T+DX\left(X^TX\right)^{-1}+\left(X^TX\right)^{-1}X^TD^T+\left(X^TX\right)^{-1}\end{aligned} \tag{14.1.535}$$

As $AX=I$, then:

$$D=A-\left(X^TX\right)^{-1}X^T\Rightarrow DX=AX-\left(X^TX\right)^{-1}X^TX=0 \tag{14.1.536}$$

and it is immediate that we have similarly $(DX)^T=X^TD^T=0$.

We therefore get:

$$AA^T=DD^T+DX\left(X^TX\right)^{-1}+\left(X^TX\right)^{-1}X^TD^T+\left(X^TX\right)^{-1}=DD^T+\left(X^TX\right)^{-1} \tag{14.1.537}$$

Using this trick we can rewrite the variance as:

$$\mathrm{V}(\tilde{\vec{\beta}})=\sigma_\varepsilon^2 DD^T+\sigma_\varepsilon^2\left(X^TX\right)^{-1}=\mathrm{V}\left(\vec{\beta}^*\right)+\sigma_\varepsilon^2 DD^T \qquad (14.1.538)$$

As $\sigma_\varepsilon^2>0$ and DD^T has by construction every component that is >0, we have:

$$\mathrm{V}(\tilde{\vec{\beta}})>\mathrm{V}\left(\vec{\beta}^*\right) \qquad (14.1.539)$$

excepted if $D=0$, in which case $\tilde{\vec{\beta}}=\vec{\beta}^*$.

■ Q.E.D.

Remark

As already mentioned at the beginning, we see then that the Normality assumption on ε is not necessary! It suffices that the errors $\{\varepsilon_i\}_{i=1,\ldots,n}$ have zero expectation, have the same finite variance σ^2 (homoscedasticity), and are not correlated with each other ($\operatorname{cov}(\varepsilon_i,\varepsilon_l)=0$ for $i\neq l$).

14.1.11.6 Weighted Least Squares (WLS)

The method of ordinary least squares[12] assumes that there is constant variance in the errors (which is named "homoscedasticity" for recall). The method of "weighted least squares" (WLS) can be used when the ordinary least squares assumption of constant variance in the errors is violated (which is named "heteroscedasticity" for recall). The model under consideration is:

$$\vec{y}=X\vec{\beta}+\vec{\varepsilon} \qquad (14.1.540)$$

where we consider now that the $\varepsilon_i=\mathcal{N}(0,\sigma_i)$. Hence the errors may not be homoscedastic!

Let us recall the likelihood for the multivariate linear gaussian regression:

$$L\left(\vec{\beta},\sigma\right)=\left(\frac{1}{\sigma\sqrt{2\pi}}\right)^n e^{-\frac{1}{2\sigma^2}\sum_{i=1}^n\left(y_i-\vec{x}_i^T\vec{\beta}\right)^2}=\left(\frac{1}{\sigma\sqrt{2\pi}}\right)^n e^{-\frac{1}{2\sigma^2}\left(\vec{y}-X\vec{\beta}\right)^T\left(\vec{y}-X\vec{\beta}\right)} \qquad (14.1.541)$$

In the heteroscedatic case that interest us here the likelihood can only be written as:

$$L\left(\vec{\beta},\vec{\sigma}\right)=e^{-\frac{1}{2}\sum_{i=1}^n\left(\frac{y_i-\vec{x}_i^T\vec{\beta}}{\sigma_i}\right)^2}\prod_{i=1}^n\frac{1}{\sigma_i\sqrt{2\pi}}=e^{-\frac{1}{2}\left(\vec{y}-X\vec{\beta}\right)^T\Sigma^{-1}\left(\vec{y}-X\vec{\beta}\right)}\prod_{i=1}^n\frac{1}{\sigma_i\sqrt{2\pi}} \qquad (14.1.542)$$

named the "generalized least squares regression likelihood".

---

[12] A rule of thumb for OLS regression is that it isn't too impacted by heteroscedasticity as long as the maximum variance is not greater than four times the minimum variance.

So in the case of standard linear regression we have $\sigma_i = \sigma\ \forall i$ and all of diagonal terms that are zero, therefore:

$$\Sigma = \begin{bmatrix} \sigma_1^2 & 0 & \ldots & 0 \\ 0 & \sigma_2^2 & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & \sigma_n^2 \end{bmatrix} = \begin{bmatrix} \sigma^2 & 0 & \ldots & 0 \\ 0 & \sigma^2 & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & \sigma^2 \end{bmatrix} \tag{14.1.543}$$

If we take the logarithm of the likelihood and ignoring the terms that doesn't content the β_i we then get:

$$\log\left(L\left(\vec{\beta},\vec{\sigma}\right)\right) \propto -\frac{1}{2}\sum_{i=1}^{n}\left(\frac{y_i - \vec{x}_i^T\vec{\beta}}{\sigma_i}\right)^2 \tag{14.1.544}$$

The idea is to rewrite the previous relation as:

$$\log\left(L\left(\vec{\beta},\vec{\sigma}\right)\right) \propto -\frac{1}{2}\sum_{i=1}^{n} w_i\left(y_i - \vec{x}_i^T\vec{\beta}\right)^2 = -\frac{1}{2}\sum_{i=1}^{n} w_i\varepsilon_i^2 = -\frac{1}{2}\sum_{i=1}^{n}(\sqrt{w_i}\varepsilon_i)^2 \tag{14.1.545}$$

with:

$$w_i = \frac{1}{\sigma_i^2} \tag{14.1.546}$$

Or in matrix form:

$$W = \Sigma^{-1} = \begin{bmatrix} \frac{1}{\sigma_1^2} & 0 & \ldots & 0 \\ 0 & \frac{1}{\sigma_2^2} & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & \frac{1}{\sigma_n^2} \end{bmatrix} \tag{14.1.547}$$

Remark

The reader must understand that the reason some statistical softwares require the matrix W is just because they will replace the calculated $\hat{\sigma}_i$ by the corresponding w_i and not multiply them together! And by the way... as all off-diagonal terms of W are zero, most statistical softwares require only a vector corresponding to the values of the diagonal of W.

Or in matrix notation this will be denoted:

$$\log\left(L\left(\vec{\beta},\vec{\sigma}\right)\right) \propto -\frac{1}{2}\left(\vec{y} - X\vec{\beta}\right)^T W\left(\vec{y} - X\vec{\beta}\right) \tag{14.1.548}$$

So for weighted regression, it is the weighted residuals that we try to make homoscedastic! Such that:

$$\varepsilon_{wi} = \sqrt{w_i}\varepsilon_i \tag{14.1.549}$$

Let us consider the univariate case:

$$\log(L(\vec{\beta},\vec{w}_i)) \propto \sum_{i=1}^{n} w_i(y_i - (\beta_0 + \beta_1 x_i))^2 \tag{14.1.550}$$

To determine the intercept we then calculate:

$$\frac{\partial \log(L(\vec{\beta},\vec{w_i}))}{\partial \beta_0}=0=\sum_{i=1}^{n} 2w_i(y_i-(\beta_0+\beta_1 x_i))(-1) \qquad (14.1.551)$$

Hence:

$$\beta_0=\frac{\displaystyle\sum_{i=1}^{n} w_i y_i}{\displaystyle\sum_{i=1}^{n} w_i}-\beta_1\frac{\displaystyle\sum_{i=1}^{n} w_i x_i}{\displaystyle\sum_{i=1}^{n} w_i}=\bar{y}_w-\beta_1\bar{x}_w \qquad (14.1.552)$$

And similarly:

$$\begin{aligned}\frac{\partial \log(L(\vec{\beta},\vec{w_i}))}{\partial \beta_1}=0&=\frac{\partial w_i \displaystyle\sum_{i=1}^{n}(y_i-(\beta_0+\beta_1 x_i))^2}{\partial \beta_1}=\frac{\partial \displaystyle\sum_{i=1}^{n} w_i(y_i-((\bar{y}_w-\beta_1\bar{x}_w)+\beta_1 x_i))^2}{\partial \beta_1}\\&=2w_i\sum_{i=1}^{n}\left((y_i-\bar{y}_w)-\beta_1(x_i-\bar{x}_w)\right)\left(-(x_i-\bar{x}_w)\right)\end{aligned} \qquad (14.1.553)$$

Hence:

$$\begin{aligned}\frac{\partial \log(L(\vec{\beta},\vec{w_i}))}{\partial \beta_1}=0&=\frac{\partial w_i \displaystyle\sum_{i=1}^{n}(y_i-(\beta_0+\beta_1 x_i))^2}{\partial \beta_1}=\frac{\partial \displaystyle\sum_{i=1}^{n} w_i(y_i-((\bar{y}_w-\beta_1\bar{x}_w)+\beta_1 x_i))^2}{\partial \beta_1}\\&=2w_i\sum_{i=1}^{n}\left((y_i-\bar{y}_w)-\beta_1(x_i-\bar{x}_w)\right)\left(-(x_i-\bar{x}_w)\right)\end{aligned} \qquad (14.1.554)$$

And similarly:

$$\beta_1=\frac{\displaystyle\sum_{i=1}^{n} w_i(y_i-\bar{y}_w)(x_i-\bar{x}_w)}{\displaystyle\sum_{i=1}^{n} w_i(x_i-\bar{x}_w)^2} \qquad (14.1.555)$$

Notice that for the two relations:

$$\boxed{\beta_0=\frac{\displaystyle\sum_{i=1}^{n} w_i y_i}{\displaystyle\sum_{i=1}^{n} w_i}-\beta_1\frac{\displaystyle\sum_{i=1}^{n} w_i x_i}{\displaystyle\sum_{i=1}^{n} w_i}=\bar{y}_w-\beta_1\bar{x}_w \qquad \beta_1=\frac{\displaystyle\sum_{i=1}^{n} w_i(y_i-\bar{y}_w)(x_i-\bar{x}_w)}{\displaystyle\sum_{i=1}^{n} w_i(x_i-\bar{x}_w)^2}} \qquad (14.1.556)$$

If $w_i=1$ for all i then we fall back on OLS.

Now let us generalize that result. First notice that:

$$\log\left(L\left(\vec{\beta},\vec{\sigma}\right)\right)\propto-\frac{1}{2}\sum_{i=1}^{n}\left(\frac{y_i-\vec{x}_i^T\vec{\beta}}{\sigma_i}\right)^2 \tag{14.1.557}$$

will be rewritten in matrix form (we get rid of the factor $-1/2$ that doesn't bring anything):

$$\log\left(L\left(\vec{\beta},\vec{\sigma}\right)\right)\propto\left\|\Sigma^{-1/2}(\vec{y}-X\vec{\beta})\right\|^2:=\left\|W^{1/2}(\vec{y}-X\vec{\beta})\right\|^2=(\vec{y}-X\vec{\beta})^TW(\vec{y}-X\vec{\beta}) \tag{14.1.558}$$

Let us expand the last equality (using the property of transposed matrices as seen on page 1951 in the section of Linear Algebra):

$$\begin{aligned}\log\left(L\left(\vec{\beta},\vec{\sigma}\right)\right)&\propto(\vec{y}-X\vec{\beta})^TW(\vec{y}-X\vec{\beta})=\vec{y}^TW\vec{y}-\vec{y}^TWX\vec{\beta}-(X\vec{\beta})^TW\vec{y}+(X\vec{\beta})^TWX\vec{\beta}\\&=\vec{y}^TW\vec{y}-\vec{y}^TWX\vec{\beta}-\vec{\beta}^TX^TW\vec{y}+\vec{\beta}^TX^TWX\vec{\beta}\end{aligned} \tag{14.1.559}$$

Now we seek the minimum of the latter relation (Weighted Sum of Squares Errors) with respect to the β_i:

$$\text{WSSE}\propto\min_{\vec{\beta}}\quad\vec{y}^TW\vec{y}-\vec{y}^TWX\vec{\beta}-\vec{\beta}^TX^TW\vec{y}+\vec{\beta}^TX^TWX\vec{\beta} \tag{14.1.560}$$

For this we differentiate with respect to $\vec{\beta}$. Obviously the first term will vanish so it remains only:

$$\vec{\nabla}_{\vec{\beta}}\text{WSSE}\propto\vec{\nabla}_{\vec{\beta}}\left(-\vec{y}^TWX\vec{\beta}-\vec{\beta}^TX^TW\vec{y}+\vec{\beta}^TX^TWX\vec{\beta}\right)=0 \tag{14.1.561}$$

Notice now that we have also using the properties of transposed matrices:

$$\vec{y}^TWX\vec{\beta}=(W\vec{y})^T(\vec{\beta}^TX^T)^T=(W\vec{y}\vec{\beta}^TX^T)^T=\vec{\beta}^TX^TW\vec{y} \tag{14.1.562}$$

without forgetting that as W is diagonal we have $W=W^T$. Therefore:

$$\begin{aligned}\vec{\nabla}_{\vec{\beta}}\text{WSSE}&\propto\vec{\nabla}_{\vec{\beta}}\left(-\vec{y}^TWX\vec{\beta}-\vec{\beta}^TX^TW\vec{y}+\vec{\beta}^TX^TWX\right)\\&=\vec{\nabla}_{\vec{\beta}}\left(-2\vec{\beta}^TX^TW\vec{y}+\vec{\beta}^TX^TWX\vec{\beta}\right)\\&=-2X^TW\vec{y}+2X^TWX\vec{\beta}=0\end{aligned} \tag{14.1.563}$$

Rearranging we get:

$$\boxed{\hat{\vec{\beta}}_{\text{WLS}}=\min_{\vec{\beta}}\sum_{i=1}^{n}(\sqrt{w_i}\varepsilon_i)^2=(X^TWX)^{-1}X^TW\vec{y}} \tag{14.1.564}$$

Again we notice that if W is a diagonal unitary matrix, we fall back on the ordinary multivariate regression coefficients.

Remark

Notice that exactly the same developments can lead us to the coefficient of the general ordinary least squares then given by:

$$\boxed{\hat{\vec{\beta}}_{\text{GLS}}=(X^T\Sigma^{-1}X)^{-1}X^T\Sigma^{-1}\vec{y}} \tag{14.1.565}$$

Since we can write $\Sigma=SS^T$, where S is a triangular matrix using the Cholesky decomposition (see section Linear Algebra page 2027), we have for the general sum of squares errors:

$$\begin{aligned}\text{GSSE}&=\left(\vec{y}-X\vec{\beta}\right)^T\Sigma^{-1}\left(\vec{y}-X\vec{\beta}\right)=\left(\vec{y}-X\vec{\beta}\right)^T S^{-T}S^{-1}\left(\vec{y}-X\vec{\beta}\right)\\&=\left(S^{-1}\vec{y}-S^{-1}X\vec{\beta}\right)^T\left(S^{-1}\vec{y}-S^{-1}X\vec{\beta}\right)\end{aligned} \tag{14.1.566}$$

So GLS is like regressing $S^{-1}X$ on $S^{-1}\vec{y}$. Furthermore:

$$\begin{aligned}\vec{y}&=X\vec{\beta}+\vec{\varepsilon}\\S^{-1}\vec{y}&=S^{-1}X\vec{\beta}+S^{-1}\vec{\varepsilon}\\\vec{y}\,'&=X'\vec{\beta}+\vec{\varepsilon}\,'\end{aligned} \tag{14.1.567}$$

So we have a new regression equation y' where as we can see from the GSSE can be assimilated a simple regression equation which has uncorrelated errors with equal variance.

In practice, for other types of dataset, the structure of W is usually unknown, so we have to perform an ordinary least squares (OLS) regression first. Provided the regression function is appropriate, the i-th squared residual from the OLS fit is an estimate of σ_i^2 and the i-th absolute residual is an estimate of σ_i (which tends to be a more useful estimator in the presence of outliers). The residuals are much too variable to be used directly in estimating the weights, w_i, so instead we use either the squared residuals to estimate a variance function or the absolute residuals to estimate a standard deviation function. We then use this variance or standard deviation function to estimate the weights.

Some key points regarding weighted least squares are:

- The difficulty, in practice to determine the right weights (in some cases, the values of the weights may be based on theory or prior research).
- Weighted least squares estimates of the coefficients will usually be nearly the same as the "ordinary" unweighted estimates[13]. In cases where they differ substantially, the procedure can be iterated until estimated coefficients stabilize (often in no more than one or two iterations); this is named "iteratively reweighted least squares".
- In designed experiments with large numbers of replicates, weights can be estimated directly from sample variances of the response variable at each combination of predictor variables.

---

[13] Same applies for the ANOVA of the regression obviously.

- Use of weights will (legitimately) impact the widths of statistical intervals.
- In the transformed model, the interpretation of the coefficient estimates can be difficult. In weighted least squares the interpretation remains the same as before.
- Weighted least squares gives us an easy way to remove one observation from a model by setting its weight equal to 0.
- We can also downweight outlier or influential points to reduce their impact on the overall model.

Remark

The reader must keep in mind that this technique of weights can be applied to numerous techniques of regression. Not only linear, but also polynomial, logistic and so on!

14.1.11.7 Model Selection Criteria

Much of modern scientific enterprise is concerned with the question of model choice. An experimenter or researcher collects data, often in the form of measurements on many different aspects of the observed units, and wants to study how these variables affect some outcome of interest. Which measures are important to the outcome? Which are not? Are there interactions between the variables that need to be taken into account? Statisticians are also naturally involved in the question of model selection, and so it should come as no surprise that many approaches have been proposed over the years for dealing with this key issue. Both frequentist and Bayesian schools have weighed in on the matter, spawning methods such as F tests, Akaike information criterion (AIC), Mallows's C_p, exhaustive search, stepwise, backward, and forward selection procedures, cross-validation, Bayes factors of various flavours (partial, intrinsic, pseudo, fractional, posterior), Bayesian information criterion (BIC), and Bayesian model averaging, to name some of the more popular and well-known methods. Some of these, such as stepwise selection, are algorithms for picking a 'good' (or maybe useful) model; others, for example, AIC, are criteria for judging the quality of a model. Given this wealth of choices, how is a statistician able to decide what to do? An approach that cannot be implemented or understood by the scientific community will not gain acceptance. This implies that, at the very least, we need a method that can be carried out easily and yields results that can be interpreted by scientifically and numerically literate end users. From a statistical point of view, we want a method that is coherent and general enough to handle a wide variety of problems. Among the demands we could make on our method would be that it obeys the likelihood principle, that it has some frequentist (asymptotic) justification, and that it corresponds to a Bayesian decision problem. So let's begin from easier do derive to the most complicated one keeping in mind that there is actually in this beginning of the 121st century (holocene calendar) no magic procedures to get you the "best model" (this still remains an unsolved problem)!

14.1.11.7.1 Mallows's C_p Linear Regression Prediction

We estimated our model by minimizing the mean squared error on our data[14]:

$$\widehat{\vec{\beta}}=\min_{\vec{b}}\frac{1}{n}(\vec{y}-X\vec{b})^T(\vec{y}-X\vec{b}) \tag{14.1.568}$$

Different linear models will amount to different choices of the design matrix X — we add or drop variables, we add or drop interactions or polynomial terms, etc., and this adds or removes columns from the design matrix (this is typical of how works the "subset method" in many statistical softwares). We might consider doing a selection among models themselves by minimizing the MSE. This may sometimes (but not always!) be a very bad idea, for a fundamental reason: Every model can be too optimistic about how well it will actually predict (sometimes the ultimate validation of a model is to test its predictive capacity).

Let's be very clear about what it would mean to predict well. The most challenging case would be that we see a new random point, with predictor values $X_1,\ldots X_p$ and response Y, and our old $\widehat{\vec{\beta}}$ has a small expected squared error:

$$\mathrm{E}\left(Y-\left(\hat{\beta}_0+\sum_{j=1}^{p}X_j\hat{\beta}_j\right)\right)^2 \tag{14.1.569}$$

Here both Y and the X's are random (hence the capital letters), so we might be asking the model for a prediction at a point it never saw before (of course if we have multiple identically distributed (X,Y) pairs, say q of them, the expected MSE over those q points is just the same as the expected squared error at one point.)

An easier task would be to ask the model for predictions at the same values of the predictor variables as before, but with different random noises. That is, we fit the model to:

$$\begin{aligned}\text{Training data}:&(X_i,y_i)_{i=1}^n, X_i=(x_{i1},x_{i2},\ldots,x_{i,p-1})\\ \text{Test data}:&(X_i,y_i^{\text{new}})_{i=1}^n, X_i=(x_{i1},x_{i2},\ldots,x_{i,p-1})\end{aligned} \tag{14.1.570}$$

The test data consist of new outcome data drawn from the same true model and at the same x-locations as the training data (notice that this is a practical construction to derive the criterion, but not a necessity to use this for model selection. However, you should not use model selection criteria for a specific range of x and assume you can predict well on a different range of x!).

Let us note for the training data the model as following:

$$\vec{Y}=X\vec{\beta}+\varepsilon \tag{14.1.571}$$

with $\varepsilon=\mathcal{N}(0,\sigma_\varepsilon^2)$ and for the test data:

$$\vec{Y}\,'=X\vec{\beta}+\varepsilon' \tag{14.1.572}$$

where ε and ε' are independent but identically distributed! The design matrix is the same, the true parameters $\vec{\beta}$ are the same, but the noise is different[15]. We now want to see if the coefficients we estimated from $(X,\vec{Y})$ can predict $(X,\vec{Y}\,')$. Since the only thing that's changed is the noise, if the coefficients can't predict well any more, that means that they were really just memorizing the noise, and not actually doing anything useful.

---

[14] The whole text and developments below are mostly a copy paste of the PDF of the professor Cosma Shalizi

[15] If we really are in an experimental setting, we really could get a realization of $\vec{Y}'$ just by running the experiment a second time. With surveys or with observational data, it would be harder to actually realize $\vec{Y}'$, but mathematically at least it's unproblematic.

Remark

If we have $p-1$ variables, there are 2^{p-1} possible subset models!

Our "out-of-sample expected MSE", then, is:

$$\text{E}\left(\frac{1}{n}\left(\vec{Y}\,'-X\hat{\vec{\beta}}\right)^T\left(\vec{Y}\,'-X\hat{\vec{\beta}}\right)\right) \tag{14.1.573}$$

It will be convenient to break this down into an average over data points, and to abbreviate $X\hat{\vec{\beta}}=\hat{\vec{m}}$, the vector of fitted values. Notice that since the predictor variables and the coefficients aren't changing, our predictions are the same both in and out of sample. At point i, we will predict $\hat{\vec{m}}_i$.

In this notation, then, the expected out-of-sample MSE is:

$$\text{E}\left(\frac{1}{n}\sum_{i=1}^{n}(y_i'-\hat{m}_i)^2\right) \tag{14.1.574}$$

We will compare this to the "expected in-sample MSE":

$$\text{E}\left(\frac{1}{n}\sum_{i=1}^{n}(y_i-\hat{m}_i)^2\right) \tag{14.1.575}$$

Notice that $\hat{m}_i$ is a function of the y_i (among other things), so those are dependent random variables, while $\hat{m}_i$ and y_i' are completely statistically independent[16].

Break this down term by term. What's the expected value of the i^{th} in-sample squared error? Using Huygens relation given for recall by $\text{V}(X)=\text{E}(X^2)-\text{E}(X)^2$ we then have:

$$\begin{aligned}\text{E}\left((y_i-\hat{m}_i)^2\right)&=\text{V}(y_i-\hat{m}_i)+(\text{E}(y_i-\hat{m}_i))^2\\&=\text{V}(y_i)+\text{V}(\hat{m}_i)-2\text{cov}(y_i,\hat{m}_i)+(\text{E}(y_i)-\text{E}(\hat{m}_i))^2\end{aligned} \tag{14.1.576}$$

The covariance term is not (usually) zero, because, as already mentioned, $\hat{m}_i$ is a function of, in part, y_i.

On the other hand, what's the expected value of the i-th squared error on new data? Using again Huygens relation we get:

$$\begin{aligned}\text{E}\,(y_i'-\hat{m}_i)^2=&\text{V}(y_i'-\hat{m}_i)+(\text{E}(y_i'-\hat{m}_i))^2\\&=\text{V}(y_i')+\text{V}(\hat{m}_i)-2\text{cov}(y_i',\hat{m}_i)+(\text{E}(y_i')-\text{E}(\hat{m}_i))^2\end{aligned} \tag{14.1.577}$$

The y_i' is independent of y_i, but has the same distribution. This tells us that:

$$\text{E}(y_i')=\text{E}(y_i)\qquad \text{V}(y_i')=\text{V}(y_i)\qquad\text{but}\qquad \text{cov}(y_i',\hat{m}_i)=0 \tag{14.1.578}$$

---

[16] That might sound weird, but remember we're holding X fixed in this exercise, so what we mean is that knowing $\hat{m}_i$ doesn't give us an extra information about y_i' beyond what we'd get from knowing the values of the X variables.

So:

$$\begin{aligned}\mathrm{E}\left((y_i'-\hat{m}_i)^2\right)&=\mathrm{V}(y_i)+\mathrm{V}(\hat{m}_i)+(\mathrm{E}(y_i)-\mathrm{E}(\hat{m}_i))^2\\&=\mathrm{E}\left((y_i-\hat{m}_i)^2\right)+2\mathrm{cov}(y_i,\hat{m}_i)\end{aligned}\tag{14.1.579}$$

Averaging over data points:

$$\mathrm{E}\left(\frac{1}{n}\sum_{i=1}^{n}(y_i'-\hat{m}_i)^2\right)=\mathrm{E}\left(\frac{1}{n}\sum_{i=1}^{n}(y_i-\hat{m}_i)^2\right)+\frac{2}{n}\sum_{i=1}^{n}\mathrm{cov}(y_i,\hat{m}_i)\tag{14.1.580}$$

Clearly, we need to get a handle on that sum of covariances.

For a linear model, though (using the results proved also during our study of influential points on page 6387):

$$\mathrm{cov}(y_i,\hat{m}_i)=\mathrm{cov}(y_i,\hat{y}_i)=\mathrm{cov}\left(y_i,\sum_{j=1}^{n}H_{ij}y_j\right)=\sum_{j=1}^{n}H_{ij}\mathrm{cov}\left(y_i,y_j\right)=\sigma_\varepsilon^2 H_{ii}\tag{14.1.581}$$

as for recall:

$$\mathrm{cov}\left(y_i,y_j\right)=\mathrm{cov}\left(\alpha+X_i\vec{\beta}_i+\varepsilon_i,\alpha+X_j\vec{\beta}_j+\varepsilon_j\right)=\mathrm{cov}\left(\varepsilon_i,\varepsilon_j\right)=\begin{cases}1 & \text{if } i=j\\ 0 & \text{if } i\neq j\end{cases}\tag{14.1.582}$$

So, for linear models:

$$\mathrm{E}\left(\frac{1}{n}\sum_{i=1}^{n}(y_i'-\hat{m}_i)^2\right)=\mathrm{E}\left(\frac{1}{n}\sum_{i=1}^{n}(y_i-\hat{m}_i)^2\right)+\frac{2}{n}\sum_{i=1}^{n}\sigma_\varepsilon^2H_{ii}=\mathrm{E}\left(\frac{1}{n}\sum_{i=1}^{n}(y_i-\hat{m}_i)^2\right)+\frac{2}{n}\sigma_\varepsilon^2\mathrm{tr}(H)\tag{14.1.583}$$

and we know that with p predictors and one intercept[17]:

$$\mathrm{tr}(H)=\mathrm{tr}(X(X^TX)^{-1}X^T)=\mathrm{tr}((X^TX)^{-1}(X^TX))=\mathrm{tr}(\mathbb{1}_p)=p+1\tag{14.1.584}$$

Thus, for linear models:

$$\mathrm{E}\left(\frac{1}{n}\sum_{i=1}^{n}(y_i'-\hat{m}_i)^2\right)=\mathrm{E}\left(\frac{1}{n}\sum_{i=1}^{n}(y_i-\hat{m}_i)^2\right)+\frac{2}{n}\mathrm{tr}(H)=\mathrm{E}\left(\frac{1}{n}\sum_{i=1}^{n}(y_i-\hat{m}_i)^2\right)+\frac{2}{n}\sigma_\varepsilon^2p\tag{14.1.585}$$

Of course, we don't actually know the expectation on the right-hand side, but we do have a sample estimate of it, which is the in-sample MSE. If the law of large numbers is still our friend:

$$\mathrm{E}\left(\frac{1}{n}\sum_{i=1}^{n}(y_i'-\hat{m}_i)^2\right)\cong\frac{1}{n}\sum_{i=1}^{n}(y_i-\hat{m}_i)^2+\frac{2}{n}\sigma_\varepsilon^2p\tag{14.1.586}$$

The second term on the right, $(2/n)\sigma_\varepsilon^2(p+1)$, is the "optimism" of the model, i.e. the amount by which its in-sample MSE systematically under-estimates its true expected squared error. Notice that this:

---

[17] Be careful, on some Internet forum, people use X_c instead of X then the result lead to p and not $p+1$ as the first component of the diagonal for X_c is equal to 0.

- Grows with σ_{ε}^2: more noise gives the model more opportunities to seem to fit well by capitalizing on chance.
- Shrinks with n: at any fixed level of noise, more data makes it harder to pretend the fit is better than it really is.
- Grows with p: every extra parameter is another control which can be adjusted to fit to the noise.

Minimizing the in-sample MSE completely ignores the bias from optimism, so it is guaranteed to pick models which are too large and predict poorly out of sample. If we could calculate the optimism term, we could at least use an unbiased estimate of the true MSE on new data. From one point of view, the optimism is just an estimate of the bias. From another point of view, it's a cost we're imposing on models for having extra parameters.

Definition (#14.1.560): If p regressors are selected from a set of $k>p$, the "Mallows's C_p" statistic for that particular set of regressors is defined as (it's the previous relation multiplied by n and divided by σ_{ε}^2):

$$C_p \cong \frac{\displaystyle\sum_{i=1}^{n}(y_i-\hat{m}_i)^2}{\sigma_{\varepsilon}^2}+2p=\frac{\text{SSE}_p}{\dfrac{\text{SSE}_q}{n-q}}-n+2p=\frac{\text{SSE}_p}{\text{MSE}_q}-n+2p \tag{14.1.587}$$

The C_p criterion, that compares the precision and bias of the full model to models with a subset of the predictors, suffers from two main limitations:

1. The C_p approximation is only valid for large sample size
2. The C_p cannot handle complex collections of models as in the variable selection (or feature selection[18]) problem.

The C_p statistic is often used as a stopping rule for various forms of stepwise regression (don't forget that it is more a feature selection technique than a regression one!).

Remark

One way to automatically select a model is to begin with the largest model you can, and then prune (simplify) it, which can be done in several way:

- Eliminate the least-significant coefficient (thanks to the p-value)
- Pick your favourite model selection criterion, consider deleting each coefficient in turn, and pick the sub-model with the best value of the criterion.

---

[18] Feature subset selection is the process of identifying and removing as much irrelevant and redundant information as possible. This reduces the dimensionality of the data and may allow learning algorithms to operate faster and more effectively. In some cases, accuracy on future classification can be improved; in others, the result is a more compact, easily interpreted representation of the target concept.

Having eliminated a variable, one then re-estimates the model, and repeats the procedure. Stop when either all the remaining coefficients are significant (under the first option), or nothing can be eliminated without worsening the criterion. That latter procedure is named "backward stepwise regression". The method that starts with intercept only and adds variables in the same fashion is named the "forward stepwise regression" (don't forget that these two methods are more feature selection techniques than regression one!). There are naturally forward-backward hybrids.

Because the inter-correlation between the regressors affect the order of term entry and removal. Since we are approaching the final model from two different directions this aspect can cause the methods to converge on different models.

Colin Lingwood Mallows proposed the statistic as a criterion for selecting among many alternative subset regressions. Under a model not suffering from appreciable lack of fit (bias), C_p has expectation nearly equal to p. Indeed, if your model with p parameters is correct it holds that $\text{SSE}_p \cong (n-p)\sigma_\varepsilon^2$. If your other model is already correct as well, it holds $\text{SSE}_q \cong (n-q)\sigma_\varepsilon^2$, therefore:

$$C_p \cong \frac{\text{SSE}_p}{\dfrac{\text{SSE}_q}{n-q}} - n + 2p = \frac{(n-p)\sigma_\varepsilon^2}{\dfrac{(n-q)\sigma_\varepsilon^2}{n-q}} - n + 2p = (n-p) - n + 2p = p \qquad (14.1.588)$$

Otherwise the expectation is roughly p plus a positive bias term.

Nevertheless, even though it has expectation greater than or equal to p, there is nothing to prevent $C_p < p$ or even $C_p < 0$ in extreme cases. It is suggested that one should choose a subset that has C_p approaching p, from above, for a list of subsets ordered by increasing p. In practice, the positive bias can be adjusted for by selecting a model from the ordered list of subsets, such that $C_p < 2p$.

To summarize, we should look for models where Mallows's C_p is small and close to the number of predictors in the model plus the constant p. A small Mallows's C_p value indicates that the model is relatively precise (has small variance) in estimating the true regression coefficients and predicting future responses. A Mallows's C_p value that is close to the number of predictors plus the constant indicates that the model is relatively unbiased in estimating the true regression coefficients and predicting future responses. Models with lack-of-fit and bias have values of Mallows's C_p larger than p.

14.1.11.7.2 Akaike Information Criterion (AIC)

The Akaike information criterion, AIC, was developed by Akaike to estimate the expected Kullback-Leibler discrepancy (relative quality of statistical models for a given set of dataset) between the model generating the data and a fitted candidate model. In instances where the sample size is large and the dimension of the candidate model is relatively small, AIC serves as an approximately unbiased estimator. In other settings, AIC may be characterized by a large negative bias which limits its effectiveness as a model selection criterion[19].

Sometimes we have a set of possible models and we want to choose the best model. Model selection methods help us choose a good model. Here are some examples:

✍**Examples:**

E1. Suppose we use a polynomial to model the regression function:

$$\mathrm{E}(Y/X=x)=\beta_0+\beta_1 x+\beta_2 x^2+\ldots+\beta_k x^k \tag{14.1.589}$$

We will need to choose the order of polynomial p. We can think of this as a sequence of models $\mathcal{M}_1,\ldots,\mathcal{M}_k$ index by k.

E2. Suppose you have data $y_1,\ldots,y_n$ on age at death of n people. You want to model the distribution of y. Some popular models are:

- $\mathcal{M}_1$: The exponential distribution: $p(y,\theta)=\theta e^{-\theta y}$
- $\mathcal{M}_2$: The gamma distribution: $p(y,a,b)=(b^a/\Gamma(a))y^{a-1}e^{-by}$
- $\mathcal{M}_3$: The log-normal distribution: we take $\log(y)\cong\mathcal{N}(\mu,\sigma^2)$

E3. Suppose you have time series data $y_1,y_2,\ldots$ A common model is the AR (autoregressive model):

$$y_t=a_1y_{t-1}+a_2y_{t-2}+\ldots+a_kY_{t-k}+\varepsilon_t \tag{14.1.590}$$

where $\varepsilon_t\cong\mathcal{N}(0,\sigma^2)$. The number k is the order of the model as we know. We need to choose k.

In a linear regression model, when we need to choose which variables to include in the regression based on return on experience or statistical indicators, we name this method "variable selection".

Here are five myths about variable selection (see [**heinze2017five**]):

- **Myth 1:** The number of variables in a model should be reduced until there are 10 events per variables (EPV) is wrong. The number of EPV depends on the desired statistical power of the study.

---

[19] For such instances, Hurvic and Tasi (11989 according to holocene calendar) proposed the corrected Akaike information criterion, AICc.

- **Myth 2:** Only variables with proven univariable-model significance should be included in a model is wrong. It depends on the context of the experiment and the return on experience (REX).

- **Myth 3:** Insignificant effects should be eliminated from a model is wrong. Eliminating weak effects may also be dangerous as in some studies, bias could result from falsely omitting an important confounder.

- **Myth 4:** The reported p-value quantifies the type I error of a variable being falsely selected is wrong. Multiple selection methods should be presented in any report: One based for example of on p-value, another on the AIC and another one on the BIC.

- **Myth 5:** Variable selection simplifies analysis is wrong. Sure it simplifies interpretation and comprehension for the decision board but analysis is automated nowadays therefore the simplification argument is not valid anymore in our era of modern computer software given the available computer processing power.

Remark

The AICc is useful for selecting between models in the same class. For example, we can use it to select an ARIMA model (see section Economy page 7989) between candidate ARIMA models or an ETS model between candidate ETS models (see section Economy page 7958). However, it cannot be used to compare between ETS and ARIMA models for example because they are most of the times based on too much different mathematical tools.

Suppose we have models $\mathcal{M}_1,\ldots,\mathcal{M}_k$ where each model is a set of densities (to simplify the notations we will consider only univariate models):

$$\mathcal{M}_j=\left\{p(y,\theta_j):\theta_j\in\vec{\Theta}_j\right\} \qquad (14.1.591)$$

We have data $y_1,\ldots,y_n$ drawn from some density f. We do not assume that f is any of the models $\mathcal{M}_j$!

Let $\hat{\theta}_j$ be the maximum likelihood estimator from model j. An estimate of P, based on model j is $\hat{p}_j(y)=p(y,\hat{\theta})$. The quality of $\hat{p}_j(y)$ as an estimate of f can be measured by the Kullback-Leibler divergence given for recall in its continuous form by (see section Statistical Mechanics page 3542):

$$D_{\text{KL}}(p_X,p_Y)=\int p_X(x)\log\left(\frac{p_X(x)}{p_Y(x)}\right)\mathrm{d}x \qquad (14.1.592)$$

That we will write here as:

$$D_{\text{KL}}(p,\hat{p}_j)=\int p(y)\log\left(\frac{p(y)}{\hat{p}_j(y)}\right)\mathrm{d}y=\int p(y)\log(p(y))\mathrm{d}y-\int p(y)\log(\hat{p}_j(y))\mathrm{d}y \qquad (14.1.593)$$

The first term does not depend on j. So minimizing $D_{\text{KL}}(p,\hat{p}_j)$ over j is the same as maximizing (don't forget that we have proved that D_{KL} was positive definite such that $D_{\text{KL}}\geq 0$):

$$D_{\text{KL},j}=\int p(y)\log(\hat{p}_j(y))\mathrm{d}y=\int p(y)\log(p(y,\hat{\theta}_j))\mathrm{d}y \qquad (14.1.594)$$

We need to estimate $D_{\text{KL,j}}$. Intuitively, a parametric estimate of $D_{\text{KL,j}}$ is given by the arithmetic average (not such as good as taking the median but more easy to deal for mathematical developments):

$$\bar{D}_{\text{KL},j}=\frac{1}{n}\sum_{i=1}^{n}\log\left(p(y_i,\hat{\theta}_j)\right) \tag{14.1.595}$$

However, apart from the fact that this estimate is non-robust, it is also probably quite biased. Akaike proved that the bias is approximately d_j/n where $d_j=\text{dim}(\vec{\Theta}_j)$. Therefore we use for the model $\mathcal{M}_j$:

$$\hat{D}_{\text{KL},j}\cong\bar{D}_{\text{KL},j}-\frac{d_j}{n} \tag{14.1.596}$$

That is to say a measure of a in-sample performance plus a penalty (or bias). Defining on the way the "Akaike information criterion[20]" (AIC):

$$\boxed{\text{AIC}(j)=2n\hat{D}_{\text{KL},j}\cong 2n\bar{D}_{\text{KL},j}-2d_j} \tag{14.1.597}$$

Notice that maximizing $\hat{D}_{\text{KL},j}$ is the same as maximizing $\text{AIC}(j)$ over j. But keep in mind that from an information theory point of view, the divergence $\hat{D}_{\text{KL},j}$ tells us how much information we lost due to our approximation of probability distribution with respect to the true probability distribution. When comparing models, we choose the models with the lowest AIC because in turn it means that the Kullback-Leibler divergence also would be minimum. Low AIC means little information bias.

And why do we multiply by $2n$? Just for historical reasons! We can multiply by any constant (that's why Data Scientists typically multiply by -1; it won't change which model we pick. In fact, different textbooks and also softwares (like R and Python™) use different versions of AIC. A few common notations we can find in Data Science textbooks are for example :

$$\text{AIC}=2k-2\ln(\mathcal{L})=2\ln\left(\frac{e^k}{\hat{\mathcal{L}}}\right) \tag{14.1.598}$$

Written in that way a smaller AIC score is preferable to a larger score. Using the rewritten formula, one can see how the AIC score of the model will increase in proportion to the growth in the value of the numerator, which contains the number of parameters in the model (i.e. a measure of model complexity). And the AIC score will decrease in proportion to the growth in the denominator which contains the maximized log likelihood of the model (which, as we just saw, is a measure of the goodness-of-fit of the model). Keep in mind that the AIC score is useful only when its used to compare two models! The $2k$ indicated well that the less parameters we will have, the less likely will be the overfitting of the model.

---

[20] Actually, in his original paper, Hirotugu Akaike, proposed using the factor 2 to simplify some calculation involving chi-squared distribution. Many subsequent specialists have since kept the factor of 2 which of course will not change which model is selected. Also some authors define AIC as negative of this, and then minimize it; again, clearly the same thing!

Remark

Some opine why the need of for AIC when cross-validation techniques are already available. Well, cross validation helps in assessing only the predictive accuracy of the model at different section of the data. Cross validation is a diagnostic not an overfitting prevention strategy. Moreover cross validation does not provide information on how parsimonious the model (number of parameters) is.

Proof 14.3.2. Let us recall that during the study of the Fisher information matrix (see section Statistics page 839) we have defined the score function for a parameter θ_j of a distribution function depending of a set of parameters $\vec{\theta}$ as (keep in mind that we can take the $\ln$ or the $\log$, the result remains the same!):

$$\mathcal{S}_j(\vec{\theta})=\frac{\partial\mathcal{L}(\vec{\theta})}{\partial\theta_j}(\hat{\theta})=\frac{\partial\ln(L(\vec{\theta}))}{\partial\theta_j}(\hat{\theta}) \quad (14.1.599)$$

We know that the score function is used to build the estimate of parameters of the distribution (when we put the score equal to zero). And that therefore if the true parameters are known, then it always equal to zero (at least for non-strange distribution functions...)!

Let us recall that also during the study of this of bivariate Taylor series (see section Sequences and Series page 1715), we have introduced the Hessian matrix, the matrix of second derivatives, that we will denote $H(\vec{\theta})$ (meaning implicitly that it is evaluated at $\hat{\vec{\theta}}$).

Let us recall that during our study of the central limit theorem (see section Statistics page 938) we have proved that:

$$Z_n=\frac{\hat{\mu}-\mu}{\sigma/\sqrt{n}}\cong\mathcal{N}(0,1) \quad (14.1.600)$$

Therefore:

$$\sqrt{n}\,(\hat{\mu}-\mu)=\mathcal{N}(0,\sigma) \quad (14.1.601)$$

For a bivariate or multivariate Normal distribution (see section Statistics page 713), this will be written:

$$\vec{Z}_n=\sqrt{n}\left(\vec{\hat{\mu}}-\vec{\mu}\right)=\mathcal{N}(0,\Sigma) \quad (14.1.602)$$

For the case that interest us here, let us denote this:

$$\vec{Z}_n=\sqrt{n}\left(\hat{\vec{\theta}}-\vec{\theta}_0\right)=\mathcal{N}(0,\Sigma(\vec{\theta})) \quad (14.1.603)$$

With as we have seen during our study of the Fisher information Matrix (see section Statistics page 839):

$$\Sigma(\vec{\theta})\cong\left[\mathrm{E}(H^{-1})\mathcal{I}(\vec{\theta})\mathrm{E}(H^{-1})\right] \quad (14.1.604)$$

Now that we have finish the recalls. Let us take the Taylor series of:

$$D_{\text{KL}}=\int p(y)\log(\hat{p}(y))\mathrm{d}y=\int p(y)\log(p(y,\hat{\theta}))\mathrm{d}y \quad (14.1.605)$$

considering $\hat{\vec{\theta}}$ as the variable and doing the development around the true value of the estimator that we will denote $\vec{\theta}_0$:

$$\begin{aligned}D_{\text{KL}}&\cong\int p(y)\left(\log(p(y,\vec{\theta}_0))+(\hat{\vec{\theta}}-\vec{\theta}_0)^T\frac{\partial p(y,\vec{\theta})}{\partial\vec{\theta}}(\vec{\theta}_0)+\frac{1}{2}(\hat{\vec{\theta}}-\vec{\theta}_0)^T H(y,\vec{\theta})(\vec{\theta}_0)(\hat{\vec{\theta}}-\vec{\theta}_0)\right)\mathrm{d}y\\&=\int p(y)\left(\log(p(y,\vec{\theta}_0))+(\hat{\vec{\theta}}-\vec{\theta}_0)^T\vec{\mathcal{S}}(\vec{\theta}_0)+\frac{1}{2}(\hat{\vec{\theta}}-\vec{\theta}_0)^T H(y,\vec{\theta})(\vec{\theta}_0)(\hat{\vec{\theta}}-\vec{\theta}_0)\right)\mathrm{d}y\end{aligned}\tag{14.1.606}$$

At the true value $\vec{\theta}_0$ we have (don't forget that this partial derivative is the score, i.e. the partial derivative of the likelihood and that latter is always equal to zero for the true model with the real parameters!):

$$\vec{\mathcal{S}}(\vec{\theta}_0)=\frac{\partial p(y,\vec{\theta})}{\partial\vec{\theta}}(\vec{\theta}_0)=\vec{0}\tag{14.1.607}$$

Then it remains:

$$D_{\text{KL}}\cong\int p(y)\left(\log(p(y,\vec{\theta}_0))+\frac{1}{2}(\hat{\vec{\theta}}-\vec{\theta}_0)^T H(y,\vec{\theta})(\vec{\theta}_0)(\hat{\vec{\theta}}-\vec{\theta}_0)\right)\mathrm{d}y\tag{14.1.608}$$

That we can also write:

$$\begin{aligned}D_{\text{KL}}&\cong\int p(y)\left(\log(p(y,\vec{\theta}_0))+\frac{1}{2}\frac{\sqrt{n}(\hat{\vec{\theta}}-\vec{\theta}_0)^T H(y,\vec{\theta})(\vec{\theta}_0)\sqrt{n}(\hat{\vec{\theta}}-\vec{\theta}_0)}{n}\right)\mathrm{d}y\\&=\int p(y)\left(\log(p(y,\vec{\theta}_0))+\frac{1}{2}\frac{\vec{Z}_n^T H(y,\vec{\theta})(\vec{\theta}_0)\vec{Z}_n}{n}\right)\mathrm{d}y\\&=\int p(y)\log(p(y,\vec{\theta}_0))\mathrm{d}y+\frac{1}{2n}\int p(y)\left(\vec{Z}_n^T H(y,\vec{\theta})(\vec{\theta}_0)\vec{Z}_n\right)\mathrm{d}y\end{aligned}\tag{14.1.609}$$

The $\vec{Z}_n$ doesn't depend explicitly on y, then we can write:

$$D_{\text{KL}}\cong\int p(y)\log(p(y,\vec{\theta}_0))\mathrm{d}y+\frac{1}{2n}\vec{Z}_n^T\left(\int p(y)H(y,\vec{\theta})(\vec{\theta}_0)\mathrm{d}y\right)\vec{Z}_n\tag{14.1.610}$$

Now let us recall that we have seen during our study of the Fisher Information matrix (see section Statistics page 839) that:

$$\mathrm{E}\left(\mathcal{I}(\vec{\theta})\right)=-\mathrm{E}\left(H(\vec{\theta})\right)=-\mathrm{E}\left(\frac{\partial^2\mathcal{L}(\vec{x},\vec{\theta})}{\partial\theta_i\partial\theta_j}\right)=-\int\frac{\partial^2\ln(L(\vec{x},\vec{\theta}))}{\partial\theta_i\partial\theta_j}L(\vec{x},\vec{\theta})\mathrm{d}x\tag{14.1.611}$$

So in the previous integral between the parenthesis we have the same expression apart of the notation: p instead of L and $\log$ instead on $\ln$ but however the manipulated objects are the same! Hence:

$$D_{\text{KL}}\cong\int p(y)\log(p(y,\vec{\theta}_0))\mathrm{d}y+\frac{1}{2n}\vec{Z}_n^T\mathrm{E}\left(H(\vec{\theta})\right)\vec{Z}_n\tag{14.1.612}$$

That we will denote to simplify the next developments as following:

$$D_{\text{KL}}\cong D_{\text{KL},0}+\frac{1}{2n}\vec{Z}_n^T J\vec{Z}_n\tag{14.1.613}$$

Now let us do the same Taylor series but for the approximate model, with the real data:

$$\begin{aligned}\bar{D}_{\text{KL}} &\cong \frac{1}{n}\sum_{i=1}^{n}\left(\log(\hat{p}(y_i,\vec{\theta}_0))+(\vec{\hat{\theta}}-\vec{\theta}_0)^T\frac{\partial\hat{p}(y_i,\vec{\theta})}{\partial\vec{\theta}}(\vec{\theta}_0)+\frac{1}{2}(\vec{\hat{\theta}}-\vec{\theta}_0)^T H(y_i,\vec{\theta})(\vec{\theta}_0)(\vec{\hat{\theta}}-\vec{\theta}_0)\right)\\ &=\frac{1}{n}\sum_{i=1}^{n}\log(\hat{p}(y_i,\vec{\theta}_0))+(\vec{\hat{\theta}}-\vec{\theta}_0)^T\left(\frac{1}{n}\sum_{i=1}^{n}\frac{\partial\hat{p}(y_i,\vec{\theta})}{\partial\vec{\theta}}(\vec{\theta}_0)\right)+\frac{1}{2}(\vec{\hat{\theta}}-\vec{\theta}_0)^T\left(\frac{1}{n}\sum_{i=1}^{n}H(y_i,\vec{\theta})(\vec{\theta}_0)\right)(\vec{\hat{\theta}}-\vec{\theta}_0)\\ &=\bar{D}_{\text{KL},0}+\frac{\vec{Z}_n^T}{\sqrt{n}}\left(\overline{\frac{\partial\hat{p}(y_i,\vec{\theta})}{\partial\vec{\theta}}(\vec{\theta}_0)}\right)+\frac{1}{2n}\vec{Z}_n^T\left(\overline{H(y_i,\vec{\theta})(\vec{\theta}_0)}\right)\vec{Z}_n\\ &=\bar{D}_{\text{KL},0}+\frac{\vec{Z}_n^T}{\sqrt{n}}\left(\overline{\frac{\partial\hat{p}(y_i,\vec{\theta})}{\partial\vec{\theta}}(\vec{\theta}_0)}\right)+\frac{1}{2n}\vec{Z}_n^T\overline{H(\vec{\theta})}\vec{Z}_n\end{aligned} \tag{14.1.614}$$

Now we assume (...) when $n\rightarrow+\infty$ that:

$$\bar{D}_{\text{KL},0}\rightarrow D_{\text{KL},0}\qquad\text{and}\qquad\overline{H(\vec{\theta})}\rightarrow J \tag{14.1.615}$$

Therefore:

$$\bar{D}_{\text{KL}}\cong\bar{D}_{\text{KL},0}+\frac{\vec{Z}_n^T}{\sqrt{n}}\left(\overline{\frac{\partial\hat{p}(y_i,\vec{\theta})}{\partial\vec{\theta}}(\vec{\theta}_0)}\right)+\frac{1}{2n}\vec{Z}_n^T\overline{H(\vec{\theta})}\vec{Z}_n=D_{\text{KL},0}+\frac{\vec{Z}_n^T}{\sqrt{n}}\left(\overline{\frac{\partial\hat{p}(y_i,\vec{\theta})}{\partial\vec{\theta}}(\vec{\theta}_0)}\right)+\frac{1}{2n}\vec{Z}_n^T J\vec{Z}_n \tag{14.1.616}$$

Remark

Notice that for obscure reasons we don't assume that for $n\rightarrow+\infty$:

$$\frac{\partial\hat{p}(y_i,\vec{\theta})}{\partial\vec{\theta}}(\vec{\theta}_0)\rightarrow\vec{0} \tag{14.1.617}$$

Then:

$$\begin{aligned}\bar{D}_{\text{KL}}-D_{\text{KL}}&\cong\left(D_{\text{KL},0}+\frac{\vec{Z}_n^T}{\sqrt{n}}\left(\overline{\frac{\partial\hat{p}(y_i,\vec{\theta})}{\partial\vec{\theta}}(\vec{\theta}_0)}\right)+\frac{1}{2n}\vec{Z}_n^T J\vec{Z}_n\right)-\left(D_{\text{KL},0}+\frac{1}{2n}\vec{Z}_n^T J\vec{Z}_n\right)\\ &\cong\frac{\vec{Z}_n^T}{\sqrt{n}}\left(\overline{\frac{\partial\hat{p}(y_i,\vec{\theta})}{\partial\vec{\theta}}(\vec{\theta}_0)}\right)=\frac{\vec{Z}_n^T\overline{\vec{S}(\vec{\theta}_0)}}{\sqrt{n}}=\frac{\vec{Z}_n^T\vec{\hat{S}}(\vec{\theta}_0)}{\sqrt{n}}=\frac{\sqrt{n}\vec{Z}_n^T\vec{\hat{S}}(\vec{\theta}_0)}{n}=\frac{\vec{Z}_n^T\sqrt{n}\vec{\hat{S}}(\vec{\theta}_0)}{n}\end{aligned} \tag{14.1.618}$$

Now let us recall that during our study of the Fisher information matrix (see section Statistics page 839) we have proved that:

$$\sqrt{n}\vec{\hat{S}}(\theta_0)=\mathcal{N}(0,\mathcal{I}(\vec{\theta})) \tag{14.1.619}$$

And we have shown earlier above that:

$$\vec{Z}_n=\sqrt{n}\left(\vec{\hat{\theta}}-\vec{\theta}_0\right)=\mathcal{N}(0,\Sigma(\vec{\theta}))\cong\mathcal{N}(0,\mathrm{E}(H^{-1})\mathcal{I}(\vec{\theta})\mathrm{E}(H^{-1})) \tag{14.1.620}$$

As Z_n is a vector, and $-\mathrm{E}(H)$ is a non-random matrix, according to the following relation we have proved during our study of the variance-covariance matrix:

$$\mathrm{V}(AX)=A\Sigma A^T \tag{14.1.621}$$

We then have for the transformed random variable $-\text{E}(H)Z_n$:

$$\text{V}(-\text{E}(H)Z_n)=\text{E}(H)\Sigma(\vec{\theta})\text{E}(H)^T\cong\text{E}(H)\left(\text{E}(H^{-1})\mathcal{I}(\vec{\theta})\text{E}(H^{-1})\right)\text{E}(H)^T \tag{14.1.622}$$

As $\text{E}(H)$ is symmetric, we have $\text{E}(H)^T=\text{E}(H)$ then:

$$\text{V}(\text{E}(H)Z_n)\cong-\text{E}(H)\left(\text{E}(H^{-1})\mathcal{I}(\vec{\theta})\text{E}(H^{-1})\right)(-\text{E}(H)^T)=\text{E}(H)\text{E}(H^{-1})\mathcal{I}(\vec{\theta})\text{E}(H^{-1})\text{E}(H)=\mathcal{I}(\vec{\theta}) \tag{14.1.623}$$

But we have proved during our study of the Fisher information matrix (see section Statistics page 839) the information matrix equality $-\text{E}(H)(\vec{\theta})=\mathcal{I}(\vec{\theta})$. Therefore:

$$\text{V}(\mathcal{I}(\vec{\theta})Z_n)=\mathcal{I}(\vec{\theta}) \tag{14.1.624}$$

ie:

$$\mathcal{I}(\vec{\theta})Z_n=\mathcal{N}(0,\mathcal{I}(\vec{\theta})) \tag{14.1.625}$$

and we recognize here $\sqrt{n}\vec{\hat{S}}(\theta_0)$. So that finally:

$$\mathcal{I}(\vec{\theta})Z_n\cong\sqrt{n}\vec{\hat{S}}(\theta_0) \tag{14.1.626}$$

So:

$$\bar{D}_{\text{KL}}-D_{\text{KL}}\cong\frac{\vec{Z}_n^T\sqrt{n}\vec{\hat{S}}(\vec{\theta}_0)}{n}\cong\frac{\vec{Z}_n^T\mathcal{I}(\vec{\theta})Z_n}{n} \tag{14.1.627}$$

Now we will use the following relation also proved during our study of the variance-covariance matrix (see section Statistics page 607):

$$\text{E}[X^TAX]=\text{tr}(A\Sigma)+\vec{\mu}^TA\vec{\mu} \tag{14.1.628}$$

Therefore:

$$\text{E}(\bar{D}_{\text{KL}}-D_{\text{KL}})\cong\frac{\text{E}(\vec{Z}_n^T\mathcal{I}(\vec{\theta})Z_n)}{n}=\frac{\text{tr}(\mathcal{I}(\vec{\theta})\Sigma(\vec{\theta}))+\mu_Z^T\mathcal{I}(\vec{\theta})\mu_Z}{n} \tag{14.1.629}$$

But by construction, $\vec{Z}_n$ we have $\vec{\mu}=\vec{0}$ and also using the matrix information equality and the definition of the Fisher information matrix:

$$\text{E}(\bar{D}_{\text{KL}}-D_{\text{KL}})\cong\frac{\text{tr}((-\text{E}(H))(-\text{E}(H^{-1})))+\vec{0}}{n}=\frac{\text{tr}((\text{E}(H))\text{E}(H^{-1}))}{n}=\frac{\text{tr}(\mathbb{1})}{n}:=\frac{d}{n} \tag{14.1.630}$$

ie:

$$\text{E}(\bar{D}_{\text{KL}})-\text{E}(D_{\text{KL}})=\bar{D}_{\text{KL}}-\hat{D}_{\text{KL}}\cong\frac{d}{n} \tag{14.1.631}$$

So that finally:

$$\boxed{\hat{D}_{\text{KL}}\cong\bar{D}_{\text{KL}}-\frac{d}{n}=\frac{1}{n}\sum_{i=1}^{n}\log\left(p(y_i,\hat{\theta}_j)\right)-\frac{d}{n}} \tag{14.1.632}$$

Remembering as we have proved it that the bigger is the better!

Remark

As we can factorize the $1/n$ and that when we compare two or more AIC by subtracting them the constants vanishes (the number of parameters d of different models may not be the same!), the latter relation is often used in the following form:

$$\hat{D}_{\text{KL}} \cong \sum_{i=1}^{n} \log\left(p(y_i,\hat{\theta}_j)\right) - d = \mathcal{L}(y_i,\hat{\theta}_j) - d \quad (14.1.633)$$

that will be used as the definition of the AIC itself (without any $2n$ factor)! These different possible choices explains why some software packages may well give completely different AICs on the same data for the same model!

■ Q.E.D.

As the reader has very likely (...) noticed it, there are several steps where we are making a bunch of approximations and assumptions! Some of these approximations (especially those involving the Taylor expansions) can be shown to be OK asymptotically (i.e. as $n \rightarrow +\infty$) by more careful maths. The last steps however, where we invoke the Fisher information matrix (see section Statistics page 839) and the score are rather more dubious. So AIC is a very crude indicator. Cross-validation is much more reliable!

✍**Examples:**

E1. Let:

$$Y_n \cong \mathcal{N}(\mu,1) \quad (14.1.634)$$

We want to compare two models (notice that the first one has zero parameters to estimate and the second one has only one parameter to estimate: μ):

$$\mathcal{M}_0 : \mathcal{N}(0,1) \qquad \text{and} \qquad \mathcal{M}_1 : \mathcal{N}(\mu,1) \quad (14.1.635)$$

We want to test:

$$H_0 : \mu = 0 \qquad \text{versus} \qquad H_1 : \mu \neq 0 \quad (14.1.636)$$

The test statistics is as we already know:

$$Z = \frac{\bar{Y}-\mu}{\sigma/\sqrt{n}} = \frac{\bar{Y}-0}{1/\sqrt{n}} = \sqrt{n}\bar{Y} \quad (14.1.637)$$

We reject H_0 if $|Z| > Z_\alpha/2$. For $\alpha = 0.05$, we reject H_0 if $|Z| > 2$, i.e. if:

$$|\bar{Y}| > \frac{2}{\sqrt{n}} \quad (14.1.638)$$

The likelihood is obviously proportional to (we ignore the value of the variance as for both models it is equal to 1):

$$L(\mu) = \prod_{i=1}^{n} e^{-(Y_i-\mu)^2/2} = e^{-\sum_n (Y_i-\mu)^2/2} \quad (14.1.639)$$

Hence:

$$\log(L(\mu)) = \mathcal{L}(\mu) = -\sum_n (Y_i - \mu)^2/2 \tag{14.1.640}$$

Recall that one of the definition of the Akaike information criterion is $\text{AIC} = \mathcal{L}(Y_i, \hat{\theta}_j) - d$. The AIC scores are then:

$$\text{AIC}_0 = \mathcal{L}(Y_i, 0) - d = -\sum_n \frac{(Y_i - \mu)^2}{2} - d = -\sum_n \frac{(Y_i - 0)^2}{2} - 0 = -\frac{1}{2}\sum_n Y_i^2 \tag{14.1.641}$$

And:

$$\text{AIC}_1 = \mathcal{L}(Y_i, \hat{\mu}) - d = -\sum_n \frac{(Y_i - \hat{\mu})^2}{2} - d = -\sum_n \frac{(Y_i - \hat{\mu})^2}{2} - 1 \tag{14.1.642}$$

After, depending on the experimental values of the Y_i, we have to compare:

$$\text{AIC}_0 = -\frac{1}{2}\sum_n Y_i^2 \qquad \text{and} \qquad \text{AIC}_1 = -\sum_n \frac{(Y_i - \hat{\mu})^2}{2} - 1 \tag{14.1.643}$$

Keeping the one that has the biggest value (as in this example their both negative, that means the one that is the nearest to zero, or the smallest AIC in absolute value)!

E2. Remember that during our study of multiple linear regression, we have proved that:

$$\ln\left(L\left(\vec{\beta}, \sigma\right)\right) = -\frac{n}{2}\left(\ln(2\pi) + \ln(\sigma^2)\right) - \frac{1}{2\sigma^2}\left(\vec{y} - X\vec{\beta}\right)^T\left(\vec{y} - X\vec{\beta}\right) \tag{14.1.644}$$

And also earlier we have proved that:

$$\hat{\sigma}^2 = \frac{1}{n}\left(\vec{y} - X\vec{\beta}\right)^T\left(\vec{y} - X\vec{\beta}\right) = \frac{1}{n}\left\|\left(\vec{y} - X\vec{\beta}\right)^2\right\| \tag{14.1.645}$$

denoted also sometimes:

$$\hat{\sigma}^2 = \frac{1}{n}\text{SSE}(\mathcal{M}) \tag{14.1.646}$$

Recall that another definition of the Akaike information criterion (the most common in statistical softwares) is $\text{AIC} = -2\mathcal{L}(Y_i, \hat{\theta}_j) + 2d$. The AIC score is then when σ is unknown for a multiple regression:

$$\begin{aligned}\text{AIC} &= -2\mathcal{L}(Y_i, \hat{\theta}_j) + 2d = -2\left(-\frac{n}{2}\left(\ln(2\pi) + \ln(\hat{\sigma}^2)\right) - \frac{1}{2\hat{\sigma}^2}n\hat{\sigma}^2\right) + 2d \\ &= n\left(\ln(2\pi) + \ln(\hat{\sigma}^2)\right) + n + 2d = n\left(\ln(2\pi) + \ln\left(\frac{\text{SSE}(\mathcal{M})}{n}\right)\right) + n + 2d\end{aligned} \tag{14.1.647}$$

What interest us when we use the AIC is to compared different models (subtract the different AIC). As n remains constant between all models, we can eliminate some useless terms that will automatically vanish, this is why in many textbooks we will found:

$$\text{AIC} = n\ln\left(\frac{\text{SSE}(\mathcal{M})}{n}\right) + 2d \tag{14.1.648}$$

And we have seen earlier that the Fisher information matrix of the multiple linear regression had $p+1$ dimension, therefore:

$$\text{AIC} = n\ln\left(\frac{\text{SSE}(\mathcal{M})}{n}\right) + 2(p+1) \tag{14.1.649}$$

What is of denoted in some textbooks as:

$$\text{AIC} = n\ln\left(\frac{\text{SSE}(\mathcal{M})}{n}\right) + 2\left(p((\mathcal{M}))+1\right) \tag{14.1.650}$$

Remark

A software like `R` deals with $\text{AIC} = -2\mathcal{L}(Y_i,\hat{\theta}_j)+2d$ that we have used above. Therefore the smaller is better!

The most common model selections methods are (among many others as we can see on the Data Science map at page 6770):

1. p-value
2. AIC (and related methods like C_p)
3. Cross-validation (see further below)
4. BIC (see further below)

AIC is motivated by the estimation of the generalization error (like Mallows's C_p, BIC,...). If you want the model for predictions, better use one of these criteria. If you want your model for explaining a phenomenon, use p-values. We need to distinguish between two goals:

1. Find the model that gives the best prediction (without assuming that any of the models are correct).
2. Assume one of the models is the true model and not the "true" model.

Generally speaking, AIC and cross-validation are used for goal (1) while BIC is used for goal (2).

AIC is founded on information theory. When a statistical model is used to represent the process that generated the data, the model will almost never be exact; so some information will be lost by using the model to represent the process. AIC estimates the relative information lost by a given model: the less information a model loses, the higher the quality of that model.

To apply AIC in practice, we start with a set of candidate models, and then find the models' corresponding AIC values. There will almost always be information lost due to using a candidate model to represent the "true model" (i.e. the process that generated the data). We wish to select, from among the candidate models, the model that minimizes the information loss. We cannot choose with certainty, but we can minimize the estimated information loss.

14.1.11.7.3 Cross-Validation metrics

In Machine Learning, "cross-validation" (CV) is a resampling method used for model evaluation to avoid testing a model on the same dataset on which it was trained. It is mainly used in settings where the goal is prediction, and one wants to estimate how accurately a predictive model will perform in practice. This is a common mistake, especially that a separate testing dataset is not always available. However, this usually leads to inaccurate performance measures (as the model will have an almost perfect score since it is being tested on the same data it was trained on). To avoid this kind of mistakes, cross validation is usually preferred.

Two types of cross-validation can be distinguished, exhaustive and non-exhaustive cross-validation:

- Exhaustive cross-validation methods are cross-validation methods which learn and test on all possible ways to divide the original sample into a training and a validation set.
- Non-exhaustive cross validation methods do not compute all ways of splitting the original sample.

Cross validation

Figure 14.18: **Some famous techniques of cross-over validation**

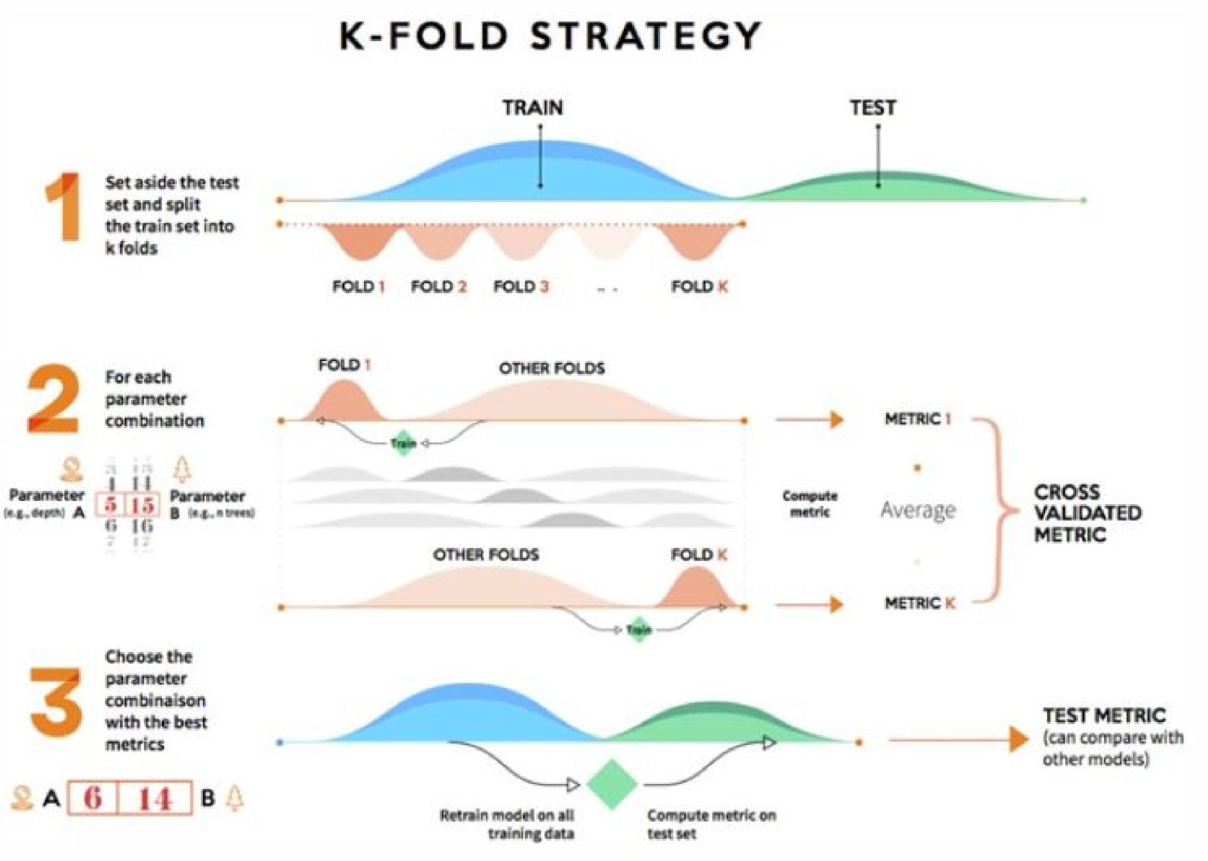
The concept of cross-validation is actually simple: Instead of using the whole dataset to train and then test on same data, we could randomly divide our data into training and testing datasets.

There are several types of cross-validation methods (LOOCV – Leave-One-Out-Cross validation[21], the holdout method, K-fold cross validation). Here, we will discuss the "K-Fold cross validation method".

The idea is illustrated as following:

---

[21] We already know that latter as it is just the Jackknife method



K-FOLD STRATEGY
TRAIN
TEST
1
Set aside the test set and split the train set into k folds
FOLD 1
FOLD 2
FOLD 3
FOLD K
2
For each parameter combination
Parameter (e.g. depth) A

15
Parameter B (e.g. n trees)
FOLD 1
OTHER FOLDS
Train
OTHER FOLDS
FOLD K
Compute metric
METRIC 1
Average
METRIC K
CROSS VALIDATED METRIC
3
Choose the parameter combination with the best metrics
A
6
14
B
Retrain model on all training data
Compute metric on test set
TEST METRIC (can compare with other models)

Figure 14.19: K-fold cross-over validation (author: ?)

So following the above illustration, the K-fold basically consists of the below steps:

1. Split the data in a train and a test set
2. Randomly split the train set into K subsets, also named "folds".
3. Train the model on all K subsets excepted the first one
4. Fit the model on the first set that was ignored previously and keep its quality metric (i.e. "cross validated metric")
5. Repeat the procedure (3) to (4) (but by ignoring the second set, after the third, and so on...)
6. Average all the quality metrics (ordinary cross-validation: OCV)
7. At the end, use all the K-folds to train the model and fit it on the test set
8. Compare if the last fit perform better that the average of all previous fits
9. If not, use one of the K as reference model based on the quality metric. If yes, keep the model made in step (8)

The typical basis of cross-over quality metrics is the mean square error MSE. Then the average quality metric, or the "ordinary cross-validation", for a K fold will be (assuming that each fitted model has a sub-sample size of n_k):

$$\text{OCV}=\frac{1}{K}\sum_{k=1}^{K}n_k\text{MSE}_k \tag{14.1.651}$$

If we denoted the model (in a univariate case) by $\hat{y}_i^{[k]}$ for the subset (submodel) k and the true values by y_i we then have:

$$\text{MSE}_k=\frac{1}{n_k}\sum_{i=1}^{n_k}\left(\hat{y}_i^{[k]}-y_i\right)^2 \tag{14.1.652}$$

Therefore the OCV for an univariate model based one the MSE is :

$$\boxed{\text{OCV}_{\text{MSE}}=\frac{1}{K}\sum_{k=1}^{K}\left(\sum_{i=1}^{n_k}\left(\hat{y}_i^{[k]}-y_i\right)^2\right)} \tag{14.1.653}$$

For example with LASSO, ridge or elastic net regularized regression, we have:

$$\text{OCV}_{\text{MSE}}(\lambda)=\frac{1}{K}\sum_{k=1}^{K}\left(\sum_{i=1}^{n_k}\left(\hat{y}_i^{[k]}(\lambda)-y_i\right)^2\right) \tag{14.1.654}$$

And the "best lambda" λ_0 is the one that minimize the OCV_{MSE} such that:

$$\lambda_0=\min_{\lambda\in\mathbb{R}^+}\text{OCV}_{\text{MSE}}(\lambda) \tag{14.1.655}$$

Let us now speak about a very common relation in statistical textbooks, the cross-validation for one of the subsets of the Leave One Out method (i.e. Jackknife):

$$\text{CV}=\sum_i\left(y_i^{[k]}-y_i\right)^2=\sum_i\left(\frac{\hat{y}_i-y_i}{1-H_{ii}}\right)^2 \tag{14.1.656}$$

Here, y_i is the actual label value of training point i, $y_i^{[k]}$ is the value predicted by the cross-validation model trained on all points except i, $\hat{y}^i$ is the value predicted by the regression model trained on all points (including point i), and H_{ii} is as we know the leverage of point i, given for recall by:

$$H_{ii}=\frac{1}{n}+\frac{(x_i-\bar{x})^2}{\displaystyle\sum_{k=1}^{n}(x_k-\bar{x})^2} \tag{14.1.657}$$

and:

$$H=X(X^TX)^{-1}X^T \tag{14.1.658}$$

Notice that the left side of the above relation is the LOOCV sum of squares error (the quantity we seek), while the right can be evaluated given only the model trained on the full data set. Fantastically, this allows us to evaluate the LOOCV error using only a single regression!!!

Proof 14.3.3. Consider the LOOCV step where we construct a model trained on all points except training example k. Using a linear model of form $y^{[k]}=\vec{x}^T\vec{\beta}^{[k]}$ - with $\vec{\beta}^{[k]}$ the coefficient vector - the sum of squares that must be minimized is:

$$\sum_{i\neq k}\left(y_i^{[k]}-y_i\right)^2=\sum_{i\neq k}\left(\vec{x}_i^T\vec{\beta}^{[k]}-y_i\right)^2 \tag{14.1.659}$$

Here, we are using an exponent k on $\vec{\beta}^{[k]}$ to highlight the fact that the above corresponds to the case where example k is held out. We minimize the above relation by taking the gradient with respect to $\vec{\beta}^{[k]}$. Setting this to zero gives the following equation:

$$2\sum_{i\neq k}\vec{x}_i\left(\vec{x}_i^T\vec{\beta}^{[k]}-y_i\right)=\vec{0} \tag{14.1.660}$$

Rearranging and simplifying a bit gives:

$$\left(\sum_{i\neq k}\vec{x}_i\vec{x}_i^T\right)\vec{\beta}^{[k]}=\sum_{i\neq k}y_i\vec{x}_i \tag{14.1.661}$$

Similarly, the full model (trained on all points) coefficient vector $\vec{\beta}$ (here the notation $\vec{\beta}$ means in fact $\vec{\hat{\beta}}$ obviously!) satisfies:

$$\left(\sum_{i}\vec{x}_i\vec{x}_i^T\right)\vec{\beta}=\sum_{i}y_i\vec{x}_i \tag{14.1.662}$$

But we have that:

$$\left(\sum_{i\neq k}\vec{x}_i\vec{x}_i^T\right)\vec{\beta}^{[k]}=\sum_{i\neq k}y_i\vec{x}_i \tag{14.1.663}$$

can we rewritten as for the left term:

$$\left(\sum_{i\neq k}\vec{x}_i\vec{x}_i^T\right)\vec{\beta}^{[k]}=\left(\sum_{i}\vec{x}_i\vec{x}_i^T-\vec{x}_k\vec{x}_k^T\right)\vec{\beta}^{[k]} \tag{14.1.664}$$

and for the right term:

$$\sum_{i\neq k}y_i\vec{x}_i=\sum_{i}y_i\vec{x}_i-y_k\vec{x}_k \tag{14.1.665}$$

Therefore:

$$\left(\sum_{i}\vec{x}_i\vec{x}_i^T-\vec{x}_k\vec{x}_k^T\right)\vec{\beta}^{[k]}=\sum_{i}y_i\vec{x}_i-y_k\vec{x}_k \tag{14.1.666}$$

But as we have proved just earlier that:

$$\sum_{i}y_i\vec{x}_i=\left(\sum_{i}\vec{x}_i\vec{x}_i^T\right)\vec{\beta} \tag{14.1.667}$$

Then substituting in the previous relation, this lead us to:

$$\left(\sum_i \vec{x}_i\vec{x}_i^T-\vec{x}_k\vec{x}_k^T\right)\vec{\beta}^{[k]}=\left(\sum_i \vec{x}_i\vec{x}_i^T\right)\vec{\beta}-y_k\vec{x}_k \tag{14.1.668}$$

Rearranging:

$$\sum_i \vec{x}_i\vec{x}_i^T\left(\vec{\beta}^{[k]}-\vec{\beta}\right)=\vec{x}_k\vec{x}_k^T\vec{\beta}^{[k]}-y_k\vec{x}_k \tag{14.1.669}$$

That can be written using the definition of $y_i^{[k]}$:

$$\sum_i \vec{x}_i\vec{x}_i^T\left(\vec{\beta}^{[k]}-\vec{\beta}\right)=\vec{x}_k y_i^{[k]}-y_k\vec{x}_k \tag{14.1.670}$$

Hence:

$$\sum_i \vec{x}_i\vec{x}_i^T\left(\vec{\beta}^{[k]}-\vec{\beta}\right)=\left(y_i^{[k]}-y_k\right)\vec{x}_k \tag{14.1.671}$$

Left multiplication by $\vec{x}_k^T\left(\sum_i \vec{x}_i\vec{x}_i^T\right)^{-1}$ (without forgetting that the term into parenthesis is a scalar) gives:

$$\cancel{\sum_i \vec{x}_i\vec{x}_i^T}\left(\vec{\beta}^{[k]}-\vec{\beta}\right)\vec{x}_k^T\cancel{\left(\sum_i \vec{x}_i\vec{x}_i^T\right)^{-1}}=\left(y_i^{[k]}-y_k\right)\vec{x}_k\vec{x}_k^T\left(\sum_i \vec{x}_i\vec{x}_i^T\right)^{-1} \tag{14.1.672}$$

So it only remains (rearranging a bit):

$$\left(\vec{\beta}^{[k]}-\vec{\beta}\right)\vec{x}_k^T=\left(y_i^{[k]}-y_k\right)\vec{x}_k\left(\sum_i \vec{x}_i\vec{x}_i^T\right)^{-1}\vec{x}_k^T \tag{14.1.673}$$

We recognize here the vector definition of H_{kk}. Therefore:

$$\left(\vec{\beta}^{[k]}-\vec{\beta}\right)\vec{x}_k^T=\left(y_i^{[k]}-y_k\right)H_{kk} \tag{14.1.674}$$

that is:

$$y_k^{[k]}-\hat{y}_k=\left(y_i^{[k]}-y_k\right)H_{kk} \tag{14.1.675}$$

That latter can be rewritten as:

$$(y_k^{[k]}-y_k)-(\hat{y}_k-y_k)=\left(y_i^{[k]}-y_k\right)H_{kk} \tag{14.1.676}$$

Hence:

$$y_k^{[k]}-y_k=\frac{\hat{y}_k-y_k}{1-H_{kk}} \tag{14.1.677}$$

Squaring and summing finally leads to:

$$\boxed{\text{CV}=\sum_k\left(y_k^{[k]}-y_k\right)^2=\sum_k\left(\frac{\hat{y}_k-y_k}{1-H_{kk}}\right)^2} \tag{14.1.678}$$

■ Q.E.D.

Again... Fantastically, this allows us to evaluate the LOOCV error using only a single regression!!!

A minor variant on cross validation is, so-named "generalized cross validation", which, of course, like most things statisticians call "generalized" isn't... It replaces the H_{kk} in the denominator with their average trace $\text{tr}(H_{kk})/n$ giving:

$$\boxed{\text{GCV} = \sum_k \left(\frac{\hat{y}_k - y_k}{1 - \text{tr}(H_{kk})/n} \right)^2} \tag{14.1.679}$$

14.1.12 Ridge, LASSO and Elastic Net regularization

"Regularization" also named "regularized regression" or "penalized regression" has been intensely studied on the interface between statistics and computer science as it is an empirical method can be used to avoid overfitting in almost all regression models (but is mainly known for its application to logistic regression).

There are two types of regularization as follows:

- L_1 Regularization or LASSO Regularization (see details further below)
- L_2 Regularization or Ridge Regularization (see details further below)

Where for recall $L_p:\mathbb{R}^n \mapsto \mathbb{R}$ (see section Topology page 2450) is defined:

$$L_p(x)=||x||_p=\left(\sum_{i=1}^{n}|x_i|^p\right)^{1/p} \tag{14.1.680}$$

with $p>0$. For $p=2$, this is the familiar Euclidean distance (don't confuse with the notation of the lost function L if possible...).

Ridge and Lasso regularizations are also known as "shrinkage methods", because they reduce or shrink the coefficients in the resulting regression. This reduces the variance in the model: as input variables are changed, the models prediction changes less than it would have without the regularization. Why would you want to reduce the variance of a model? To avoid overfit!

L_1 and L_2 are the most common types of regularization. These update the general cost function by adding another term known as the "regularization term":

$$\text{Cost function} = \text{Loss} + \text{Regularization term} \tag{14.1.681}$$

Or more formally if we denote by $R(f)$ the regularization term :

$$\boxed{\min_f \sum_{i=1}^{n} V(f(x_i),y_i)+\lambda R(f)} \tag{14.1.682}$$

where V is an underlying loss function (most of times for regression models it's the residual sum of squares RSS) that describes the cost of predicting $f(x)$ when the label is y and λ is a parameter which controls the importance of the regularization term. $R(f)$ is typically chosen to impose a penalty on the complexity of f. Concrete notions of complexity used include restrictions for smoothness and bounds on the vector space norm.

Notice that softwares compute estimates for a large number of values for λ at once. The optimal λ is selected by cross validation of some sort... The most common one in the end of the 121st century (holocene calendar) being the generalized cross-validation metric (see further below page 6434).

From a Bayesian point of view, many regularization techniques correspond to imposing certain prior distributions on model parameters.

Proof 14.3.4. Consider that the regularized loss function L has a similar role as the probability of a parameter configuration β given the observations X,$\vec{y}$. Applying the Bayes theorem (see section Probabilities page 492), we get:

$$P(\theta|X,\vec{y}) = \frac{P(X,\vec{y}|\theta)P(\theta)}{P(X,\vec{y})} \tag{14.1.683}$$

Taking the log of the expression gives us:

$$\log(P(\theta|X,\vec{y})) = \log(P(X,\vec{y}|\theta)) + \log(P(\theta)) - \log(P(X,\vec{y})) \tag{14.1.684}$$

Now, let's say $L(\theta)$ is the negative[22] log-posterior, $-\log(P(\theta|X,\vec{y}))$. Since the last term does not depend on θ, we can ignore it without changing the minimum. We are left with two terms:

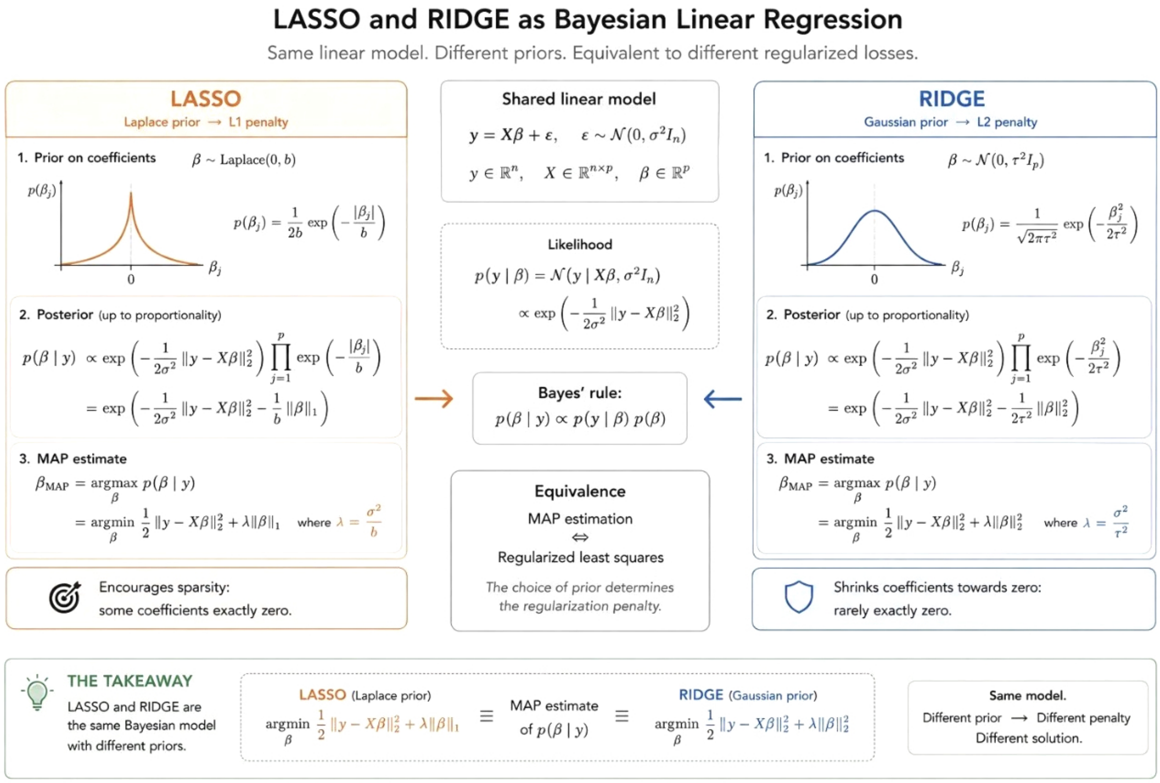
- the likelihood term $\log(P(X,\vec{y}|\theta))$ depending on X and $\vec{y}$, and
- the prior term $\log(P(\theta))$ depending on θ only. These two terms correspond exactly to the loss and the regularization term.

■ Q.E.D.

Remark

It can be proved (see further below) that L_2 regularization is the case with a Gaussian prior analytically and the L_1 is equivalent to a Laplacian prior.

We can also see regularization as an application of the Lagrange Multiplier method (see previously page 6667).



LASSO and RIDGE as Bayesian Linear Regression

Same linear model. Different priors. Equivalent to different regularized losses.

LASSO

Laplace prior → L1 penalty

1. Prior on coefficients $\beta \sim \text{Laplace}(0,b)$

$$p(\beta_j) = \frac{1}{2b}\exp\left(-\frac{|\beta_j|}{b}\right)$$

2. Posterior (up to proportionality)

$$\begin{aligned} p(\beta \mid y) &\propto \exp\left(-\frac{1}{2\sigma^2}\|y - X\beta\|_2^2\right)\prod_{j=1}^{p}\exp\left(-\frac{|\beta_j|}{b}\right) \\ &= \exp\left(-\frac{1}{2\sigma^2}\|y - X\beta\|_2^2 - \frac{1}{b}\|\beta\|_1\right) \end{aligned}$$

3. MAP estimate

$$\begin{aligned} \beta_{\text{MAP}} &= \underset{\beta}{\text{argmax}}\; p(\beta \mid y) \\ &= \underset{\beta}{\text{argmin}}\; \frac{1}{2}\|y - X\beta\|_2^2 + \lambda\|\beta\|_1 \quad \text{where } \lambda = \frac{\sigma^2}{b} \end{aligned}$$

Encourages sparsity:
some coefficients exactly zero.

Shared linear model

$$y = X\beta + \varepsilon, \quad \varepsilon \sim \mathcal{N}(0,\sigma^2 I_n)$$

$$y \in \mathbb{R}^n, \quad X \in \mathbb{R}^{n\times p}, \quad \beta \in \mathbb{R}^p$$

Likelihood

$$\begin{aligned} p(y \mid \beta) &= \mathcal{N}(y \mid X\beta, \sigma^2 I_n) \\ &\propto \exp\left(-\frac{1}{2\sigma^2}\|y - X\beta\|_2^2\right) \end{aligned}$$

Bayes' rule:

$$p(\beta \mid y) \propto p(y \mid \beta)\, p(\beta)$$

Equivalence

MAP estimation
⇔
Regularized least squares

The choice of prior determines the regularization penalty.

RIDGE

Gaussian prior → L2 penalty

1. Prior on coefficients $\beta \sim \mathcal{N}(0,\tau^2 I_p)$

$$p(\beta_j) = \frac{1}{\sqrt{2\pi\tau^2}}\exp\left(-\frac{\beta_j^2}{2\tau^2}\right)$$

2. Posterior (up to proportionality)

$$\begin{aligned} p(\beta \mid y) &\propto \exp\left(-\frac{1}{2\sigma^2}\|y - X\beta\|_2^2\right)\prod_{j=1}^{p}\exp\left(-\frac{\beta_j^2}{2\tau^2}\right) \\ &= \exp\left(-\frac{1}{2\sigma^2}\|y - X\beta\|_2^2 - \frac{1}{2\tau^2}\|\beta\|_2^2\right) \end{aligned}$$

3. MAP estimate

$$\begin{aligned} \beta_{\text{MAP}} &= \underset{\beta}{\text{argmax}}\; p(\beta \mid y) \\ &= \underset{\beta}{\text{argmin}}\; \frac{1}{2}\|y - X\beta\|_2^2 + \lambda\|\beta\|_2^2 \quad \text{where } \lambda = \frac{\sigma^2}{\tau^2} \end{aligned}$$

Shrinks coefficients towards zero:
rarely exactly zero.

THE TAKEAWAY

LASSO and RIDGE are the same Bayesian model with different priors.

LASSO (Laplace prior) $\underset{\beta}{\text{argmin}}\; \frac{1}{2}\|y - X\beta\|_2^2 + \lambda\|\beta\|_1$ ≡ MAP estimate of $p(\beta \mid y)$ ≡ RIDGE (Gaussian prior) $\underset{\beta}{\text{argmin}}\; \frac{1}{2}\|y - X\beta\|_2^2 + \lambda\|\beta\|_2^2$

Same model.
Different prior ⟶ Different penalty
Different solution.

---

[22] Negative since we want to maximize the probability but minimize the cost.

14.1.12.1 L_2 Regularization or Ridge Regularization

When learning a linear function f, characterized by an unknown vector $\vec{\beta}$ such that $f(x)=\vec{\beta}\circ\vec{x}$, the L_2-norm loss corresponds to "Tikhonov regularization". This is one of the most common forms of regularization, is also known as "ridge regression", and is expressed as:

$$\min_{\beta}\sum_{i=1}^{n} V(\vec{x}_i\circ\vec{w},\vec{y}_i)+\lambda L_2(\vec{\beta})=\min_{\beta}\sum_{i=1}^{n} V(\vec{x}_i\circ\vec{w},\vec{y}_i)+\lambda\|\vec{\beta}\|^2 \qquad (14.1.685)$$

where λ is the "tuning parameter" or "shrinkage parameter".

Remark

If the different predictor variables don't have physically comparable units it's a good idea to standardize them first, so they all have mean 0 and variance 1 and also no physical units. Otherwise penalizing the p predictor with the L_2-norm using $\sum_{i=1}^{p}\beta_i^2$ seems to be adding up apples, oranges, and the occasional bout of regret (some people always pre-standardize the predictors).

The learning problem with the least squares loss function and Tikhonov regularization can be solved analytically. Written in matrix form, the optimal $\vec{\beta}$ will be the one for which the gradient of the loss function with respect to $\vec{\beta}$ is $\vec{0}$.

Let us write this explicitly:

$$\boxed{\text{PRSS}(\vec{\beta})_{L_2}=\min_{\vec{\beta}}\frac{1}{n}(X\vec{\beta}-\vec{y})^T(X\vec{\beta}-\vec{y})+\lambda\|\vec{\beta}\|^2} \qquad (14.1.686)$$

which is just the usual least squares criterion with a penalty determined by λ for large coefficient estimates. This is why it's named "penalized residual sum of squares" (PRSS). If $\lambda=0$ the lasso is the same as OLS; as λ increases, shorter coefficients are preferred. Therefore we can say that most of times (but now always!) if we increase the value of λ then the magnitude of the coefficients decreases.

Notice also that this is a well defined, convex, differentiable optimization problem even after including L_2 function. The L_2 function acts as a penalizer: $\|\vec{\beta}\|^2$ grows large as the coefficients $\vec{\beta}$ grow large, thus the minimization program tries to make w smaller.

There are many variations on this procedure, including application of it to other-than the linear model.

We take the derivative:

$$\vec{\nabla}_{\vec{\beta}}=\frac{2}{n}X^T(X\vec{\beta}-\vec{y})+2\lambda\vec{\beta} \qquad (14.1.687)$$

To find the optimum we put:

$$\vec{0}=X^T(X\vec{\beta}-\vec{y})+n\lambda\vec{\beta} \qquad (14.1.688)$$

Therefore:

$$\hat{\vec{\beta}}_{\lambda}^{\text{ridge}}=(X^TX+\lambda n\mathbb{1})^{-1}(X^T\vec{y}) \qquad (14.1.689)$$

By construction of the optimization problem, other values of $\vec{\beta}$ would give larger values for the loss function. Notice that in particular the regularization term solves the problem of non-invertibility of the first term between parenthesis.

Notice that the solution is indexed by the parameter λ. So for each λ, we have a solution. The fact that we add $\lambda n\mathbb{1}$ to the diagonal of X^TX (which correspondence to the correlation matrix if X is previously centered and reduced) is why this method is named "ridged" (and the term $\lambda n\mathbb{1}$ is often named the "ridged").

The reader may also notice that with:

$$\hat{\vec{\beta}}_{\lambda}^{\text{ridge}} = \frac{X^T\vec{y}}{X^TX+\lambda n\mathbb{1}} \tag{14.1.690}$$

excepted is some very special cases, the ridge regression will never take the coefficients $\hat{\vec{\beta}}_{\lambda}^{\text{ridge}}$ to zero as the denominator will never be practically infinite! But we can see obviously that as $\lambda \to +\infty$ then $\hat{\vec{\beta}}_{\lambda}^{\text{ridge}} \to \vec{0}$.

Remark

Inclusion of λ makes problem non-singular even if X^TX is not invertible. It seems that this was the original motivation for ridge regression (Hoerl and Kennard, 11970 according to holocene calendar).

Let us prove now that the ridge regression corresponds indeed to a Gaussian prior on the coefficients.

Proof 14.3.5. Let us imagine that you want to infer some parameter β from some observed input-output pairs $(x_1,y_1),\ldots,(x_n,y_n)$. Let us assume that the outputs are linearly related to the inputs via β and that the data are corrupted by some noise ε:

$$y_n = \beta x_n + \varepsilon \tag{14.1.691}$$

where ε is Gaussian noise with as we know mean 0 and variance σ_{ε}^2. This gives rise to a Gaussian likelihood:

$$\prod_{n=1}^{N} \mathcal{N}(y_n|\beta x_n,\sigma_{\varepsilon}^2) \tag{14.1.692}$$

Let us regularise parameter β by imposing the Gaussian prior $\mathcal{N}(\beta|0,\lambda^{-1})$, where λ is a strictly positive scalar. Hence, combining the likelihood and the prior we simply have:

$$\prod_{n=1}^{N} \mathcal{N}(y_n|\beta x_n,\sigma_{\varepsilon}^2)\mathcal{N}(\beta|0,\lambda^{-1}) \tag{14.1.693}$$

Let us take the logarithm of the above expression. Dropping some constants we get:

$$\sum_{n=1}^{N} -\frac{1}{\sigma_{\varepsilon}^2}(y_n-\beta x_n)^2 - \lambda\beta^2 \tag{14.1.694}$$

If we maximise the above expression with respect to β, we get the so named "maximum a-posteriori estimate" for β, or "MAPE for ridge regression" for short. In this expression it becomes apparent why the Gaussian prior can be interpreted as a L_2 regularisation term.

■ Q.E.D.

Let us now prove that the $\hat{\vec{\beta}}_\lambda^{\text{ridge}}$ are biased.

Proof 14.3.6. First let us recall that we have proved that:

$$\hat{\vec{\beta}}_\lambda^{\text{ridge}} = (\hat{X}^T X + \lambda n \mathbb{1})^{-1}(X^T \vec{y}) \tag{14.1.695}$$

Now let us rewrite this:

$$\begin{aligned}
\hat{\vec{\beta}}_\lambda^{\text{ridge}} &= (X^T \hat{X} + \lambda n \mathbb{1})^{-1}(X^T \vec{y}) = (X^T X + \lambda n \mathbb{1})^{-1} \left((X^T X)(X^T X)^{-1}\right)(X^T \vec{y}) \\
&= (X^T X + \lambda n \mathbb{1})^{-1} X^T X \left((X^T X)^{-1} X^T \vec{y}\right) \\
&= \left[(X^T X)(\mathbb{1} + \lambda n (X^T X)^{-1})\right]^{-1} X^T X \left((X^T X)^{-1} X^T \vec{y}\right)
\end{aligned} \tag{14.1.696}$$

Remember that we have proved in the section of Linear Algebra that if A and B are invertible, then:

$$(AB)^{-1} = B^{-1} A^{-1} \tag{14.1.697}$$

Then:

$$\begin{aligned}
\hat{\vec{\beta}}_\lambda^{\text{ridge}} &= \left[(X^T X)(\mathbb{1} + \lambda n (X^T X)^{-1})\right]^{-1} X^T X \left((X^T X)^{-1} X^T \vec{y}\right) \\
&= (\mathbb{1} + \lambda n (X^T X)^{-1})^{-1} (X^T X)^{-1} X^T X \left((X^T X)^{-1} X^T \vec{y}\right) \\
&= (\mathbb{1} + \lambda n (X^T X)^{-1})^{-1} \underbrace{(X^T X)^{-1} X^T X}_{=\mathbb{1}} \left((X^T X)^{-1} X^T \vec{y}\right) \\
&= (\mathbb{1} + \lambda n (X^T X)^{-1})^{-1} \mathbb{1} \left((X^T X)^{-1} X^T \vec{y}\right) \\
&= (\mathbb{1} + \lambda n (X^T X)^{-1})^{-1} \left((X^T X)^{-1} X^T \vec{y}\right) \\
&= (\mathbb{1} + \lambda n (X^T X)^{-1})^{-1} \hat{\beta}^{\text{OLS}}
\end{aligned} \tag{14.1.698}$$

So:

$$\begin{aligned}
\text{E}(\hat{\vec{\beta}}_\lambda^{\text{ridge}}) &= \text{E}((\mathbb{1} + \lambda n (X^T X)^{-1})^{-1} \hat{\beta}^{\text{OLS}}) \\
&= (\mathbb{1} + \lambda n (X^T X)^{-1})^{-1} \text{E}(\hat{\beta}^{\text{OLS}}) \\
&= (\mathbb{1} + \lambda n (X^T X)^{-1})^{-1} \beta^{\text{OLS}}
\end{aligned} \tag{14.1.699}$$

Therefore if $\lambda \neq 0$ then:

$$\text{E}(\hat{\vec{\beta}}_\lambda^{\text{ridge}}) \neq \beta^{\text{OLS}} \tag{14.1.700}$$

■ Q.E.D.

We know that if we actually have the "right" model, then, say, OLS parameter estimates will be unbiased and have minimal variance among all unbiased (linear) estimators (they are BLUE). Predictions from an OLS model will be best linear unbiased predictions (BLUPs). That sounds good.

So we have $\hat{\vec{\beta}}_\lambda^{\text{ridge}} = (X^T X + \lambda \mathbb{1})^{-1} X^T Y$ which is biased; but if X is ill conditioned then $\text{V}(\hat{\beta}) \propto (X^T X)^{-1}$ may be monstrous whereas $\text{V}(\hat{\vec{\beta}}_\lambda^{\text{ridge}})$ can be much more modest. Indeed, let us recall that we have proved during our study of multiple linear regression that (see above page 6401):

$$\text{V}\left(\hat{\vec{\beta}}\right) = \sigma_\varepsilon^2 (X_c^T X_c)^{-1} \tag{14.1.701}$$

Exactly the same developments would lead us to:

$$\text{V}(\hat{\vec{\beta}}_\lambda^{\text{ridge}}) = \sigma_\varepsilon^2 (X_c^T X_c + \lambda n \mathbb{1})^{-1} \tag{14.1.702}$$

So increasing λ decrease indeed the variances of the $\hat{\vec{\beta}}_\lambda^{\text{ridge}}$.

Remark

If we assume the coefficients of the regression to be Gaussian distributed with mean 0 and variance σ_ε^2 and we take $\lambda = 1/\sigma_\varepsilon^2$, we speak sometimes then of "Gauss reguralization".

14.1.12.2 L_1 Regularization or LASSO Regularization

We describe the basic idea through the "LASSO regularization" (LASSO stands for: Least Absolute Shrinkage and Selection Operator) as applied in the context of linear regression. The method starts by assuming a model like:

$$\boxed{\text{PRSS}(\vec{\beta})_{L_1}=\min_{\vec{\beta}}\frac{1}{n}(\hat{X}\vec{\beta}-\vec{y})^T(\hat{X}\vec{\beta}-\vec{y})+\lambda L_1(\vec{\beta})=\min_{\vec{\beta}}\frac{1}{n}(\hat{X}\vec{\beta}-\vec{y})^T(\hat{X}\vec{\beta}-\vec{y})+\lambda\sum_i|\beta_i|} \tag{14.1.703}$$

which is just the usual least squares criterion with a penalty determined by λ for large coefficient estimates. Again, if $\lambda=0$ the lasso is the same as OLS; as λ increases, shorter vectors are preferred.

Remark

If the different predictor variables don't have physically comparable units it's a good idea to standardize them first, so they all have mean 0 and variance 1 and also no physical units. Otherwise penalizing the p predictor with the L_1-norm using $\sum_{i=1}^p|\beta_i|$ seems to be adding up apples, oranges, and the occasional bout of regret (some people always pre-standardize the predictors).

Immediately we lose the differentiability of the optimization function: the absolute values are non-differentiable.

Thus we cannot solve the optimization problem using standard calculus techniques in the most general case. What do we gain then? First we can consider only the case $\vec{\beta}\neq\vec{0}$.

We take the derivative:

$$\vec{\nabla}_{\vec{\beta}}=\frac{2}{n}X^T(X\vec{\beta}-\vec{y})+\lambda \tag{14.1.704}$$

To find the optimum we put:

$$\vec{0}=X^T(X\vec{\beta}-\vec{y})+\frac{n\lambda}{2} \tag{14.1.705}$$

Therefore:

$$\hat{\vec{\beta}}_\lambda^{\text{LASSO}}=\frac{X^T\vec{y}-\dfrac{n\lambda}{2}}{X^TX}=\frac{2X^T\vec{y}-n\lambda}{2X^TX} \tag{14.1.706}$$

If you observe the numerator, it may be equal to zero, since we are subtracting some value of λ. And therefore the values of $\hat{\vec{\beta}}_\lambda^{\text{LASSO}}$ may be all equal to zero at the opposite of the ridge regression!

One can show that for some large enough λ, the solution is a sparse solution. A sparse solution means a solution for $\vec{\beta}$ that has many zeros in it, effectively removing the corresponding variable from the system. There are then two immediate consequences:

1. The system will give a coefficient of zero to non-relevant variables, instead of some insanely small coefficient. This means independent or near-independent variables will be discarded instead of included.

2. It gives us the most important variables in the regression model! We can speak confidently that variable i has a strong connection with the response variable $\vec{y}$.

Again notice that softwares compute estimates for a large number of values for λ at once. The optimal λ is selected by cross validation of some sort.

Let us prove now that the LASSO regression corresponds to a Laplace prior on the coefficients.

Proof 14.3.7. Let us imagine that you want to infer some parameter β from some observed input-output pairs $(x_1,y_1),\ldots,(x_n,y_n)$. Let us assume that the outputs are linearly related to the inputs via β and that the data are corrupted by some noise ε:

$$y_n=\beta x_n+\varepsilon \tag{14.1.707}$$

where ε is Gaussian noise with as we know mean 0 and variance σ_ε^2. This gives rise to a Gaussian likelihood:

$$\prod_{n=1}^N \mathcal{N}(y_n|\beta x_n,\sigma_\varepsilon^2) \tag{14.1.708}$$

First, let us recall that a Laplace distribution is given by (difference of two exponential distribution as we have proved it in the section of Statistics at page 800):

$$\mathcal{L}(x\,|\,\mu,b)=\frac{1}{2b}\exp\left(-\frac{|x-\mu|}{b}\right)=\frac{1}{2b}\begin{cases}\exp\left(-\frac{\mu-x}{b}\right) & \text{if } x<\mu\\ \exp\left(-\frac{x-\mu}{b}\right) & \text{if } x\geq\mu\end{cases} \tag{14.1.709}$$

Remark

Notice that the Normal and Laplace prior have a strong similitude. This is why they are commonly denoted:

$$P_{\lambda,p}=C^{te}(\lambda,p)e^{-\lambda L_p(\vec{\beta})} \tag{14.1.710}$$

Ridge regression $(p=2)$ corresponds to a Gaussian prior and the LASSO $(p=1)$ to a Laplacian (or double-exponential) prior.

Let us regularise parameter β by imposing the Laplace prior $\mathcal{L}(\beta|0,b)$, where b is a strictly positive scalar (and mean $\mu=0$). Hence, combining the likelihood and the prior we simply have:

$$\prod_{n=1}^N \mathcal{N}(y_n|\beta x_n,\sigma_\varepsilon^2)\mathcal{L}(\beta|0,b)=\prod_{n=1}^N \mathcal{N}(y_n|\beta x_n,\sigma_\varepsilon^2)\frac{1}{2b}\exp\left(-\frac{|\beta|}{b}\right) \tag{14.1.711}$$

Let us take the logarithm of the above expression. Dropping some constants we get:

$$\sum_{n=1}^N -\frac{1}{\sigma_\varepsilon^2}(y_n-\beta x_n)^2-\frac{1}{b}|\beta| \tag{14.1.712}$$

Let $1/b=\lambda$, we get then:

$$\sum_{n=1}^{N}-\frac{1}{\sigma_\varepsilon^2}(y_n-\beta x_n)^2-\lambda|\beta| \tag{14.1.713}$$

If we maximise the above expression with respect to β, we get the so named "maximum a-posteriori estimate" for β, or "MAPE for LASSO regression" for short. In this expression it becomes apparent why the Laplace prior can be interpreted as a L_1 regularisation term.

■ Q.E.D.

Remark

If we assume the coefficients of the regression to be Laplace distributed with variance σ_ε^2 and we take $\lambda=\sqrt{2}/\sigma_\varepsilon$, we speak sometimes then of "Laplace reguralization".

14.1.12.3 L_1+L_2 Regularization or Elastic Net Regularization

In statistics and, in particular, in the fitting of linear or binomial logistic regression models, the elastic net is a regularized regression method that linearly combines the L_1 and L_2 penalties of the lasso and ridge methods.

The elastic net method overcomes the limitations of the LASSO (least absolute shrinkage and selection operator) method which uses a penalty function based for recall on:

$$\lambda\sum_{i=1}^{n}|\beta_i| \tag{14.1.714}$$

Use of this penalty function seems to have several limitations. For example, in the "large n, small N" case (high-dimensional data with few examples), the LASSO seems to select at most n variables before it saturates. Also if there is a group of highly correlated variables, then the LASSO tends to select one variable from a group and ignore the others (i.e. LASSO tends to select only one predictor among the predictors that are highly correlated). To overcome these limitations, the elastic net adds a quadratic part to the penalty $||\beta||^2$, which when used alone is ridge regression. The estimates from the elastic net method are defined by:

$$\hat{\beta}^{\text{EN}}_{\lambda_1,\lambda_2}=\min_{\vec{\beta}}\ ||\vec{y}-X\vec{\beta}||^2+\lambda_2||\vec{\beta}||^2+\lambda_1\sum_i|\beta_i| \tag{14.1.715}$$

The quadratic penalty term makes the loss function strictly convex, and it therefore has a unique minimum. The elastic net method includes the LASSO and ridge regression: in other words, each of them is obviously a special case where $\lambda_1=\lambda$, $\lambda_2=0$ or $\lambda_1=0$, λ_2.

Another very common notation is:

$$\boxed{\hat{\beta}^{\text{EN}}_{\lambda,\alpha}=\min_{\vec{\beta}}\ \frac{1}{n}||\vec{y}-X\vec{\beta}||^2+\lambda\left((1-\alpha)||\vec{\beta}||^2+\alpha\sum_i|\beta_i|\right)} \tag{14.1.716}$$

where $0\leq\alpha\leq 1$ is a compromise between ridge ($\alpha=0$) and lasso ($\alpha=1$).

Remark

Depending on the softwares, the algorithms implement some variations of the relation above. The most common one are:

$$\hat{\beta}^{\text{EN}}_{\lambda,\alpha}=\min_{\vec{\beta}}\ \|\vec{y}-X\vec{\beta}\|^2+\lambda\left((1-\alpha)\|\vec{\beta}\|^2+\alpha\sum_i|\beta_i|\right) \tag{14.1.717}$$

or:

$$\hat{\beta}^{\text{EN}}_{\lambda,\alpha}=\min_{\vec{\beta}}\ \frac{1}{2n}\|\vec{y}-X\vec{\beta}\|^2+\lambda\left(\frac{(1-\alpha)}{2}\|\vec{\beta}\|^2+\alpha\sum_i|\beta_i|\right) \tag{14.1.718}$$

and so on.... Hence the sometimes the huge differences in the optimal λ value.

A common question about regularization is that in traditional statistics models, while building a model, we check for multicollinearity using methods such as estimates of the variance inflation factor (VIF), but in Machine Learning, we instead use regularization for feature selection and don't seem to check whether features are correlated at all. Why do we do that?

The reason is because the goals of "traditional statistics" are different from many Machine Learning techniques.

In traditional statistics regressions, we are trying to understand the impact the independent variables have on the dependent variable. If there is strong multicollinearity, this is simply not possible. No algorithm is going to fix this. If studiousness is correlated with class attendance and grades, we cannot know what is truly causing the grades to go up - attendance or studiousness.

However, in Machine Learning techniques that focus on predictive accuracy, all we care about is how we can use a set of variables to predict another set. We don't care about the impact these variables have on each other.

Basically, the fact that we don't check for multicollinearity in Machine Learning techniques isn't a consequence of the algorithm, it's a consequence of the goal!

Remark

For more information we strongly recommend the reader to refer to the excellent lecture notes of Wessel N. van Wieringen [572].

14.1.12.4 Polynomial regression

We will now see how to determine the for example of the best second degree polynomial that passes by any number of points, but without transforming the function contrary to what we have just done just before! As we like physics in this textbook, we will take a classic case of Kinematic to join business with pleasure...

So consider that we are looking for a polynomial of the second degree of the form:

$$x=x_0+v_0t+\frac{1}{2}at^2 \tag{14.1.719}$$

knowing that the method is easily applicable to higher order polynomials (at least as far as we know).

Relation that it is customary to write in the field of polynomial regression as follows:

$$d_i=c_1+c_2t_i+c_3t_i^2 \tag{14.1.720}$$

where i represents the number of points available to us.

For the rest, let us once again base our developments on the least squares method. In other words, we seek the coefficients c_1,c_2,c_3 that minimize the error:

$$\text{SSR}=\sum_{i=1}^n(d_i-d_i')^2=\sum_{i=1}^n(d_i'-d_i)^2=\sum_{i=1}^n\left(\left(c_1+c_2t_i+c_3t_i^2\right)-d_i\right)^2=\Phi(c_1,c_2,c_3) \tag{14.1.721}$$

and we attack again with partial derivatives for each coefficient:

$$\frac{\partial\Phi}{\partial c_1}=\sum_{i=1}^n 2\left(c_1+c_2t_i+c_3t_i^2-d_i\right)=2\left(nc_1+c_2\sum_{i=1}^n t_i+c_3\sum_{i=1}^n t_i^2-\sum_{i=1}^n d_i\right)=0 \tag{14.1.722}$$

Therefore after a small rearrangement and simplification:

$$nc_1+c_2\sum_{i=1}^n t_i+c_3\sum_{i=1}^n t_i^2=\sum_{i=1}^n d_i \tag{14.1.723}$$

Similarly:

$$\frac{\partial\Phi}{\partial c_2}=\sum_{i=1}^n 2t_i\left(c_1+c_2t_i+c_3t_i^2-d_i\right)=2\left(c_1\sum_{i=1}^n t_i+c_2\sum_{i=1}^n t_i^2+c_3\sum_{i=1}^n t_i^3-\sum_{i=1}^n d_it_i\right)=0 \tag{14.1.724}$$

Therefore after a small rearrangement and simplification:

$$c_1\sum_{i=1}^n t_i+c_2\sum_{i=1}^n t_i^2+c_3\sum_{i=1}^n t_i^3=\sum_{i=1}^n d_it_i \tag{14.1.725}$$

And finally:

$$\frac{\partial\Phi}{\partial c_3}=\sum_{i=1}^n 2t_i^2\left(c_1+c_2t_i+c_3t_i^2-d_i\right)=2\left(c_1\sum_{i=1}^n t_i^2+c_2\sum_{i=1}^n t_i^3+c_3\sum_{i=1}^n t_i^4-\sum_{i=1}^n d_it_i^2\right)=0 \tag{14.1.726}$$

Therefore after a small rearrangement and simplification:

$$c_1\sum_{i=1}^{n}t_i^2+c_2\sum_{i=1}^{n}t_i^3+c_3\sum_{i=1}^{n}t_i^4=\sum_{i=1}^{n}d_it_i^2 \tag{14.1.727}$$

So using the notation of linear algebra, we finally have to solve the following system:

$$\begin{bmatrix} n & \sum\limits_{i=1}^{n}t_i & \sum\limits_{i=1}^{n}t_i^2 \\ \sum\limits_{i=1}^{n}t_i & \sum\limits_{i=1}^{n}t_i^2 & \sum\limits_{i=1}^{n}t_i^3 \\ \sum\limits_{i=1}^{n}t_i^2 & \sum\limits_{i=1}^{n}t_i^3 & \sum\limits_{i=1}^{n}t_i^4 \end{bmatrix}\begin{pmatrix} c_1 \\ c_2 \\ c_3 \end{pmatrix}=\begin{pmatrix} \sum\limits_{i=1}^{n}d_i \\ \sum\limits_{i=1}^{n}d_it_i \\ \sum\limits_{i=1}^{n}d_it_i^2 \end{pmatrix} \tag{14.1.728}$$

and so we just have to solve this simple linear system either by hand using the relations proved in the section of Linear Algebra, or with a simple spreadsheet software (like Microsoft® Excel® for example).

14.1.12.5 Kernel regression

We have already discussed and introduce quite in details the concepts of kernel smoothing in the section Statistics at page 1143.

We estimate a regression model $\hat{y}(x)$ by the "kernel regression estimate" defined by:

$$\hat{y}(x)=\frac{\displaystyle\sum_{i=1}^{n} y_i K\left(\frac{x-x_i}{h}\right)}{\displaystyle\sum_{i=1}^{n}\left(\frac{x-x_i}{h}\right)} \tag{14.1.729}$$

Note that each $\hat{y}(x)$ is a weighted average of the y_i, which is the operation:

$$p_1 y_1+\ldots+p_n y_n \tag{14.1.730}$$

where the p_i are non-negative constants that sum to one and obviously given by:

$$p_i=\frac{K\left(\dfrac{x-x_i}{h}\right)}{\displaystyle\sum_{i=1}^{n}\left(\frac{x-x_i}{h}\right)} \tag{14.1.731}$$

Again, a very common smoother is for example the gaussian kernel:

$$K(x)=e^{-x^2/2} \tag{14.1.732}$$

For examples of such kernel regression, the reader can refer to our R companion book.

An improvement to kernel smoothing is "local polynomial smoothing" or also named "locally estimated scatterplot smoothing" (LOESS), which does the following: suppose we choose to use a first degree polynomial (that is, use linear regression), then for each x we gave $\hat{\alpha}(x)$ and $\hat{\beta}(x)$ that minimize the weighted residual sum of squares:

$$\sum_{i=1}^{n} K\left(\frac{x-x_i}{h}\right)(y_i-(\alpha+\beta x_i))^2 \tag{14.1.733}$$

and set:

$$\hat{y}(x)=\hat{\alpha}(x)+\hat{\beta}(x)x \tag{14.1.734}$$

Note that we have to do this for each x for which we wish to evaluate $\hat{y}(x)$.

In the general case, the above relation we will be written:

$$\boxed{\min_{\vec{\beta}}\ \text{PRSS}\left(\vec{\beta}_K^{\text{LOESS}}(x)\right)=\sum_{i=1}^{n} K\left(\frac{\|\vec{x}-\vec{x}_i\|}{h}\right)(y_i-\vec{x}_i^T\vec{\beta})^2} \tag{14.1.735}$$

Again, for an example of such kernel regressions, the reader can refer to our R companion book.

Remark

As far as we know there is no closed form inferential techniques for the coefficients or any other regression diagnostics.

14.1.12.6 Logistic regressions (LOGIT)

Often, statistics data are relative to qualitative informations (prediction if a customer is at risk for a credit, prediction if an individual is at risk for sickness, prediction of customer crunch[23], prediction of buying a next given item, etc.) or bounded in a $[0,1]$ interval (quite common case in Design of Experiments!). However, as we shall see, the traditional inference methods do not allow to model and study this type of variables (in fact they can do but performs poorly most of time!).

A well known simple model that performs most of time quite poorly for binary classification is the "signum least squares classifier" defined as:

$$f(x)=\text{sgn}(\vec{x}^T\vec{\beta}+\beta_0) \tag{14.1.736}$$

where we used the signum function already defined in the section of Arithmetic Operators page 327.

The intuition behind this "least squares classifier" is simple. The value $f(\vec{x})$ is a number, which ideally is near $+1$ when $y_i=+1$, and near -1 when $y_i=-1$. When $f(\vec{x})$ is near $+1$ we have confidence in our guess $y_i=+1$; when it is small and negative (say, $f(x)=-0.03$), we guess that $y_i=-1$ but our confidence in the guess will be low. So we won't pursue this idea further as we can't associate any probability with it and furthermore the signum function is not continuous (of class $\mathcal{C}^1$) and this can make problems in some computer implementations).

Specific methods should be used taking into account for example the lack of continuity of the processed variables or absence of the natural order between the terms that can take the qualitative variable. We will therefore see now the most simple of these methods.

Remark

We can use Logistic Regression in a non classification way (!), in that latter case it is named "decile analysis". Decile analysis has become more like a lost art, even if it was once a popularly used technique, however the convention of teaching and bucketing machine learning problems into either "classification" or "regression" types, lead many people to forget decile analysis type analyses (excepted in finance, insurance and risk management). It is very likely that most freshly minted data scientists would not have even heard of Decile analysis. So, decile analysis is simply used to categorize dataset from highest to lowest values or vice versa (based on predicted probabilities). As obvious from the name, the analysis involves dividing the dataset (thanks to the response variable) into ten groups.

---

[23] Prediction if a customer will leave your business

14.1.12.6.1 Binomial Logistic regression

As we have seen above, the simple linear regression therefore aims to model the relation between an unbounded quantitative dependent variable and an unbounded quantitative explanatory variable.

When the "class variable" to explain Y is binary (yes-no, presence-absence, 0-1, etc.), the idea is to approach it at first by a probability function $P(Y=1)$ which gives at the opposite the probability of belonging to the class $Y=0$ or $Y=1$, which we will name the "logistic binomial regression" or "logit regression" or simply "binomial regression" and also "binary regression" (often used in the context of artificial neural networks that we will see later). Then, in a second step, we define a for a binary case a "cutoff" value. For example, if we take a cutoff of 0.5 then the cases for which $P(Y=1)>0.5$ will belong to the class 1 (and vice versa in the opposite case). This is why the binomial[24] logistic regression is often qualified of "binary classifier".

Remarks

R1. In fact, logistic regression is a simple probability distribution law in our case (we will see another logistic regression in the section Economy during our study of time series and yet another one in the section of Populations Dynamics).

R2. It is obviously not possible to apply systematically logistic regression to any type of data sample! Sometimes we have to look elsewhere...

R3. When the number of modalities is equal to 2, we talk about "dummy variable" (yes-no) or a "dichotomic model" or even of "indicator variable"; if it is greater than 2, we talk about "polytomous variables" (polytomous logistic regression) or "multinomial logistic regression" (see further below). Therefore the logit binomial model is a "dichotomous model".

For example, consider the dichotomous variable: "graduation". This takes two forms: "ongoing", "finished". Age is a possible predictor of this variable and we seek to model the probability of completing studies as a function of age.

---

[24] The reader should remember that the Bernoulli distribution is a special case of the binomial distribution where a single trial is conducted!

✍**Example:**

To build the graph below, we calculated and shown on the ordinate, for youth of various ages x, the percentage of those who have left school.

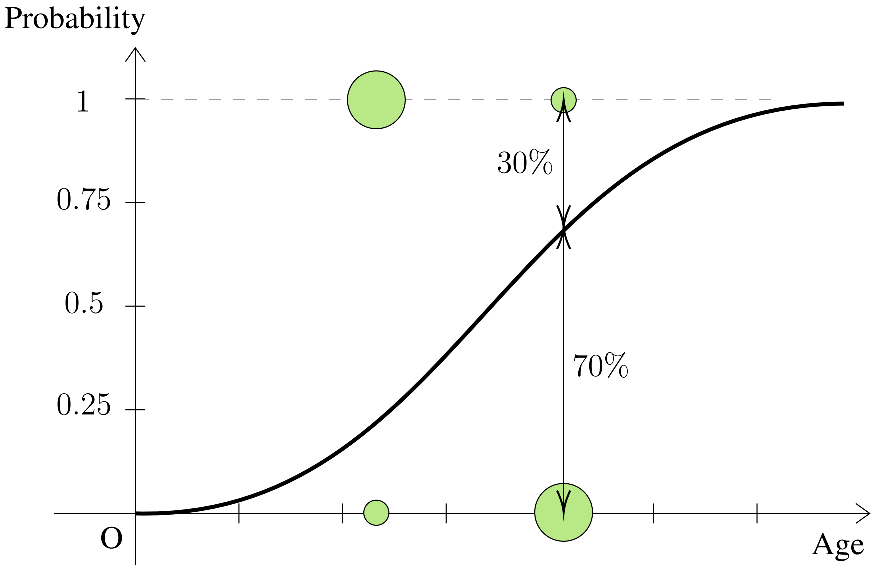


Figure 14.20: **Part at school according to Age**

But how do we obtain such a graph with a dichotomic (dummy) variable ??? In fact it's relatively simple ... Imagine a sample of 100 individuals. For these 100 individuals assume for a given age that 70% "has finished" and 30% are "ongoing". Well the curve is simply the ratio of the two classes for a given age x. It is sometimes given the size of classes with circles over the length of the horizontal asymptotes to mean that this is a dichotomous variable.

Points are distributed according to an S-curve ("sigmoid"): there are two horizontal asymptotes as the proportion is between 0 and 1. We see immediately that a linear model would be manifestly inadequate (especially as the dependent variable a linear model sweeps the whole real numbers $\mathbb{R}$ and is not confined to the range $[0,1]$).

This curve evokes for some, rightly, a cumulative curve representing a distribution function (of a Normal distribution for instance, but other continuous distributions have almost the same shape). Thus, to fit a curve to this representation, we could move towards the distribution function of a Normal distribution, and instead of estimating the parameters a and b of the linear regression, we could estimate the parameters μ, σ of the Normal law (which is very similar to the logistic law as will be shown below). We then speak of a "probit model" (probability-unit). We could also move towards a Student distribution. We then speak of a "robit model" (robust-unit model) because the T-distribution has fatter tails than the Normal distribution, the model allows for occasional large errors, and as a result the estimate for β is less affected by outliers. Robit regression is equivalent to probit regression when its degrees of freedom $k \rightarrow +\infty$, and is close to logistic regression when $k=7$.

Note that various sources and softwares interpret gompit, Cloglog, loglog, nloglog in different ways. All these models are closely related to each other and one can obtain any of them by using the gompit link function. For instance, if another source names complementary loglog (Cloglog) the function we name here gompit, one can switch between the two models by reversing the 0s and 1s in the dependent variable (in binary dependent variable models).

Remark

Is logit better than probit, or vice versa? Both methods will yield similar inferences (though not identical: in practice the end result of these different distributional assumptions is that coefficients differ, usually logit estimate should be divided by approx 1.6 to match probit estimate of the same data). But if we look at marginal effects (meaning the effects on the predicted mean of the outcome holding other covariates at the mean or averaging over observed values) the logit and probit models will make essentially the same predictions.

On the other hand, if we are not going to go about calculating the margins then logit has the obvious advantage of generating coefficients that can be transformed into the familiar odds ratio by exponentiating the coefficient. Probit and Robit coefficients are essentially uninterpretable.

Logit – also known as logistic regression – is more popular in health sciences like epidemiology partly because coefficients can be interpreted in terms of odds ratios. Probit models can be generalized to account for non-constant error variances in more advanced econometric settings (known as heteroskedastic probit models) and hence are used in some contexts by economists and political scientists. If these more advanced applications are not of relevance, than it does not matter which method you choose to go with.

The law that will interest us, however, is the logistic law. Unlike the Normal distribution, we know how to evaluate the expression of its distribution function (cumulative probability) that is of the type (his first advantage!):

$$\boxed{P(Y)=\frac{e^{ax+b}}{1+e^{ax+b}}} \tag{14.1.737}$$

for a single predictor variable x where P is obviously a probability between 0 and 1. We will see a little further the historical reason for this choice.

We immediately see that this last relation being the integral of a density function (see the proof a little bit further below) it is therefore indeed a cumulative function as:

$$\int\limits_{-\infty}^{+\infty} f(x)\mathrm{d}x=F(x)|_{-\infty}^{+\infty}=\left.\frac{e^{ax+b}}{1+e^{ax+b}}\right|_{-\infty}^{+\infty}=1-0=1 \tag{14.1.738}$$

If there are several predictor variables then we write:

$$P(Y)=\frac{e^{a_0+a_1x_1+a_2x_2+\ldots+a_nx_n}}{1+e^{a_0+a_1x_1+a_2x_2+\ldots+a_nx_n}}=\frac{e^{\vec{x}^T\vec{\beta}}}{1+e^{\vec{x}^T\vec{\beta}}} \tag{14.1.739}$$

When we choose the logistic distribution function, we get the logistic regression model, or "logit model" for the choice of the "link function" and this is its second advantage (the most important one in fact!): we can make statistics on binary variable as if we were doing a simple linear regression!

Thus, to come back on our previous example, we estimate the cumulative probability for an individual of age x to have finish his studies (there are several ways to write the law following the traditions and the context) with the following logistic distribution function:

$$P(Y)=\frac{e^{ax+b}}{1+e^{ax+b}}=\frac{1}{\dfrac{1+e^{ax+b}}{e^{ax+b}}}=\frac{1}{1+e^{-(ax+b)}} \tag{14.1.740}$$

Remark

Again, the logit and probit mainly differ on the link function:

- In Logit: $P(Y=1|\vec{x})=\left(1+e^{-\vec{x}^T\vec{\beta}}\right)^{-1}$
- In Probit: $P(Y=1|\vec{x})=\Phi(\vec{x}^T\vec{\beta})$ (cumulative Normal probability density function)

In other way, logistic has slightly flatter tails. i.e the probit curve approaches the axes more quickly than the logit curve.

Notice that in probit models latent variable is assumed to be of the form: $Y=a+bx+\varepsilon$ with $\varepsilon=\mathcal{N}(0,1)$.

A question that may arise is what if $\varepsilon=\mathcal{N}(0,\sigma)$? In fact as we know by the property of the Normal distribution it is equivalent to: $Y=a+bx+\sigma\varepsilon$ with $\varepsilon=\mathcal{N}(0,1)$. Then:

$$P(Y=1|X)=P(Y>0)=P(\varepsilon<\tfrac{1}{\sigma}(a+bx))=\Phi\left(\frac{a+bx}{\sigma}\right)=\Phi\left(\frac{a}{\sigma}+\frac{b}{\sigma}x\right)=\Phi\left(\tilde{a}+\tilde{b}x\right) \tag{14.1.741}$$

The only thing that change are the parameters!

It therefore follows the distribution function[25]:

$$f(x)=\frac{\mathrm{d}P(Y)}{\mathrm{d}x}=\frac{\mathrm{d}}{\mathrm{d}x}\left(1+e^{-(ax+b)}\right)^{-1}=-\left(1+e^{-(ax+b)}\right)^{-2}\left(-ae^{-(ax+b)}\right)=\frac{ae^{-(ax+b)}}{\left(1+e^{-(ax+b)}\right)^2} \tag{14.1.742}$$

Obviously, depending on the value of the probability we associate with the age x the fact of not having finished his studies (state associated with the binary value: 0) or have them finished (state associated with the binary value: 1).

---

[25] If the reader is looking for the second derivative and inflection point of the sigmoid function, see page 7498

Remark

After a change of variables, we fall back on the logistic law as defined on Wikipedia:

$$f(x)=\frac{ae^{-(ax+b)}}{\left(1+e^{-(ax+b)}\right)^2}\underset{\substack{a:=\frac{1}{s}\\ b:=\frac{\mu}{s}}}{=}\frac{ae^{-\left(\frac{x}{s}+\frac{\mu}{s}\right)}}{\left(1+e^{-\left(\frac{x}{s}+\frac{\mu}{s}\right)}\right)^2}=\frac{ae^{-\left(\frac{x+\mu}{s}\right)}}{\left(1+e^{-\left(\frac{x+\mu}{s}\right)}\right)^2}\qquad(14.1.743)$$

Let us indicate that if a is set as 1, and b as 0, then we have the "standard logistic law" given by:

$$P(Y)=\frac{1}{1+e^{-x}}\qquad(14.1.744)$$

We can also calculate the mean of the distribution of the function by applying what has already been study in the Statistics section but part of this integral can only be solved numerically (at least as far as we know)... if we put:

$$t=ax+b\qquad(14.1.745)$$

as being the random variable then we can formally calculate the mean of the logistic law (the reader may have noticed that it is as if we posed as $a=1$ and $b=0$). Indeed, starting from:

$$P(Y)=\frac{1}{1+e^{-(ax+b)}}=\frac{1}{1+e^{-t}}\Leftrightarrow f(x)=\frac{e^{-t}}{(1+e^{-t})^2}\qquad(14.1.746)$$

Therefore it comes:

$$\text{E}(Y)=\int\limits_{-\infty}^{+\infty}f(t)t\mathrm{d}t=\int\limits_{-\infty}^{+\infty}\frac{e^{-t}}{(1+e^{-t})^2}t\mathrm{d}t\qquad(14.1.747)$$

that after a numerical integration gives 0. We then also get the following result:

$$\text{V}(X)=\text{E}(X^2)-\text{E}(X)^2=\text{E}(X^2)=\int\limits_{-\infty}^{+\infty}f(t)t^2\mathrm{d}t=\int\limits_{-\infty}^{+\infty}\frac{e^{-t}}{(1+e^{-t})^2}t^2\mathrm{d}t\qquad(14.1.748)$$

Let us calculate the integral:

$$\begin{aligned}\int\limits_{-\infty}^{+\infty}\frac{x^2e^{-x}}{(1+e^{-x})^2}\mathrm{d}x&=\int\limits_{-\infty}^{0}\frac{x^2e^{-x}}{(1+e^{-x})^2}\mathrm{d}x+\int\limits_{0}^{+\infty}\frac{x^2e^{-x}}{(1+e^{-x})^2}\mathrm{d}x=\int\limits_{0}^{+\infty}\frac{x^2e^{x}}{(1+e^{x})^2}\mathrm{d}x+\int\limits_{0}^{+\infty}\frac{x^2e^{-x}}{(1+e^{-x})^2}\mathrm{d}x\\&=\int\limits_{0}^{+\infty}\frac{x^2e^{x}}{e^{2x}(1+e^{-x})^2}\mathrm{d}x+\int\limits_{0}^{+\infty}\frac{x^2e^{-x}}{(1+e^{-x})^2}\mathrm{d}x\\&=2\int\limits_{0}^{+\infty}\frac{x^2e^{-x}}{(1+e^{-x})^2}\mathrm{d}x=2\int\limits_{0}^{+\infty}x^2\sum_{n=1}^{+\infty}n(-1)^{n-1}e^{-nx}\mathrm{d}x\\&=2\sum_{n=1}^{+\infty}n(-1)^{n-1}\int\limits_{0}^{+\infty}x^2e^{-nx}\mathrm{d}x=2\sum_{n=1}^{+\infty}n(-1)^{n-1}\frac{2}{n^3}=4\sum_{n=1}^{+\infty}(-1)^{n-1}\frac{1}{n^2}=\frac{\pi^2}{3}\end{aligned}\qquad(14.1.749)$$

Thus we see that if we put:

$$P(Y) = \frac{1}{1+e^{-\frac{\pi}{\sqrt{3}}}(ax+b)} \tag{14.1.750}$$

We fall back on a distribution function with the same position and dispersion parameters of a Normal distribution centered reduced variable (zero mean and unit variance).

The distribution function:

$$P(Y) = \frac{e^{(ax+b)}}{1+e^{(ax+b)}} = \frac{1}{1+e^{-(ax+b)}} \tag{14.1.751}$$

can also be transformed in a very well known and important form!:

$$P \cdot \left(1+e^{(ax+b)}\right) = e^{(ax+b)} \Leftrightarrow P = e^{(ax+b)} \cdot (1-P) \tag{14.1.752}$$

Therefore:

$$\boxed{ax+b = \ln\left(\frac{P}{1-P}\right) = \text{logit}(P)} \tag{14.1.753}$$

In fact this is where lies historically the trick of the origin of logistic regression. We transform a variable P taking values in the in the range $[0,1]$ thanks to the logarithm of the ratio $P/(1-P)$ in a variable taking its values on the set $\mathbb{R}$ and therefore it is possible to associate to it a standard linear regression. Certainly it is empirical, but the idea was pretty good!

What some also write...:

$$\text{logit}\left(P(Y=1/X=x)\right) = \log\left(\frac{P(Y=1/X=x)}{1-P(Y=1/X=x)}\right) \tag{14.1.754}$$

The result of the last transformation is named the "logit". It is equal to the logarithm of the "odds" (which will be discussed in more detail soon):

$$\text{odds} = \frac{P}{1-P} \tag{14.1.755}$$

So this is just the ratio of a likelihood of an event on the probability of the complementary event (or opposite event if you prefer).

Remark

So what logit and probit do, in essence, is take the linear model and feed it through a function to yield a non-linear relationship. Whereas the linear regression predictor looks like:

$$Y = ax+b \tag{14.1.756}$$

The logit and probit predictor can be written as:

$$Y = f(ax+b) \tag{14.1.757}$$

Both functions will take any number and rescale it to fall between 0 and 1. Hence, whatever $ax+b$ equals, it can be transformed by the function to yield a predicted probability.

So when the coefficients a and b have been determined, the above expression is used to determine P knowing x easily (it comes to solve a linear equation) and vice versa! Moreover, since x is a dichotomic (dummy) variable coefficients are easily interpretable.

Link type	**CDF**	**Link function**	**Tolerance model**
Logit	Logistic	$\vec{x}_i^T\vec{\beta}=\ln\left(\dfrac{\pi_i}{1-\pi_i}\right)$	$\pi_i=\dfrac{\exp\left(\vec{x}_i^T\vec{\beta}\right)}{1+\exp\left(\vec{x}_i^T\vec{\beta}\right)}$
Probit	Normal	$\vec{x}_i^T\vec{\beta}=\Phi^{-1}\left(\pi_i\right)$	$\pi_i=\Phi\left(\vec{x}_i^T\vec{\beta}\right)$
Robit	Student	$\vec{x}_i^T\vec{\beta}=T^{-1}_{(\nu-1)/\nu}\left(\pi_i\right)$	$\pi_i=T_{(\nu-1)/\nu}\left(\vec{x}_i^T\vec{\beta}\right)$
loglog (nloglog)	Gumbel	$\vec{x}_i^T\vec{\beta}=-\log(-\log(\pi_i))$	$\pi_i=\exp\left(-\exp\left(\vec{x}_i^T\vec{\beta}\right)\right)$
Cloglog (gompit)	Gumbel	$\vec{x}_i^T\vec{\beta}=\log\left(-\log\left(1-\pi_i\right)\right)$	$\pi_i=1-\exp\left(-\exp\left(\vec{x}_i^T\vec{\beta}\right)\right)$
Cauchit	Cauchy	$\vec{x}_i^T\vec{\beta}=\tan(\Phi(\pi-0.5))$	$\pi_i=\dfrac{1}{\pi}\arctan(\vec{x}_i^T\vec{\beta})+0.5$

Table 14.8: **Some binomial regression models and their corresponding tolerance model and link function (using most common notation in multivariate case)**

Remark

The odds is also sometimes named the "rating" by analogy to the rating of horses to the triple forecast. For example, if a horse has 3 chances on 4 to be a winner (thus verbatim 1 on 4 chance of being non-winner) its rating is a 3 against 1 ratio, that is to say an odds equal to 3:

$$\text{O.R.}=\frac{3/4}{1-3/4}=3$$

We can also introduce the concept of "odds ratio" (O.R.) for the rating ratio which is a very widely used indicator in medicine. Thus, if the occurrence of an event in a group A is p, and q in the group B, the odds ratio is then simply given by:

$$\text{O.R.}=\frac{\text{odds of } p}{\text{odds of } q}=\frac{\dfrac{p}{1-p}}{\dfrac{q}{1-q}}=\frac{p(1-q)}{q(1-p)} \tag{14.1.758}$$

The odds ratio is always by design greater than or equal to zero. If the odds ratio is close to 1, the event is independent of the group, if it is greater than 1, the event is more common in group A than in group B, if it is less than 1 the event is less frequent in group A than in group B.

Odds ratio or "crude ratio" are obtained when we consider the effect of only one predictor variable. However when we include more variables in the analysis we get what is named the "adjusted odds ratio".

Let us come back over the odds because it is possible to introduce the concept of logistics function by doing the opposite approach from the one presented above (i.e. to start with the definition of odds to get to the logit) and this can sometimes be even more educational.

Let us suppose we start from the size (height) of a person to predict whether this person is a man or a woman. So we can talk about probability of being a man or a woman. Suppose the probability of a man for a given height is 90%. So the odds of being a man is:

$$\boxed{\text{odds} = \frac{P}{1-P}} \tag{14.1.759}$$

In our example, the odds will be $0.90/0.10$ therefore equal to 9. Now, the probability of being a woman will be $0.10/0.90$ therefore equal to 0.11. This asymmetry of values is not talking because the odds of being a man should be the opposite of the odds of being a woman ideally. We solve precisely this asymmetry using the natural logarithm. Thus we have:

$$\ln\left(\frac{P}{1-P}\right) = \ln(9) = 2.197 \tag{14.1.760}$$

and:

$$\ln\left(\frac{1-P}{1-(1-P)}\right) = \ln\left(\frac{1-P}{P}\right) = \ln(0.11) = -2.197 \tag{14.1.761}$$

In this way the logit (logarithm of the odds) is exactly the opposite of this of being a woman by the property of the logarithm:

$$\ln\left(\frac{x}{y}\right) = \ln(x) - \ln(y) = -\left(\ln(y) - \ln(x)\right) = -\ln\left(\frac{y}{x}\right) \tag{14.1.762}$$

To introduce this tool let us suppose a bank wants to make a scoring of its debtors. As it has several subsidiaries it (the bank) built the following data tables for some of them (all subsidiaries are then not presented):

- 1st Subsidiary:

Credit Amount	Paid	Not Paid
27,200	1	9
27,700	7	3
28,300	13	0
28,400	7	3
29,900	10	1

Table 14.9: Debtors Scoring by credit amount of subsidiary 1

- 2nd Subsidiary:

Credit Amount	Paid	Not Paid
27,200	0	8
27,700	4	2
28,300	6	3
28,400	5	3
29,900	8	0

Table 14.10: Debtors Scoring by credit amount of subsidiary 2

- 3rd Subsidiary:

Credit Amount	**Paid**	**Not Paid**
$27,200$	1	8
$27,700$	6	2
$28,300$	7	1
$28,400$	7	2
$29,900$	9	0

Table 14.11: **Debtors Scoring by credit amount of subsidiary 3**

We can see that the total proportion of good debtors in the three subsidiaries is of $91/136 \cong 0.67$.

When the credit is less than $27,500$, the percentage of good debtors is of $2/27 \cong 0.07$. When the amount of credit is less than $28,000$ the proportion of good debtors is of $19/51 \cong 0.37$.

When the amount of credit is less than $28,500$, the percentage of good debtors is of $64/108 \cong 0.59$ and for amounts below $30,000$ the proportion is of $91/936 \cong 0.67$.

We will put for this logistic regression that $Y = 1$ is a good credit risk and that $Y = 0$ is a bad risk. Next, we create the following table that is a summary of data from all subsidiaries:

Credit Amount	**Proportion** P
$27,200$	$=2/27=0.0741$
$27,700$	$=17/24=0.7083$
$28,300$	$=26/30=0.8667$
$28,400$	$=19/27=0.7037$
$29,900$	$=27/28=0.9643$

Table 14.12: **Proportion of good debtors**

Which gives graphically in Kilo-dollars:

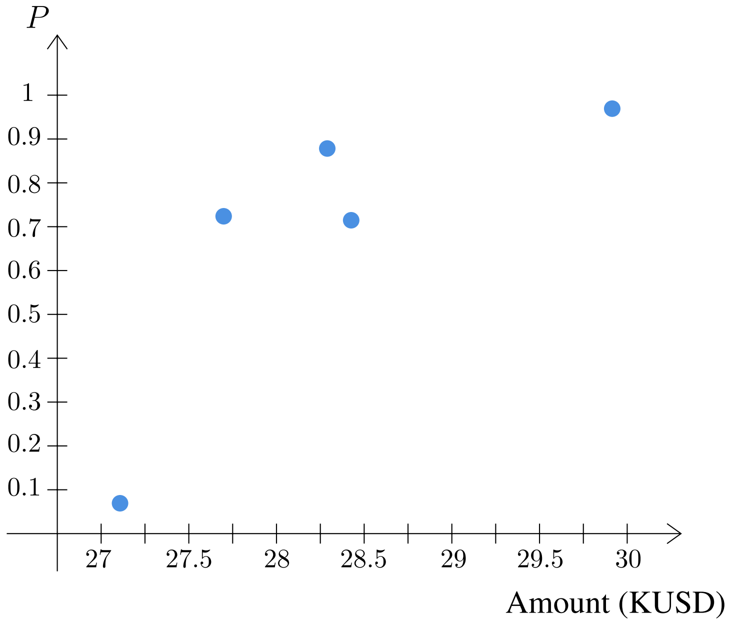

Figure 14.21: Cumulative percentage of good debtors based on credit

Once done, we use the logit transformation:

$$ax+b=\ln\left(\frac{P}{1-P}\right)=\text{logit}(P) \tag{14.1.763}$$

Which gives:

Credit Amount	Proportion P	Logit
$27,200$	0.0741	-2.5257
$27,700$	0.7083	0.8873
$28,300$	0.8667	1.8718
$28,400$	0.7037	0.8650
$29,900$	0.9643	3.2958

Table 14.13: Proportion of good debtors and logit

Remark

The reader must keep in mind the social responsibilities when running such models! First their accuracy (wrong rate of classification), but also especially the confidence interval of the predicted proportion (probability). A statistician or data scientist should never communicate punctual values alone, but always with their confidence interval!

Be careful also to have balanced (unbiased and correctly sampled) datasets, or to weight them correctly if necessary, to not have biased results especially when your classification methods or algorithms have important social impacts on people!!!

A linear regression by least squares method gives:

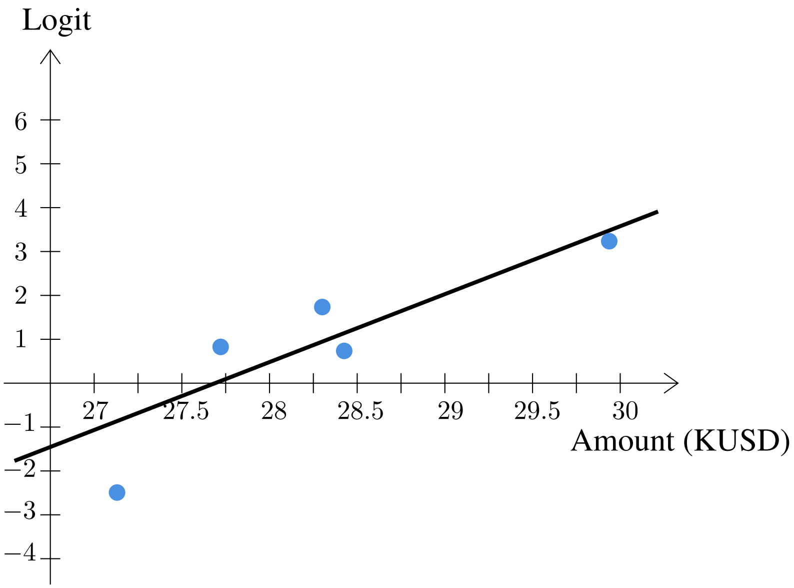

Figure 14.22: **Logit of good debtors based on the credit amount**

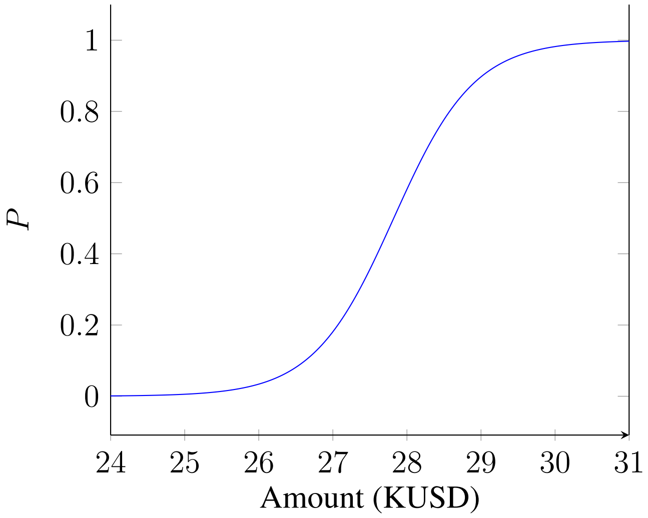
with for equation (where x is in USD and not in KUSD):

$$-51.1116+0.001837x=\ln\left(\frac{P}{1-P}\right)=\text{logit}(P) \qquad (14.1.764)$$

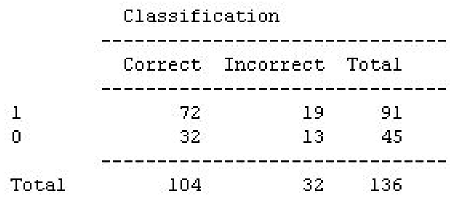
The logistic function with its representation comes then immediately (the x units are in thousands of francs)

$$P(Y)=\frac{1}{1+e^{-(-51.1116+0.001837x)}} \qquad (14.1.765)$$



Thus, it is possible to say in this example, what is the proportion P of good or bad debtors according to the credit value X smaller than or equal to a certain given value. Since 0 is a bad credit risk, we see that the bigger is the credit amount, the lower is the risk (in this hypothetical case...). Moreover, with software like Minitab (see the corresponding companion book), the difference between the quick calculations carried out by hand and those made with the binary logistic regression tool of the software is in the order of 10% (because of course ... Minitab uses the concept of maximum likelihood estimators seen in the Statistics section to determine the coefficients and the constant).

A software like Minitab gives automatically an interesting output which is the "confusion matrix $\mathcal{C}$". It compares the model to reality with a traditional cutoff set at 50% (obviously if the model perfectly match to the sample, the following matrix is a diagonal one):



```
              Classification
            --------------------------------
              Correct  Incorrect  Total
            --------------------------------
1                  72         19     91
0                  32         13     45
            --------------------------------
Total             104         32    136
```

Figure 14.23: **Confusion matrix Minitab 15.0 output example (screenshot)**

where the good debtors have the value 1 (no credit risk) and the bad one the value 0 (credit risk). We will detail further below how to get this matrix with a spreadsheet software. Finally let us indicate that in many Data Mining softwares, it is customary to define the "score" of the model as (in the specific case of one unique explanatory variable but can easily be generalized to many):

$$\text{Score}=1-P(Y)=\frac{1}{1+e^{-(ax+b)}} \tag{14.1.766}$$

Remark

In some statistical softwares, when you run a logistic regression, you can get sometimes a message of the type: *«complete separation of data points»*. Indeed, take a look at the following data set consisting of the response variable, Y, and one predictor variable, X:

X	1	2	3	4	4	5	5	6
Y	0	0	0	0	0	1	1	1

Notice the key pattern... This data set can be simply described as follows: if $X\leq 4$, then $Y=0$ without fail. Similarly, if $X>4$, then $Y=1$, again without fail. This is hat is knows as "separation". This perfect prediction of the response is what causes the estimates, and thus the model, to fail.

Following the request of a reader, here is the maximum likelihood approach of the logistic regression.

Let us consider the notation:

$$P(Y=1|X=\vec{x})=\frac{1}{1+e^{-f(\vec{x})}} \tag{14.1.767}$$

Assuming that the observations are independent of one another, we can define $L(D,\vec{\beta})$, the likelihood of the data D with respect to the logistic model parameter by $\vec{\beta}$. It is the product of the probabilities according to this model that each individual in D belongs to the observed class with $y_i=1$ or $y_i=0$:

$$\begin{aligned}L(D,\vec{\beta})&=\prod_{i=1}^{n}P(Y=y_i|X=\vec{x})\\&=\prod_{i=1}^{n}P(y_i=1|\vec{x})^{y_i}P(y_i=0|x_i)^{1-y_i}\\&=\prod_{i=1}^{n}P(y_i=1|\vec{x})^{y_i}(1-P(y_i=1|\vec{x}))^{1-y_i}\end{aligned}\tag{14.1.768}$$

It is therefore necessary to determine the vector of parameters $\hat{\vec{\beta}}$ maximizing the likelihood of the data D:

$$\hat{\vec{\beta}}=\max_{\vec{\beta}}(L(D,\vec{\beta}))\tag{14.1.769}$$

To identify $\hat{\vec{\beta}}$, the first thing to do is to derive the likelihood with respect to each component of $\vec{\beta}$, $\dfrac{\partial}{\partial\beta_j}L(D,\vec{\beta})$, then solve:

$$\frac{\partial}{\partial\beta_j}L(D,\vec{\beta})=0\tag{14.1.770}$$

since $L(D,\vec{\beta})$ is convex in $\vec{\beta}$ and $\dfrac{\partial}{\partial\beta_j}L(D,\vec{\beta})$ vanishes when the maximum is reached.

However, the logarithm is a strictly increasing function, maximizing the likelihood is equivalent to maximizing the logarithm of the likelihood as we already know it, whose expression is easier to take the derivative (the logarithm transforming the products into sums and the exponents into factors):

$$\begin{aligned}\ln\left(L(D,\vec{\beta})\right)&=\ln\left(\prod_{i=1}^{n}P(y_i=1|x_i)^{y_i}(1-P(y_i=1|\vec{x}))^{1-y_i}\right)\\&=\sum_{i=1}^{n}y_i\ln(P(y_i=1|\vec{x}))+(1-y_i)\ln((1-P(y_i=1|\vec{x})))\end{aligned}\tag{14.1.771}$$

Notice that some statistical softwares return the "deviance of the proposed model" defined as:

$$\text{DEV}(P(\vec{\beta})|y_i)=-2\ln\left(L(D,w)\right)=-2\sum_{i=1}^{n}y_i\ln(P(y_i=1|\vec{x}))+(1-y_i)\ln((1-P(y_i=1|\vec{x})))\tag{14.1.772}$$

The deviance is always larger or equal than zero, being zero only if the fit is perfect.

A benchmark for evaluating the magnitude of the deviance is the "deviance of the null model":

$$\text{DEV}_0(P(\beta_0)|y_i)=-2\ln\left(L(D,\beta_0)\right)\tag{14.1.773}$$

which is the deviance of the worst model, the one fitted without any predictor (i.e. only with the intercept)! The null deviance serves for comparing how much the model has improved by adding the predictors.

Here is a summary of what you can see in some statistical software (be careful! the concept of "null deviance" must not be confused with the concept of "deviance of the null"!):

$$\begin{aligned}\text{Null Deviance} &= 2\left[\ln\left(L(\text{Saturated Model})\right)-\ln\left(L(\text{Null Model})\right)\right] \quad \text{on df} = \text{df}_{\text{Sat}}-\text{df}_{\text{Null}}\\ \text{Residual Deviance} &= 2\left[\ln\left(L(\text{Saturated Model})\right)-\ln\left(L(\text{Proposed Model})\right)\right] \quad \text{on df} = \text{df}_{\text{Sat}}-\text{df}_{\text{Prop}}\end{aligned} \tag{14.1.774}$$

where:

- The "saturated model" is a model that assumes each data point has its own parameters (which means we have n parameters to estimate).
- The "null model" assumes the exact opposite, in that it assumes one parameter for all of the data points, which means we have only to estimate 1 parameter.
- The "proposed model" assumes we can explain our data points with p parameters + an intercept term, so we have $p+1$ parameters.

Having defined these two deviances we can if we wish build a likelihood-ratio test from them (see section Statistics page 1150). That test is sometimes named the "deviance test".

Let us now just prove that the log-likelihood of the saturated model is always zero. As the saturated model is the model that perfectly fits the observed response.

Let us remind that the likelihood as already seen above is given by:

$$L(D,\vec{\beta})=\prod_{i=1}^{n}P(y_i=1|\vec{x})^{y_i}(1-P(y_i=1|\vec{x}))^{1-y_i} \tag{14.1.775}$$

Therefore as the model is perfect:

$$L(D,\vec{\beta})=\prod_{i=1}^{n}P(y_i=1|\vec{x})^{y_i}(1-P(y_i=1|\vec{x}))^{1-y_i}=1^n=1 \tag{14.1.776}$$

and clearly the logarithm of this is 0.

Remark

Notice that we define the "cross-entropy":

$$\boxed{H(p,q)=\sum_i p_i\log(q_i)=\mathrm{E}(\log(q_i))} \tag{14.1.777}$$

where p and q denote a "true" and an "empirical/estimated" distribution, respectively. Both are discrete distributions, hence we can sum over their individual components, denoted with i. Above, when we refer to a "distribution", it means with respect to a single training data point, and not the "distribution of training data points". That's a different concept.

So we have now therefore to determine the vector $\hat{\vec{\beta}}$ maximizing the log-likelihood of the data D:

$$\hat{\vec{\beta}} = \max_{\vec{\beta}}(\ln(L(D,w))) = \max_{\vec{\beta}}(L(D,w)) \qquad (14.1.778)$$

We shall therefore have to express $\dfrac{\partial}{\partial \beta_j}\ln(L(D,\vec{\beta}))$. Before that, we can agree a slightly different notation, in order to improve the readability of the formulas. We consider that each vector $\vec{x} \in D$ has an additional component, x_0, always equal to 1 (same technique as the one used to generalize the univariate regression). Thus we can rewrite P, so that the parameter of the sigmoid function is the dot product of the vectors $\vec{\beta}$ and $\vec{x}$ (both of dimension $d+1$):

$$P(Y=1|X=\vec{x}) = \frac{1}{1+e^{-\vec{\beta}\circ\vec{x}}} = S(\vec{\beta}\circ\vec{x}) = S(\vec{\beta}^T\vec{x}) \qquad (14.1.779)$$

Where $\vec{\beta}\circ\vec{x}$ is commonly known as the "prognostic index" (PI). The expression to be derived is thus:

$$\begin{aligned}
\frac{\partial}{\partial \beta_j}\ln(L(D,\vec{\beta})) &= \frac{\partial}{\beta_i}\sum_{i=1}^{n} y_i \log(P(y_i=1|\vec{x})) + (1-y_i)\log(1-P(y_i=1|\vec{x}))\\
&= \frac{\partial}{\partial \beta_j}\sum_{i=1}^{n} y_i \ln(S(\vec{\beta}\circ\vec{x})) + (1-y_i)\log(1-S(\vec{\beta}\circ\vec{x}))\\
&= \sum_{i=1}^{n} y_i \frac{\partial}{\partial \beta_j}\ \ln(S(\vec{\beta}\circ\vec{x})) + (1-y_i)\frac{\partial}{\partial \beta_j}\log(1-S(\vec{\beta}\circ\vec{x}))
\end{aligned} \qquad (14.1.780)$$

First we compute the first term:

$$\begin{aligned}
\frac{\partial}{\partial \beta_j}\ln(S(\vec{\beta}\circ\vec{x})) &= \frac{\partial}{\partial \beta_j}\ln\left(\frac{1}{1+e^{-\vec{\beta}\circ\vec{x}}}\right) = \frac{\partial}{\partial \beta_j}\ln(1) - \frac{\partial}{\partial \beta_j}\ln(1+e^{-\vec{\beta}\circ\vec{x}})\\
&= \frac{\partial}{\partial \beta_j}\cdot 0 - \frac{\partial}{\partial \beta_j}\ln(1+e^{-\vec{\beta}\circ\vec{x}}) = -\frac{-x_{ij}e^{-\vec{\beta}\circ\vec{x}}}{1+e^{-\vec{\beta}\circ\vec{x}}}\\
&= x_{ij}\left(1-\frac{1}{1+e^{-\vec{\beta}\circ\vec{x}}}\right) = x_{ij}(1-S(\vec{\beta}\circ\vec{x}))
\end{aligned} \qquad (14.1.781)$$

Now we compute the second term:

$$\begin{aligned}\frac{\partial}{\partial\beta_j}\ln(1-S(wx_i)) &= \frac{\partial}{\partial\beta_j}\ln\left(1-\frac{1}{1+e^{-\vec{\beta}\circ\vec{x}}}\right)=\frac{\partial}{\partial\beta_j}\ln\left(\frac{1+e^{-\vec{\beta}\circ\vec{x}}}{1+e^{-\vec{\beta}\circ\vec{x}}}-\frac{1}{1+e^{-\vec{\beta}\circ\vec{x}}}\right)\\ &=\frac{\partial}{\partial\beta_j}\ln\left(\frac{e^{-\vec{\beta}\circ\vec{x}}}{1+e^{-\vec{\beta}\circ\vec{x}}}\right)=\frac{\partial}{\partial\beta_j}\left[\ln\left(e^{-\vec{\beta}\circ\vec{x}}\right)-\ln\left(1+e^{-\vec{\beta}\circ\vec{x}}\right)\right]\\ &=\frac{\partial}{\partial\beta_j}\left[-\vec{\beta}\circ\vec{x}-\ln\left(1+e^{-\vec{\beta}\circ\vec{x}}\right)\right]\\ &=-\vec{\beta}\circ\vec{x}-\ln\left(1+e^{-\vec{\beta}\circ\vec{x}}\right)=-x_{ij}+x_{ij}(1-S(\vec{\beta}\circ\vec{x}))\\ &=-x_{ij}S(\vec{\beta}\circ\vec{x})\end{aligned}\tag{14.1.782}$$

So finally:

$$\begin{aligned}\frac{\partial}{\partial\beta_j}\ln(L(D,\vec{\beta})) &= \sum_{i=1}^{n} y_i\frac{\partial}{\partial\beta_j}\ln(S(\vec{\beta}\circ\vec{x}))+(1-y_i)\frac{\partial}{\partial\beta_j}\log(1-S(\vec{\beta}\circ\vec{x}))\\ &=\sum_{i=1}^{n} y_ix_{ij}(1-S(\vec{\beta}\circ\vec{x}))-x_{ij}(1-y_i)S(\vec{\beta}\circ\vec{x})\\ &=\sum_{i=1}^{n} y_ix_{ij}-y_ix_{ij}S(\vec{\beta}\circ\vec{x})-x_{ij}S(\vec{\beta}\circ\vec{x})+y_ix_{ij}S(\vec{\beta}\circ\vec{x})\\ &=\sum_{i=1}^{n} y_ix_{ij}-x_{ij}S(\vec{\beta}\circ\vec{x})=\sum_{i=1}^{n} x_{ij}(y_i-S(\vec{\beta}\circ\vec{x}))\end{aligned}\tag{14.1.783}$$

As far as we know... we can not solve this analytically:

$$\frac{\partial}{\partial\beta_j}\ln(L(D,\vec{\beta}))=\sum_{i=1}^{n} y_ix_{ij}-x_{ij}S(\vec{\beta}\circ\vec{x})=\sum_{i=1}^{n} x_{ij}(y_i-S(\vec{\beta}\circ\vec{x}))=0\tag{14.1.784}$$

Therefore we will have to approach the solution by a numerical method anyway... (gradient descent again)!

14.1.12.6.1.1 Binomial Logistic regression relative variable importance

We have seen for the Gaussian multivariate linear model how to calculate variable importance earlier above (see page 6395). Now for logistic regression we use rather "relative variable importance".

To introduce that latter let us first calculate the partial derivative of the logistic regression relatively to one predictor (we used the quotient rule proved in the section of Differential and

Integral Calculus page 1481):

$$\begin{aligned}\frac{\partial P(Y)}{\partial x_i}=\frac{\partial}{\partial x_i}\left(\frac{e^{\beta_0+\vec{\beta}^T\vec{x}}}{1-e^{\beta_0+\vec{\beta}^T\vec{x}}}\right)&=\frac{\dfrac{\partial}{\partial x_i}\left[e^{\beta_0+\vec{\beta}^T\vec{x}}\right]\left(1-e^{\beta_0+\vec{\beta}^T\vec{x}}\right)-e^{\beta_0+\vec{\beta}^T\vec{x}}\dfrac{\partial}{\partial x_i}\left[1-e^{\beta_0+\vec{\beta}^T\vec{x}}\right]}{\left(1-e^{\beta_0+\vec{\beta}^T\vec{x}}\right)^2}\\&=\frac{\beta_i\left[e^{\beta_0+\vec{\beta}^T\vec{x}}\right]\left(1-e^{\beta_0+\vec{\beta}^T\vec{x}}\right)+\beta_i e^{\beta_0+\vec{\beta}^T\vec{x}}e^{\beta_0+\vec{\beta}^T\vec{x}}}{\left(1-e^{\beta_0+\vec{\beta}^T\vec{x}}\right)^2}\\&=\frac{\beta_i e^{\beta_0+\vec{\beta}^T\vec{x}}-\beta_i e^{2\beta_0+2\vec{\beta}^T\vec{x}}+\beta_i e^{2\beta_0+2\vec{\beta}^T\vec{x}}}{\left(1-e^{\beta_0+\vec{\beta}^T\vec{x}}\right)^2}\\&=\beta_i\frac{e^{\beta_0+\vec{\beta}^T\vec{x}}}{\left(1-e^{\beta_0+\vec{\beta}^T\vec{x}}\right)^2}\end{aligned}\tag{14.1.785}$$

So this result measures the effect of x_i on $P(Y)$. This effect is a function of x_i. However, the relative importance of two predictors is:

$$\frac{\dfrac{\partial P(Y)}{\partial x_i}}{\dfrac{\partial P(Y)}{\partial x_j}}=\frac{\beta_i}{\beta_j}\tag{14.1.786}$$

which is independent of $\vec{x}$. Thus, provided we have standardized all predictors, we can look at the estimates of the model coefficients as indicators of the relative importance of the predictors for what it concerns the variation of the output.

14.1.12.6.1.2 Binomial logistic regression residuals

Residual analysis for logistic regression is more difficult than for linear regression models because the responses y_i take only the values 0 and 1. Consequently the ith ordinary residual between the real value y_i and the model fitted value, that we will denote now by $\hat{\pi}$, is given obviously by:

$$e_i=y_i-\hat{\pi}_i\tag{14.1.787}$$

And obviously we have that (as y_i take only the values 0 and 1):

$$e_i=\begin{cases}1-\hat{\pi}_i & \text{if } y_i=1\\ -\hat{\pi}_i & \text{if } y_i=0\end{cases}\tag{14.1.788}$$

The ordinary residuals will not be normally distributed and, indeed, their distribution under the assumption that the fitted model is correct is unknown. Plots of ordinary residuals against fitted values or predictor variables will generally be uninformative.

The ordinary residuals can be made more comparable by dividing them by the estimated standard deviation of y_i, namely for the binomial distribution (as we have proved it during our study of the binomial distribution):

$$\sqrt{\hat{\pi}_i\left(1-\hat{\pi}_i\right)}\tag{14.1.789}$$

The resulting "Pearson residuals" are given by:

$$r_{P_i}=\frac{y_i-\hat{\pi}_i}{\sqrt{\hat{\pi}_i\left(1-\hat{\pi}_i\right)}} \tag{14.1.790}$$

If we square:

$$r_{P_i}^2=\frac{\left(y_i-\hat{\pi}_i\right)^2}{\hat{\pi}_i\left(1-\hat{\pi}_i\right)} \tag{14.1.791}$$

Now notice that this can be written:

$$\begin{aligned}r_{P_i}^2&=\frac{\left(y_i-\hat{\pi}_i\right)^2}{\hat{\pi}_i\left(1-\hat{\pi}_i\right)}=\frac{\left(y_i-\hat{\pi}_i\right)^2}{1-\hat{\pi}_i}+\frac{\left(y_i-\hat{\pi}_i\right)^2}{\hat{\pi}_i}\\&=\frac{\left(\left(1-y_i\right)-\left(1-\hat{\pi}_i\right)\right)^2}{1-\hat{\pi}_i}+\frac{\left(y_i-\hat{\pi}_i\right)^2}{\hat{\pi}_i}\end{aligned} \tag{14.1.792}$$

So we recognize here that all the terms are of the form:

$$\frac{(O_i-E_i)^2}{E_i} \tag{14.1.793}$$

Therefore the same applies to the sum of square of the Pearson residuals and we can write the "Pearson chi-square statistic":

$$\sum_{i=1}^{n} r_{P_i}^2=\sum_{i=1}^{n}\frac{\left(y_i-\hat{\pi}_i\right)^2}{\hat{\pi}_i\left(1-\hat{\pi}_i\right)}=\chi^2(n-1) \tag{14.1.794}$$

Hence, we see that the sum of the squares of the Pearson residuals is numerically equal to the Pearson chi-square test statistic. Therefore the square of each Pearson residual measures the contribution of each binary response to the Pearson chi-square test statistic and can be used as an adequation test for our model.

Remark

Notice that some practitioners run not only a chi-square test on residuals but also on the resulting contingency classification table of all discrete x values of the binomial regression. For our example above the corresponding contingency table being:

Credit Amount	Expected	Observed
$27,200$	0	2
$27,700$	0	17
$28,300$	30	26
$28,400$	27	10
$29,900$	28	27

Unfortunately, it is common that there are not enough observations (or even worse...: zero observations) for each possible combinations of values of the x variables, so the Pearson chi-squared statistic cannot be readily calculated (see a practical example in our `R` companion book). A solution to this problem is the Hosmer-Lemeshow statistic (see below). The key concept of the Hosmer-Lemeshow statistic is that, instead of observations being grouped by the values of the x variable(s), the observations are grouped by expected probability. That is, observations with similar expected probability are put into the same group, usually to create approximately 10 groups.

14.1.12.6.1.3 Hosmer–Lemeshow test

The Hosmer–Lemeshow test is a statistical test for goodness of fit for binary logistic regression models (however a generalized Hosmer–Lemeshow goodness-of-fit test for multinomial logistic regression models exists!). It is used frequently in risk prediction models. The test assesses whether or not the observed event rates match expected event rates in subgroups of the model population. The Hosmer–Lemeshow test specifically identifies subgroups as the deciles of fitted risk values. Models for which expected and observed event rates in subgroups are similar are said to be "well calibrated".

The Hosmer-Lemeshow test statistic is given by:

$$\begin{aligned} H &= \sum_{g=1}^{G}\left(\frac{(O_{1g}-E_{1g})^2}{E_{1g}}+\frac{(O_{0g}-E_{0g})^2}{E_{0g}}\right) \\ &= \sum_{g=1}^{G}\left(\frac{(O_{1g}-E_{1g})^2}{N_g\pi_g}+\frac{((N_g-O_{1g})-(N_g-E_{1g}))^2}{N_g(1-\pi_g)}\right) \\ &= \sum_{g=1}^{G}\frac{(O_{1g}-E_{1g})^2}{N_g\pi_g(1-\pi_g)}=\sum_{g=1}^{G}\frac{(O_{1g}-N_g\pi_g)^2}{N_g\pi_g(1-\pi_g)} \end{aligned} \quad (14.1.795)$$

Here $O_{1g}, E_{1g}, O_{0g}, E_{og}, N_g$, and π_g denote the observed $Y=1$ events, expected $Y=1$ events, observed $Y=0$ events, expected $Y=0$ events, total observations, predicted risk for the g^{th} risk decile group, and G is the number of groups. The test statistic asymptotically follows a χ^2 distribution with $G-2$ degrees of freedom (see remark further below!!!). Hence:

$$H=\sum_{g=1}^{G}\frac{(O_{1g}-E_{1g})^2}{N_g\pi_g(1-\pi_g)}=\chi^2_{G-2} \quad (14.1.796)$$

The number of risk groups may be adjusted depending on how many fitted risks are determined by the model. This helps to avoid singular decile groups.

Another very common notation that we can find in textbooks is, given m_j the number of observations:

$$\hat{C}=\sum_{k=1}^{g}\left[\frac{(o_{1k}-\hat{e}_{1k})^2}{\hat{e}_{1k}}+\frac{(o_{0k}-\hat{e}_{0k})^2}{\hat{e}_{0k}}\right] \quad (14.1.797)$$

where:

$$o_{1k}=\sum_{j=1}^{c_k}y_j \quad o_{0k}=\sum_{j=1}^{c_k}(m_j-y_j) \quad \hat{e}_{1k}=\sum_{j=1}^{c_k}m_j\hat{\pi}_j \quad \hat{e}_{0k}=\sum_{j=1}^{c_k}m_j(1-\hat{\pi}_j) \quad (14.1.798)$$

and c_k is the number of covariate patterns in the kth group. With a bit algebra we have therefore:

$$\hat{C}=\sum_{k=1}^{g}\frac{\left(o_{1k}-n_k'\bar{\pi}_k\right)^2}{n_k'\bar{\pi}_k(1-\bar{\pi}_k)} \tag{14.1.799}$$

where $\bar{\pi}_k$ is the average estimated probability in the kth group:

$$\bar{\pi}_k=\frac{1}{n_k'}\sum_{j=1}^{c_k}m_j\hat{\pi}_j \tag{14.1.800}$$

The Hosmer–Lemeshow test seems to have some limitations. Frank Harrell describes several in an answer on the forum *Cross Validated*:

- The Hosmer-Lemeshow test is for overall calibration error, not for any particular lack of fit such as quadratic effects. It does not properly take overfitting into account, is arbitrary to choice of bins and method of computing quantiles, and often has power that is too low.
- For these reasons the Hosmer-Lemeshow test is no longer recommended. Hosmer et al. have a better one df omnibus test of fit, implemented in the `R` software rms package residuals.lrm function.
- Other alternatives have been developed to address the limitations of the Hosmer-Lemeshow test. These include the Osius-Rojek test and the Stukel test.

Remark

In the 11982 (holocene calendar) paper by Lemeshow and Hosmer *A review of goodness of fit statistics for use in the development of logistic regression models*, American Journal of Epidemiology 115:92-106. In this they write (page 96) in reference to their statistic that:

"The theoretical development given by Hosmer and Lemeshow (1980) requires only that $G>(p+1)$."

where p is the number of parameters in the model and following this that:

« Hosmer and Lemeshow (1980) have shown via computer simulations that if the number of covariates plus one is less than the number of groups (i.e. $p+1<G$), then the statistic C_G^* has a distribution which is closely approximated by a chi-square distribution with $G-2$ degrees of freedom when H_0 is true. »

To be more precise, in Hosmer and Lemeshow's 11980 (holocene calendar) paper, Theorem 2 states that the asymptotic distribution of $\hat{C}_g^*$ (the usual Hosmer-Lemeshow test statistic) is:

$$\chi^2_{2g-g-(p+1)}+\sum_{i=1}^{p+1}\lambda_i\chi_i^2(1)$$

where the λ_i are eigenvalues of a matrix (specified in the paper, not relevant to this question). Then, they show through simulations that $\sum_{i=1}^{p+1}\lambda_i\chi_i^2(1)$ is approximately

χ^2_{p-1}, which leads to the usual $g-2$ degrees of freedom in the Hosmer-Lemeshow test.

This means that given our fitted model, the p-value can be calculated as the right hand tail probability of the corresponding chi-squared distribution using the calculated test statistic. If the p-value is small, this is indicative of poor fit.

It should be emphasized, same as any other null hypothesis statistical test, that a large p-value does not mean the model fits well, since lack of evidence against a null hypothesis is not equivalent to evidence in favour of the alternative hypothesis. In particular, if our sample size is small, a high p-value from the test may simply be a consequence of the test having lower power to detect misspecification, rather than being indicative of good fit.

The reader can refer to our `R` companion book where we provide simulation evidence that the above claim is quite accurate!

14.1.12.6.1.4 Logistic Kolmogorov-Smirnov statistic

The "KS Statistic", also named "maximum Kolmogorov-Smirnov vertical difference" or "Kolmogorov-Smirnov statistic", is the maximum difference between the cumulative true positive and cumulative false positive rate. It is often used as the deciding metric to judge the efficacy of models in credit scoring. The higher the KS stat, the more efficient is the model at capturing the responders (Ones).

In other words:

$$\begin{aligned}\text{KS} &= \text{Maximum difference between Cumulative \% Event and Cumulative \% Non-Event}\\ &= \max(\text{True positive rate} - \text{False positive rate})\end{aligned} \tag{14.1.801}$$

More technically and more precise, let us remind, the null hypothesis for a logistic regression of a binary/dichotomous random variable Y_k on real numbers $x_{j,k}$ (with $k=1,2,\ldots,n$, and $j=1,2,\ldots,m \ll n$), given observations $y_1,y_2,\ldots,y_n$ of $Y_1,Y_2,\ldots,Y_n$, respectively, is H_0 : $y_1,y_2,\ldots,y_n$ are draws from independent Bernoulli distributions with means $\hat{\mu}_1,\hat{\mu}_2,\ldots,\hat{\mu}_n$, respectively:

$$\text{logit}\,(\hat{\mu}_k)=\hat{\beta}^{(0)}+\sum_{j=1}^{l}\hat{\beta}^{(j)}x_{j,k} \tag{14.1.802}$$

for $k=1,2,\ldots,n$, where the vector β is a nuisance parameter, $\hat{\beta}$ is its maximum-likelihood estimate, l is a nonnegative integer no greater than m, and:

$$\text{logit}(p)=\ln\left(\frac{p}{1-p}\right) \tag{14.1.803}$$

or something similarly aggregative). A cumulative measure of the distance between the observed data and the model assumed under the null hypothesis is the discrete KolmogorovSmirnov statistic (recommended by Horn (1977) and many others), namely:

$$\boxed{\text{KS}=\max_{1\leq j\leq n}\left|\sum_{k=1}^{j}y_{\sigma_k}-\sum_{k=1}^{j}\hat{\mu}_{\sigma_k}\right|=\max_{1\leq j\leq n}\left|\sum_{k=1}^{j}r_{\sigma_k}\right|} \tag{14.1.804}$$

where the ordering σ is a permutation of the integers $1, 2, \ldots, n$, and the residual r_k is:

$$r_k = y_k - \hat{\mu}_k \tag{14.1.805}$$

for $k = 1, 2, \ldots, n$.

Let us see a small example:

Decile	**Non Event**	**Event**	**% Non Event**	**% Event**	**Cum %Event**	**Cum % Non-Event**	**KS**
1	51	49	5.7%	48.5%	48.5%	5.7%	42.8%
2	81	19	9.0%	18.8%	67.3%	14.7%	52.6%
3	84	16	9.3%	15.8%	83.2%	24.0%	59.1%
4	90	10	10.0%	9.9%	93.1%	34.0%	59.0%
5	95	5	10.6%	5.0%	98.0%	44.6%	53.4%
6	99	1	11.0%	1.0%	99.0%	55.6%	43.4%
7	99	1	11.0%	1.0%	100.0%	66.6%	33.4%
8	100	0	11.1%	0.0%	100.0%	77.8%	22.2%
9	100	0	11.1%	0.0%	100.0%	88.9%	11.1%
10	100	0	11.1%	0.0%	100.0%	100.0%	0.0%

In this case, KS is maximum at third decile and KS score is 59.1. Ideally, it should be in first three deciles and score lies between 40 and 70. And there should not be more than 10 points (in absolute) difference between training and validation KS score. Score above 70 is susceptible and might be overfitting so rigorous validation is required.

Remark

The tests of Hosmer and Lemeshow (11980, 12000 according to holocene calendar) replace the Kolmogorov-Smirnov statistics KS defined earlier above with χ^2 for the model of binomial distributions corresponding to quantiles (typically the deciles) for the estimated means of the postulated Bernoulli distributions. It has also the advantage of being a statistical test rather than a simple statistical estimator.

14.1.12.6.1.5 Equivalence between the 2-sample Wald's Z-test and the Rao score test over logistic regression with a single binary predictor

For information, the proof that follows if provided by .

Remeber that the Wald's Z-statistic for difference in 2 proportions with unpooled variances is of the following form:

$$Z = \frac{\hat{p}_B - \hat{p}_A}{\sqrt{p(1-p)\left(\frac{1}{n_A} + \frac{1}{n_B}\right)}} \sim \mathcal{N}(0,1) \tag{14.1.806}$$

Where $\hat{p}_A$ stands for the estimated probability (sample proportion, $\%$) in the 1st group, $\hat{p_B}$ is the estimated probability in the 2nd group, n_A and n_B denote respective group sizes, and p is the pooled probability:

$$p = \frac{x_A + x_B}{n_A + n_B} \tag{14.1.807}$$

Let's start from the equation of the logistic regression with a single binary predictor:

$$\text{logit}\left(E(Y\,|\,X)\right) = \text{logit}(\hat{p}(Y=1\,|\,X)) = \ln\left(\frac{\hat{p}(Y=1\,|\,X)}{1-\hat{p}(Y=1\,|\,X)}\right) = \beta_0 + X_1\beta_1 \tag{14.1.808}$$

or equivalently, after applying the inverse-logit, i.e. sigmoid function (let's also simplify X_1 to just X):

$$\hat{p}(Y=1\,|\,X) = \frac{e^{\beta_0+X\beta_1}}{1+e^{\beta_0+X\beta_1}} = \frac{e^{\eta}}{1+e^{\eta}} \tag{14.1.809}$$

where Y_i are independent Bernoulli random variables with probabilities p_i. The second, simpler form with $\eta = \beta_0 + X\beta_1$ will facilitate later calculations.

Let's also encode the two levels $\{A, B\}$ using a single binary predictor X such that: $A : X = 0, B : \mathrm{X} = 1$, let's simplify notation and express $\hat{p}_A$ and $\hat{p}_B$ in terms of beta coefficients:

$$\begin{cases} \hat{p}_A = P(Y=1, X=0) = \frac{e^{\beta_0}}{1+e^{\beta_0}} \\ \hat{p}_B = P(Y=1, X=1) = \frac{e^{\beta_0+\beta_1}}{1+e^{\beta_0+\beta_1}} \end{cases} \tag{14.1.810}$$

As in this special case the classification is binary but also X is discrete, we cannot have any error on the estimator $\hat{p}_i$ so we will write them without the hat symbol.

Under H_0, i.e. $\beta_1 = 0, \hat{p}_A = \hat{p}_B$ and the best estimator of this common proportion is the pooled proportion p. Let's find its form. We need to assume that the data consists of two independent binomial samples:

$$\begin{cases} \text{group } A = X_A : \text{ Binomial } (n_A, p_A) \\ \text{group } B = X_B : \text{ Binomial } (n_B, p_B) \end{cases} \tag{14.1.811}$$

So the likelihood function is:

$$L\left(p_A, p_B\right) = \binom{n_A}{x_A} p_A^{x_A}\left(1-p_A\right)^{n_A-x_A} \cdot \binom{n_B}{x_B} p_B^{x_B}\left(1-p_B\right)^{n_B-x_B} \tag{14.1.812}$$

where x_A and x_B are the observed number of successes in groups A and B, respectively, and n_A and n_B are the total sample sizes in each group.

Under the null hypothesis $H_0 : p_A = p_B = p_{\text{pooled}}$. The pooled p is of some form yet unknown. Knowing that:

$$\begin{aligned} L\left(p_{\text{pooled}}\right) &= \binom{n_A}{x_A}\binom{n_B}{x_B} p_{\text{pooled}}^{x_A+x_B}\left(1-p_{\text{pooled}}\right)^{(n_A-x_A)+(n_B-x_B)} \\ &= \binom{n_A}{x_A}\binom{n_B}{x_B} p_{\text{pooled}}^{x_A+x_B}\left(1-p_{\text{pooled}}\right)^{(n_A+n_B-x_A-x_B)} \end{aligned} \tag{14.1.813}$$

We get a single binomial likelihood where the total number of successes is $x_A + x_B$ and the total number of trials is $n_A + n_B$, i.e.:

$$X_A + X_B : \text{ Binomial}\left(n_A + n_B, p_{\text{pooled}}\right) \tag{14.1.814}$$

Now, the log-likelihood, $\log(L(p_{\text{pooled}}))=\mathcal{L}(p_{\text{pooled}})$, is given by:

$$\mathcal{L}(p_{\text{pooled}})=c^{te}\cdot(x_A+x_B)\cdot\log(p_{\text{pooled}})+(n_A+n_B-x_A-x_B)\cdot\log(1-p_{\text{pooled}}) \tag{14.1.815}$$

We wrote c^{te} to highlight that this term will disappear after taking the derivative further below.

Now by taking ${}^{\mathrm{d}\mathcal{L}}/_{\mathrm{d}p_{\text{pooled}}}$:

$$\begin{aligned}\frac{\mathrm{d}\mathcal{L}(p_{\text{pooled}})}{\mathrm{d}p_{\text{pooled}}}=\frac{x_A+x_B}{p_{\text{pooled}}}-\frac{n_A+n_B-x_A-x_B}{1-p_{\text{pooled}}}&=0\\(x_A+x_B)(1-p_{\text{pooled}})&=(n_A+n_B-x_A-x_B)\cdot p_{\text{pooled}}\\x_A+x_B&=(n_A+n_B)\cdot p_{\text{pooled}}\\p_{\text{pooled}}&=\frac{x_A+x_B}{n_A+n_B}\end{aligned} \tag{14.1.816}$$

Or, alternatively, since $p_i={}^{x_i}/_{n_i}$:

$$p_{\text{pooled}}=\frac{p_An_A+p_Bn_B}{n_A+n_B} \tag{14.1.817}$$

The log-likelihood function of the logistic regression with a single binary predictor is of the form:

$$\mathcal{L}(\vec{\beta})=\log(L(\vec{\beta}))=\log\left(\prod_{i=1}^{n}p_i^{y_i}\cdot(1-p_i)^{1-y_i}\right)=\sum_{i=1}^{n}\left[y_i\log\left(p_i\right)+(1-y_i)\log\left(1-p_i\right)\right] \tag{14.1.818}$$

where $\vec{\beta}$ is the vector of estimated coefficients, i.e. (β_0,β_1).

Let's express p and $1-p$ in terms of $\eta=\beta_0+X\beta_1$:

$$\begin{cases}p=\frac{e^{\eta}}{1+e^{\eta}}\\1-p=\frac{1}{1+e^{\eta}}\end{cases} \tag{14.1.819}$$

Then:

$$\begin{aligned}\mathcal{L}(\vec{\beta})&=\sum_{i=1}^{n}\left[y_i\log\left(\frac{e^{\eta_i}}{1+e^{\eta_i}}\right)+(1-y_i)\log\left(\frac{1}{1+e^{\eta_i}}\right)\right]\\&=\sum_{i=1}^{n}\left[y_i\left(\log\left(e^{\eta_i}\right)-\log\left(1+e^{\eta_i}\right)\right)-(1-y_i)\log\left(1+e^{\eta_i}\right)\right]\\&=\sum_{i=1}^{n}\left[y_i\eta_i-y_i\log\left(1+e^{\eta_i}\right)-(1-y_i)\log\left(1+e^{\eta_i}\right)\right]\\&=\sum_{i=1}^{n}y_i\eta_i-\log\left(1+e^{\eta_i}\right)\end{aligned} \tag{14.1.820}$$

We will now need both the gradient and Hessian (see section Sequences and Series page 1715) of this log-likelihood. For future use, we will name the gradient as "Rao score function" denoted by $\vec{U}$ and the Hessian matrix as H. First, let's find the form of $U(\vec{\beta})$:

$$\vec{U}(\vec{\beta})=\begin{bmatrix}\frac{\partial\mathcal{L}(\vec{\beta})}{\partial\beta_0}\\\frac{\partial\mathcal{L}(\vec{\beta})}{\partial\beta_1}\end{bmatrix} \tag{14.1.821}$$

By noticing that:

$$\frac{\partial \eta_i}{\partial \beta_0}=1,\ \frac{\partial \eta_i}{\partial \beta_1}=x_i \tag{14.1.822}$$

and remembering that:

$$p=\frac{e^{\eta}}{1+e^{\eta}} \tag{14.1.823}$$

we get:

$$\frac{\partial \mathcal{L}(\vec{\beta})}{\partial \beta_0}=\sum_{i=1}^{n}\left(y_i\frac{\partial \eta_i}{\partial \beta_0}-\frac{1}{1+e^{\eta_i}}e^{\eta_i}\frac{\partial \eta_i}{\partial \beta_0}\right)=\sum_{i=1}^{n}\left(y_i.1-\frac{e^{\eta_i}}{1+e^{\eta_i}}\cdot 1\right)=\sum_{i=1}^{n}(y_i-p_i) \tag{14.1.824}$$

and:

$$\frac{\partial \mathcal{L}(\vec{\beta})}{\partial \beta_1}=\sum_{i=1}^{n}\left(y_i\frac{\partial \eta_i}{\partial \beta_1}-\frac{1}{1+e^{\eta_i}}e^{\eta_i}\frac{\partial \eta_i}{\partial \beta_1}\right)=\sum_{i=1}^{n}\left(y_ix_i-\frac{e^{\eta_i}}{1+e^{\eta_i}}x_i\right)=\sum_{i=1}^{n}x_i(y_i-p_i) \tag{14.1.825}$$

So finally we have for the Rao score function:

$$U(\vec{\beta})=\begin{bmatrix}\sum_{i=1}^{n}(y_i-p_i)\\ \sum_{i=1}^{n}x_i(y_i-p_i)\end{bmatrix} \tag{14.1.826}$$

Now, the Hessian:

$$H(\vec{\beta})=\begin{bmatrix}\frac{\partial^2 \mathcal{L}(\vec{\beta})}{\partial \beta_0^2} & \frac{\partial^2 \mathcal{L}(\vec{\beta})}{\partial \beta_0\beta_1}\\ \frac{\partial^2 \mathcal{L}(\vec{\beta})}{\partial \beta_1\beta_0} & \frac{\partial^2 \mathcal{L}(\vec{\beta})}{\partial \beta_1^2}\end{bmatrix} \tag{14.1.827}$$

The partial derivatives are as follows:

$$\begin{gathered}\frac{\partial^2 \mathcal{L}(\vec{\beta})}{\partial \beta_0^2}=\frac{\partial}{\partial \beta_0}\sum_{i=1}^{n}(y_i-p_i)=\sum_{i=1}^{n}-\frac{\partial p_i}{\partial \beta_0}=-\sum_{i=1}^{n}\frac{\partial p_i}{\partial \beta_0}=-\sum_{i=1}^{n}\frac{\partial p_i}{\partial \eta_0}\frac{\partial \eta_0}{\partial \beta_0}=-\sum_{i=1}^{n}p_i(1-p_i)\\ \frac{\partial^2 \mathcal{L}(\vec{\beta})}{\partial \beta_1^2}=\frac{\partial}{\partial \beta_1}\sum_{i=1}^{n}x_i(y_i-p_i)=\sum_{i=1}^{n}x_i\left(-\frac{\partial p_i}{\partial \beta_1}\right)=-\sum_{i=1}^{n}x_ip_i(1-p_i)x_i=-\sum_{i=1}^{n}x_i^2p_i(1-p_i)\\ \frac{\partial^2 \mathcal{L}(\vec{\beta})}{\partial \beta_0\beta_1}=\frac{\partial^2 \mathcal{L}(\vec{\beta})}{\partial \beta_1\beta_0}=\frac{\partial}{\partial \beta_1}\sum_{i=1}^{n}(y_i-p_i)=-\sum_{i=1}^{n}\frac{\partial p_i}{\partial \beta_1}=-\sum_{i=1}^{n}p_i(1-p_i)x_i\end{gathered} \tag{14.1.828}$$

Therefore:

$$H(\vec{\beta})=\begin{bmatrix}-\sum_{i=1}^{n}p_i(1-p_i) & -\sum_{i=1}^{n}p_i(1-p_i)x_i\\ -\sum_{i=1}^{n}p_i(1-p_i)x_i & -\sum_{i=1}^{n}x_i^2p_i(1-p_i)\end{bmatrix} \tag{14.1.829}$$

Let's also determine the Fisher Information matrix (see section Statistics 839):

$$I(\beta) = -\mathrm{E}(H(\vec{\beta})) = \begin{bmatrix} \sum_{i=1}^{n} p_i\left(1-p_i\right) & \sum_{i=1}^{n} p_i\left(1-p_i\right)x_i \\ \sum_{i=1}^{n} p_i\left(1-p_i\right)x_i & \sum_{i=1}^{n} x_i^2 p_i\left(1-p_i\right) \end{bmatrix} = \begin{bmatrix} \sum_{i=1}^{n} p_i q_i & \sum_{i=1}^{n} p_i q_i x_i \\ \sum_{i=1}^{n} p_i q_i x_i & \sum_{i=1}^{n} p_i q_i x_i^2 \end{bmatrix} \tag{14.1.830}$$

where $q_i = 1 - p_i$.

Remark

As the Hessian matrix above doesn't content any estimator (no variable with a hat symbol!), but only directly perfectly known observed quantities, its mean expectation is equal to itself!

This can be further expanded, by substituting sums with appropriate (per respective group, A and B) counts of elements, remembering that $n = n_A + n_B,\ \mathrm{A}: X = 0,\ \mathrm{B}: X = 1, p_A = p(Y = 1 \,|\, X = A)$ and $p_B = p(Y = 1 \,|\, X = B)$, and:

$$I(\vec{\beta}) = \begin{bmatrix} \sum\limits_{i:X_i=0} p_i q_i + \sum\limits_{i:X_i=1} p_i q_i & \sum\limits_{i:X_i=1} 1 p_i q_i \\ \sum\limits_{i:X_i=1} 1 p_i q_i & \sum\limits_{i:X_i=1} 1 p_i q_i \end{bmatrix} = \begin{bmatrix} n_A p_A q_A + n_B p_B q_B & n_B p_B q_B \\ n_B p_B q_B & n_B p_B q_B \end{bmatrix} \tag{14.1.831}$$

Let us see now the Rao Score and Information Matrix under $H_0 : \beta_1 = 0$.

We start with the Rao Score vector, and for this purpose remember that n_A and n_B depict the respective number of individuals corresponding to group A and B, for group $A : X = 0$ and for $B : X = 1$ and $n = n_A + n_B$. Also, under $H_0, p_A = p_B = p$ (i.e. $\forall_i p_i = p$), where p is the pooled probability. Therefore:

$$U\left(\beta_0, \beta_1 = 0\right) = \begin{bmatrix} \sum_{i=1}^{n}\left(y_i - p_i\right) \\ \sum_{i=1}^{n} x_i\left(y_i - p_i\right) \end{bmatrix} = \begin{bmatrix} \left(\sum_{i=1}^{n} y_i\right) - \left(n_A + n_B\right)\cdot p \\ \left(\sum\limits_{i:X_i=1} y_i\right) - n_B p \end{bmatrix} \tag{14.1.832}$$

Here, y_i is the response vector containing $1s$ in respective group. Summing all those 1s yields the total number of successes in this group, which can be expressed as:

$$\sum_{i=1}^{n} y_i = \sum_{i:X_i\in\{0,1\}} y_i = n_A p_A + n_B p_B \overset{H_0}{\Rightarrow} \left(n_A + n_B\right)\cdot p \tag{14.1.833}$$

So, the first element of the vector becomes 0 out and finally:

$$U\left(\beta_0, \beta_1 = 0\right) = \begin{bmatrix} 0 \\ n_B\left(p_B - p\right) \end{bmatrix} \tag{14.1.834}$$

Now for the Information matrix:

$$I(\vec{\beta})=\begin{bmatrix} n_A p_A q_A + n_B p_B q_B & n_B p_B q_B \\ n_B p_B q_B & n_B p_B q_B \end{bmatrix} \tag{14.1.835}$$

we get under the same hypothesis $H_0: p_A=p_B=p$:

$$I\left(\beta_0,\beta_1=0\right)=\begin{bmatrix} pq\left(n_A+n_B\right) & n_B pq \\ n_B pq & n_B pq \end{bmatrix} \tag{14.1.836}$$

Let's also calculate I^{-1} (see section Linear Algebra 1981):

$$\Sigma=I\left(\beta_0,\beta_1=0\right)^{-1}=\frac{1}{pq\left(n_A+n_B\right)\cdot n_B pq-\left(n_B pq\right)^2}\begin{bmatrix} n_B pq & -n_B pq \\ -n_B pq & pq\left(n_A+n_B\right) \end{bmatrix} \tag{14.1.837}$$

After simplifying the denominator term:

$$pq\left(n_A+n_B\right)\cdot n_B pq-\left(n_B pq\right)^2=p^2q^2n_An_B+p^2q^2n_B^2-p^2q^2n_B^2=p^2q^2n_An_B \tag{14.1.838}$$

we finally get:

$$\Sigma\left(\beta_0,\beta_1=0\right)=I\left(\beta_0,\beta_1=0\right)^{-1}=\frac{1}{p^2q^2n_An_B}\begin{bmatrix} n_B pq & -n_B pq \\ -n_B pq & pq\left(n_A+n_B\right) \end{bmatrix}=\begin{bmatrix} \frac{1}{n_Apq} & -\frac{1}{n_Apq} \\ -\frac{1}{n_Ap^2} & \frac{n_A+n_B}{n_An_Bpq} \end{bmatrix} \tag{14.1.839}$$

The "Rao score test", named also "Lagrange multiplier test", under H_0 is defined as the following quadratic form:

$$\boxed{R=U\left(\beta_0,\beta_1=0\right)^T\cdot I\left(\beta_0,\beta_1=0\right)^{-1}\cdot U\left(\beta_0,\beta_1=0\right)} \tag{14.1.840}$$

But since the first element of U is 0, this reduces to just scalar operation:

$$R=U\cdot I^{-1}\cdot U=U^2\Sigma \tag{14.1.841}$$

$$\begin{aligned} R&=U\left(\beta_0,\beta_1=0\right)^2\Sigma\left(\beta_0,\beta_1=0\right)\\ &=\left[n_B\left(p_B-p\right)\right]^2\cdot\frac{n_A+n_B}{pqn_An_B}=\frac{\left[n_B\left(p_B-p\right)\right]^2}{pq\frac{n_An_B}{n_A+n_B}}\\ &=\frac{n_B^2\left(p_B-\frac{n_Ap_A+n_Bp_B}{n_A+n_B}\right)^2}{pq\frac{n_An_B}{n_A+n_B}}=\frac{n_B^2\left(\frac{p_Bn_A+p_Bn_B-n_Ap_A-n_Bp_B}{n_A+n_B}\right)^2}{pq\frac{n_An_B}{n_A+n_B}}\\ &=\frac{\frac{n_B^2\left(p_Bn_A-n_Ap_A\right)^2}{\left(n_A+n_B\right)^2}}{pq\frac{n_An_B}{n_A+n_B}}=\frac{\frac{n_B^2n_A^2\left(p_B-p_A\right)^2}{\left(n_A+n_B\right)^2}}{pq\frac{n_An_B}{n_A+n_B}}\\ &=\frac{\left(p_B-p_A\right)^2}{pq\frac{n_An_B}{n_A+n_B}\frac{\left(n_A+n_B\right)^2}{n_B^2n_A^2}}=\frac{\left(p_B-p_A\right)^2}{pq\frac{n_A+n_B}{n_An_B}}=\frac{\left(p_B-p_A\right)^2}{pq\left(\frac{1}{n_B}+\frac{1}{n_A}\right)}\\ &=\frac{\left(p_B-p_A\right)^2}{p(1-p)\left(\frac{1}{n_A}+\frac{1}{n_B}\right)}=Z^2 \end{aligned} \tag{14.1.842}$$

And this finish the proof of the equivalence between the 2-sample Wald's Z-test and the Rao score test over logistic regression with a single binary predictor.

A practical and numerical example is provided in our `R` companion book.

14.1.12.6.2 Multinomial Logistic regression

"Multinomial logistic regression" is a classification method that generalizes logistic regression to multiclass problems, i.e. with more than two possible discrete outcomes. That is, it is a model that is used to predict the probabilities of the different possible outcomes of a categorically distributed dependent variable, given a set of independent variables (which may be real-valued, binary-valued, categorical-valued, etc.).

Multinomial logistic regression is known by a variety of other names, "including polytomous LR", "multiclass LR", "softmax regression", "multinomial logit", the "maximum entropy (MaxEnt) classifier", and the "conditional maximum entropy model".

The basic setup is the same as in logistic regression, the only difference being that the dependent variables are categorical rather than binary, i.e. there are K possible outcomes rather than just two. The following description is somewhat shortened.

As in other forms of linear regression, multinomial logistic regression uses a linear predictor function $f(k,i)$ to predict the probability that observation i has outcome k, of the following form:

$$f(k,i)=\beta_{0,k}+\beta_{1,k}x_{1,i}+\beta_{2,k}x_{2,i}+\cdots+\beta_{M,k}x_{M,i} \tag{14.1.843}$$

where $\beta_{m,k}$ is a regression coefficient associated with the mth explanatory variable and the kth outcome. As it is common, the regression coefficients and explanatory variables are normally grouped into vectors of size $M+1$, so that the predictor function can be written more compactly:

$$f(k,i)=\vec{\beta}_k\circ\vec{x}_i \tag{14.1.844}$$

where $\vec{\beta}_k$ is the set of regression coefficients associated with outcome k, and $\vec{x}_i$ (a row vector) is the set of explanatory variables associated with observation i.

One fairly simple way to arrive at the multinomial logit model is to imagine, for K possible outcomes, running $K-1$ independent binary logistic regression models, in which one outcome is chosen as a "pivot" and then the other $K-1$ outcomes are separately regressed against the pivot outcome. This would proceed as follows, if outcome K (the last outcome) is chosen as the pivot:

$$\begin{aligned}\ln\left(\dfrac{P(Y_i=1)}{P(Y_i=K)}\right)&=\vec{\beta}_1\circ\vec{x}_i\\ \ln\left(\dfrac{P(Y_i=2)}{P(Y_i=K)}\right)&=\vec{\beta}_2\circ\vec{x}_i\\ &\cdots\\ \ln\left(\dfrac{P(Y_i=K-1)}{P(Y_i=K)}\right)&=\vec{\beta}_{K-1}\circ\vec{x}_i\end{aligned} \tag{14.1.845}$$

Note that we have introduced separate sets of regression coefficients, one for each possible outcome.

That latter relation is also often denoted:

$$\ln\left(\frac{\pi_i^{(j)}}{\pi_i^0}\right)=\alpha^{(j)}+\beta_1^{(j)}X_{1i}+\ldots+\beta_k^{(j)}X_{ki} \tag{14.1.846}$$

for each $j=1,\ldots,K-1$.

If we exponentiate both sides, and solve for the probabilities, we get:

$$\begin{aligned}P(Y_i=1)&=P(Y_i=K)e^{\vec{\beta}_1\circ\vec{x}_i}\\P(Y_i=2)&=P(Y_i=K)e^{\vec{\beta}_2\circ\vec{x}_i}\\&\ldots\\P(Y_i=K-1)&=P(Y_i=K)e^{\vec{\beta}_{K-1}\circ\vec{x}_i}\end{aligned} \tag{14.1.847}$$

Using the fact that all K of the probabilities must sum to one, we find:

$$P(Y_i=K)=1-\sum_{k=1}^{K-1}P(Y_i=k)=1-\sum_{k=1}^{K-1}\mathrm{Pr}(Y_i=K)e^{\vec{\beta}_k\circ\vec{x}_i}\Rightarrow P(Y_i=K)=\frac{1}{1+\displaystyle\sum_{k=1}^{K-1}e^{\vec{\beta}_k\circ\vec{x}_i}} \tag{14.1.848}$$

That latter relation is also often denoted (notation that we will use further below):

$$P(Y_i=J)=\pi_{iJ}=\frac{1}{1+\displaystyle\sum_{j=1}^{J-1}e^{\vec{\beta}_j\circ\vec{x}_i}} \tag{14.1.849}$$

Re-injecting in the previous relations sets, we get:

$$\begin{aligned}P(Y_i=1)&=\frac{e^{\vec{\beta}_1\circ\vec{x}_i}}{1+\displaystyle\sum_{k=1}^{K-1}e^{\vec{\beta}_k\circ\vec{x}_i}}\\P(Y_i=2)&=\frac{e^{\vec{\beta}_2\circ\vec{x}_i}}{1+\displaystyle\sum_{k=1}^{K-1}e^{\vec{\beta}_k\circ\vec{x}_i}}\\&\ldots\\P(Y_i=K-1)&=\frac{e^{\vec{\beta}_{K-1}\circ\vec{x}_i}}{1+\displaystyle\sum_{k=1}^{K-1}e^{\vec{\beta}_k\circ\vec{x}_i}}\end{aligned} \tag{14.1.850}$$

Hence:

$$\boxed{P(Y_i=k)=\frac{e^{\vec{\beta}_k\circ\vec{x}_i}}{1+\displaystyle\sum_{k=1}^{K}e^{\vec{\beta}_k\circ\vec{x}_i}}=\frac{e^{\vec{\beta}_k^T\vec{x}_i}}{1+\displaystyle\sum_{k=1}^{K}e^{\vec{\beta}_k^T\vec{x}_i}}} \tag{14.1.851}$$

Often denoted (as the sum in the denominator is a constant[26]):

$$P(Y_i = k) = \frac{e^{\vec{\beta}_k \circ \vec{x}_i}}{1+Z} \tag{14.1.852}$$

The fact that we run multiple regressions reveals why the model relies on the assumption of independence of irrelevant alternatives!

Note that the prior-previous relation is also denoted:

$$P(Y_i = j) = \pi_{ij} = \frac{e^{\vec{\beta}_j \circ \vec{x}_i}}{1+\displaystyle\sum_{k=1}^{K} e^{\vec{\beta}_j \circ \vec{X}_i}} \tag{14.1.853}$$

So we have:

$$\boxed{\begin{aligned} P(Y_i = j) = \pi_{ij} &= \frac{e^{\vec{\beta}_j \circ \vec{x}_i}}{1+\displaystyle\sum_{k=1}^{K} e^{\vec{\beta}_j \circ \vec{x}_i}} \quad j<J \\ P(Y_i = J) = \pi_{iJ} &= \frac{1}{1+\displaystyle\sum_{j=1}^{J-1} e^{\vec{\beta}_j \circ \vec{x}_i}} \end{aligned}} \tag{14.1.854}$$

Remark

Note that when $K=2$ the multinomial and logistic regression models become one and the same. Also for information, the softmax function is used in multi-class classification neural networks as activation function as we will see further below during our study of neural networks (page 6951).

The following function:

$$\text{softmax}(k, x_1, \ldots, x_n) = \frac{e^{x_k}}{\displaystyle\sum_{i=1}^{n} e^{x_i}} \tag{14.1.855}$$

is referred to as the "softmax function". The reason is that the effect of exponentiating the values $x_1, \ldots, x_n$ is to exaggerate the differences between them. As a result $\text{softmax}(k, x_1, \ldots, x_n)$ will return a value close to 0 whenever x_k is significantly less than the maximum of all the values, and will return a value close to 1 when applied to the maximum value, unless it is extremely close to the next-largest value.

When using multinomial logistic regression, one category of the dependent variable is chosen as the reference category. Separate odds ratios are determined for all independent variables for each category of the dependent variable with the exception of the reference category, which is omitted from the analysis. The exponential beta coefficient represents the change in the odds of the dependent variable being in a particular category vis-a-vis the reference category, associated with a one unit change of the corresponding independent variable.

---

[26] However, it is definitely not constant with respect to the explanatory variables, or crucially, with respect to the unknown regression coefficients $\vec{\beta}_k$, which we will need to determine through some sort of optimization procedure.

Following the request of a reader, here is the maximum likelihood approach of the logistic regression.

Let us recall that the multinomial distribution is given (see section Statistics page 679) by:

$$\mathcal{M}(\vec{k},\vec{p},m)=\frac{n!}{\prod\limits_{i=1}^{m}k_i!}\prod_{i=1}^{m}p_i^{k_i}=\frac{\left(\sum\limits_{i=1}^{m}k_i\right)!}{\prod\limits_{i=1}^{m}k_i!}\prod_{i=1}^{m}p_i^{k_i}=\binom{n}{k_1,k_2,\ldots,k_m}\prod_{i=1}^{m}p_i^{k_i} \qquad (14.1.856)$$

In other words if there are m random variables, i.e. X_i, $i\in[1,n]$, where X_i represents the number of occurrences of item i in a choice of n items, with entry i in the vector of probabilities $\vec{P}$, P_i giving the probability of drawing item i. The probability of selecting k_1 of item 1... k_m of item m is then given by $\mathcal{M}$ above!

Remark

Remember that if $m=2$ then the above relation becomes:

$$\mathcal{M}=\frac{(k_1+k_2)!}{k_1!k_2!}p_1^{k_1}p_2^{k_2} \qquad (14.1.857)$$

But as $k_1+k_2=n$ then:

$$\mathcal{M}=\frac{n!}{k_1!(n-k_1)!}p_1^{k_1}p_2^{n-k_1} \qquad (14.1.858)$$

and as $p_1+p_2=1$ we finally have:

$$\mathcal{M}=\frac{n!}{k_1!(n-k_1)!}p_1^{k_1}(1-p_1)^{n-k_1} \qquad (14.1.859)$$

We recognize here the binomial distribution!

Let us denote the joint probability density (likelihood) function for the multinomial logistic function as:

$$L(D,\vec{\beta})=\prod_{i=1}^{N}\left[\frac{n_i!}{\prod_{j=1}^{J}y_{ij}!}\prod_{j=1}^{J}\pi_{ij}^{y_{ij}}\right] \qquad (14.1.860)$$

Since we want to maximize the above relation with respect to $\vec{\beta}$, the factorial terms that do not contain any of the π_{ij} terms can be treated as constants. Thus, the kernel of the log likelihood function for multinomial logistic regression models is:

$$L(D,\vec{\beta})\propto\prod_{i=1}^{N}\prod_{j=1}^{J}\pi_{ij}^{y_{ij}} \qquad (14.1.861)$$

Replacing the Jth terms, the previous relations becomes:

$$\begin{aligned}L(D,\vec{\beta}) &\propto \prod_{i=1}^{N}\prod_{j=1}^{J-1}\pi_{ij}^{y_{ij}}\pi_{iJ}^{n_i-\sum_{j=1}^{J-1}y_{ij}}\\ &=\prod_{i=1}^{N}\prod_{j=1}^{J-1}\pi_{ij}^{y_{ij}}\frac{\pi_{iJ}^{n_i}}{\pi_{iJ}^{\sum_{j=1}^{J-1}y_{ij}}}\\ &=\prod_{i=1}^{N}\prod_{j=1}^{J-1}\pi_{ij}^{y_{ij}}\frac{\pi_{iJ}^{n_i}}{\prod_{j=1}^{J-1}\pi_{iJ}^{y_{ij}}}\end{aligned} \tag{14.1.862}$$

Since $a^{x+y}=a^x a^y$, the sum in the exponent in the denominator of the last term becomes a product over the first $J-1$ terms of j. Continue by grouping together the terms that are raised to the y_{ij} power for each j up to $J-1$:

$$L(D,\vec{\beta}) \propto \prod_{i=1}^{N}\prod_{j=1}^{J-1}\left(\frac{\pi_{ij}}{\pi_{iJ}}\right)^{y_{ij}}\pi_{iJ}^{n_i} \tag{14.1.863}$$

Now we substitute for π_{ij} and π_{iJ} the both relations that we have derived earlier:

$$\begin{aligned}P(Y_i=j)=\pi_{ij}&=\frac{e^{\vec{\beta}_j\circ\vec{x}_i}}{1+\sum\limits_{k=1}^{K}e^{\vec{\beta}_j\circ\vec{X}_i}} \qquad j<J\\ P(Y_i=J)=\pi_{iJ}&=\frac{1}{1+\sum\limits_{j=1}^{J-1}e^{\vec{\beta}_j\circ\vec{X}_i}}\end{aligned} \tag{14.1.864}$$

This gives us then:

$$\begin{aligned}L(D,\vec{\beta}) &\propto \prod_{i=1}^{N}\prod_{j=1}^{J-1}\left(e^{\vec{\beta}_j\circ\vec{X}_i}\right)^{y_{ij}}\left(\frac{1}{1+\sum\limits_{j=1}^{J-1}e^{\vec{\beta}_j\circ\vec{X}_i}}\right)^{n_i}\\ &=\prod_{i=1}^{N}\prod_{j=1}^{J-1}e^{y_{ij}\vec{\beta}_j\circ\vec{X}_i}\left(1+\sum_{j=1}^{J-1}e^{\vec{\beta}_j\circ\vec{X}_i}\right)^{-n_i}\end{aligned} \tag{14.1.865}$$

Taking the logarithm of the above relation gives us the log-likelihood function for the multinomial logistic regression model:

$$\ln(L(D,\vec{\beta}))\propto\sum_{i=1}^{N}\sum_{j=1}^{J-1}\left(y_{ij}\vec{\beta}_j\circ\vec{X}_i\right)-n_i\ln\left(1+\sum_{j=1}^{J-1}e^{\vec{\beta}_j\circ\vec{X}_i}\right) \tag{14.1.866}$$

14.1.12.6.2.1 F_1 score

Now that we have introduced a well known multiclass classifier, it is time to introduce the "F_1 score" (also named "F-score" or "F-measure") which is a measure of a classifier quality (among many others empirical quality indicators...). It considers both the precision P and the recall R of the test to compute the score. To introduce these two indicators, let us consider for companion example, the following generic three-class ($n=3$) confusion matrix $\mathcal{C}$ for a total of N records to classify:

		Predicted		
		Class 1	**Class** 2	**Class** 3
Actual	**Class** 1	$\mathcal{C}_{11}$	$\mathcal{C}_{12}$	$\mathcal{C}_{13}$
	Class 2	$\mathcal{C}_{21}$	$\mathcal{C}_{22}$	$\mathcal{C}_{23}$
	Class 3	$\mathcal{C}_{31}$	$\mathcal{C}_{32}$	$\mathcal{C}_{33}$

Table 14.14: **A typical three class confusion matrix**

Let us recall first that the "accuracy" is given by:

$$\text{ACC}=\frac{\text{tr}(\mathcal{C})}{N} \tag{14.1.867}$$

The "precision" P_i for a multiclass classifier (of n classes) is defined as the fraction of correct predictions for a certain class[27]!:

$$P_i=\frac{\mathcal{C}_{ii}}{\sum\limits_j \mathcal{C}_{ij}} \tag{14.1.868}$$

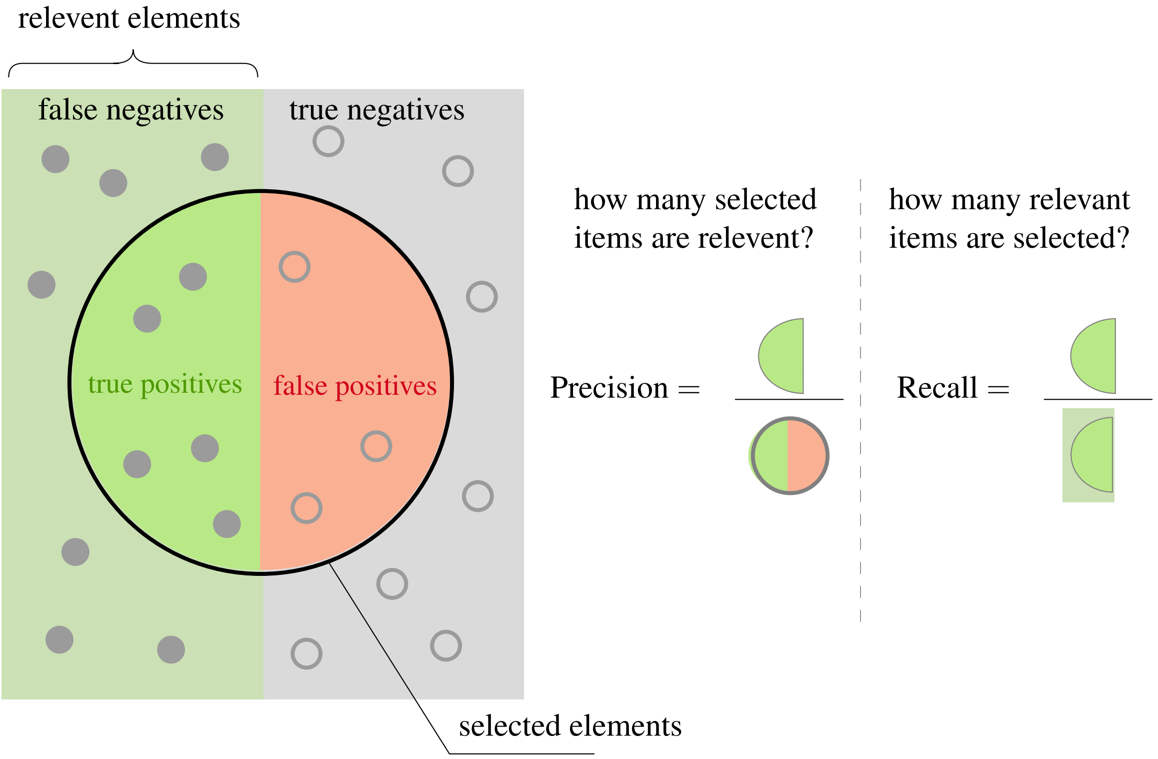
and the "recall" R_i for a multiclass classifier (of n classes) is the number of correct positive results divided by the number of all relevant samples (all samples that should have been identified as positive):

$$R_i=\frac{\mathcal{C}_{ii}}{\sum\limits_j \mathcal{C}_{ji}} \tag{14.1.869}$$

This can nicely be illustrated as following:

---

[27] For a practical example, see our `R` companion book on the F-score.



relevent elements
false negatives
true negatives
true positives
false positives
selected elements
how many selected items are relevent?
how many relevant items are selected?
Precision =
Recall =

Figure 14.24: **Precision and Recall (source: Wikipedia)**

The F_1 score is the harmonic average of the precision and recall (for a given class i) where a F_1 score reaches its best value at 1 (perfect precision and recall) and worst at 0 (it will seems obvious to the reader with the details given further below).

The F-score is also used in Machine Learning as a suitable measure of models tested with unbalanced datasets. Note, however, that the F-measures do not take the true negatives into account, and that measures such as the Matthews correlation coefficient, Informedness or Cohen's kappa may be preferable to assess the performance of a binary classifier.

David Hand and others criticize the widespread use of the F-score since it gives equal importance to precision and recall. In practice, different types of miss-classifications incur different costs. In other words, the relative importance of precision and recall is an aspect of the problem.

Remark

The text that follows is completely inspired and copied from the excellent publication of Professor Yutaka Sasaki (see [479]) with it's kind authorization.

The F-measure is defined as a harmonic mean (see section Statistics page 563) of precision P and recall R:

$$F = \frac{2PR}{P+R} \quad (14.1.870)$$

If you are satisfied with this definition and need no further information, that's it. However, if you are deeply interested in the definition of the F-measure, you should recap the definitions of the arithmetic and harmonic means.

The arithmetic mean μ_a (an average in a usual sense) and the harmonic mean μ_h are defined for recall as follows:

$$\begin{aligned}\mu_a &= \frac{1}{n}\sum_{i=1}^{n} x_i = \frac{1}{n}(x_1+x_2+\ldots+x_n)\\ \mu_h &= \frac{n}{\displaystyle\sum_{i=1}^{n}\frac{1}{x_i}} = \frac{n}{\dfrac{1}{x_1}+\ldots+\dfrac{1}{x_n}}\end{aligned} \tag{14.1.871}$$

When $x_1 = P$ and $x_2 = R$, μ_a and μ_h will be:

$$\begin{aligned}\mu_a &= \frac{1}{2}(P+R)\\ \mu_h &= \frac{2}{\dfrac{1}{P}+\dfrac{1}{R}} = \frac{2}{\dfrac{P+R}{PR}} = \frac{2PR}{P+R}\end{aligned} \tag{14.1.872}$$

Let us recall that harmonic mean is more intuitive than the arithmetic mean when computing a mean of ratios. Indeed, suppose that you have a finger print recognition system and its precision and recall be 1.0 and 0.2, respectively. Intuitively, the total performance of the system should be very low because the system covers only 20% of the registered finger prints, which means it is almost useless.

The arithmetic mean of 1 and 0.2 is 0.6 whereas the harmonic mean of them is:

$$\mu_h = \frac{2\cdot 1\cdot\dfrac{2}{10}}{1+\dfrac{2}{10}} = \frac{4}{12} = \frac{1}{3} \tag{14.1.873}$$

As you see in this example, the harmonic mean ($0.\bar{3}$) is a more reasonable score than the arithmetic mean (0.6).

Some researchers named the definition of the F-measure given earlier above the "F_1-measure". What is stands the 1 of F_1 for?

The full definition of the F-measure is given as follows:

$$F_\beta = \frac{(\beta^2+1)\,PR}{\beta^2 P + R} \qquad (0 \leq \beta \leq +\infty) \tag{14.1.874}$$

β is a parameter that controls a balance between P and R. When $\beta = 1$, F_1 comes to be equivalent to the harmonic mean of P and R. If $\beta > 1$, F becomes more recall-oriented and if $\beta < 1$, it becomes more precision-oriented, e.g., $F_0 = P$.

However it seems that the real original definition comes from the E "effectiveness function" given by:

$$E = 1 - \frac{1}{\alpha\dfrac{1}{P}+(1-\alpha)\dfrac{1}{R}} \tag{14.1.875}$$

where:

$$\alpha = \frac{1}{\beta^2+1} \tag{14.1.876}$$

Let's remove α using β:

$$\begin{aligned} E &= 1 - \frac{1}{\frac{1}{\beta^2+1}\frac{1}{P} + \left(1 - \frac{1}{\beta^2+1}\right)\frac{1}{R}} \\ &= 1 - \frac{PR}{\frac{1}{\beta^2+1}R + \frac{\beta^2+1-1}{\beta^2+1}P} \\ &= 1 - \frac{(\beta^2+1)\,PR}{R+\beta^2 P} \end{aligned} \tag{14.1.877}$$

Now you see that:

$$E = 1 - F_\beta \tag{14.1.878}$$

Note that F rises if R or P gets better whereas E becomes small if R or P improves. This seems the reason why F is more commonly used than E.

Some people use α as a parameter of F:

$$F_\alpha = \frac{1}{\alpha\frac{1}{P} + (1-\alpha)\frac{1}{R}} \qquad (0 \leq \alpha \leq 1) \tag{14.1.879}$$

There is nothing wrong with this definition of F but use of this definition might cause an unnecessary confusion because $F_{\alpha=0.5} = F_{\beta=1}$. An attention is needed that the commonly used notation F_1 means $F_{\beta=1}$, not $F_{\alpha=1}$.

Still, some of you are not sure why β^2 is used instead of β in $\alpha = \frac{1}{\beta^2+1}$ let my try an explanation of the reason.

β is the parameter that controls the weighting between P and R. Formally, is defined as follows:

$$\beta = \frac{R}{P} \tag{14.1.880}$$

where:

$$\frac{\partial E}{\partial P} = \frac{\partial E}{\partial R} \tag{14.1.881}$$

The motivation behind this condition is that at the point where the gradients of E with respect to P and R are equal, the ratio of R against P should be a desired ratio β.

Please recall that E is defined as follows:

$$\begin{aligned} E &= 1 - \frac{1}{\alpha\frac{1}{P} + (1-\alpha)\frac{1}{R}} \\ &= 1 - \frac{PR}{\alpha R + (1-\alpha)P} \end{aligned} \tag{14.1.882}$$

Now we calculate $\partial E/\partial P$ and $\partial E/\partial R$. By the quotient rule on the derivative of a composite function:

$$(f/g)'=\frac{f'g-fg'}{g^2} \tag{14.1.883}$$

For conciseness, let;

$$g=\alpha R+(1-\alpha)P \tag{14.1.884}$$

Then:

$$\begin{aligned}\frac{\partial E}{\partial P}&=-\frac{R(\alpha R+(1-\alpha)P)-PR(1-\alpha)}{g^2}\\ \frac{\partial E}{\partial R}&=-\frac{P(\alpha R+(1-\alpha)P)-PR\alpha}{g^2}\end{aligned} \tag{14.1.885}$$

Then:

$$\frac{\partial E}{\partial P}=\frac{\partial E}{\partial R} \tag{14.1.886}$$

is equivalent to:

$$R(\alpha R+(1-\alpha)P)-PR(1-\alpha)=P(\alpha R+(1-\alpha)P)-PR\alpha \tag{14.1.887}$$

which can be simplified to:

$$\alpha R^2=(1-\alpha)P^2 \tag{14.1.888}$$

As $\beta=R/P$, we can replace R with βP^2:

$$\begin{aligned}&\alpha\beta^2P^2=(1-\alpha)P^2\\ \Rightarrow&\alpha\beta^2=1-\alpha\\ \Rightarrow&\alpha\left(\beta^2+1\right)=1\\ \Rightarrow&\alpha=\frac{1}{\beta^2+1}\end{aligned} \tag{14.1.889}$$

Remark

The per-class metrics above (precision P_i, recall R_i and $F_{1,i}$-score) can be averaged over all the classes n resulting in "macro-averaged precision" (MP), macro-averaged recall" (MR) and "macro-averaged F_1" (MF$_1$):

$$\text{MP}=\frac{\sum_i P_i}{n}\qquad \text{MR}=\frac{\sum_i R_i}{n}\qquad \text{MF}_1=\frac{\sum_i F_{1,i}}{n} \tag{14.1.890}$$

When the instances are not uniformly distributed over the classes, it is useful to look at the performance of a multi-class classifier with respect to one class at a time before averaging the metrics. The idea is to compute the "one-vs-all confusion matrix for each class" (3 matrices in the case of our companion example here!). You can think of the problem as three binary classification tasks where one class is considered the positive class while the combination of all the other classes make up the negative class.

Summing up the values of all these matrices results in a unique confusion matrix and allows us to compute weighted metrics such as "average accuracy" and "micro-averaged R, P and F_1 metrics". Similar to the overall accuracy, the average accuracy is defined as the fraction of correctly classified instances in the sum of one-vs-all matrices matrix!

14.1.12.6.3 Ordinal Logistic regression

In statistics, ordinal regression (also named "ordinal classification") is a type of regression analysis used for predicting an ordinal variable, i.e. a variable whose value exists on an arbitrary scale where only the relative ordering between different values is significant.

To introduce the "ordinal logistic regression", let us recall that given a response variable Y having K ordered categories $j=1,2,\ldots,K$, with probabilities:

$$P(Y_i=j)=\pi_i^{(j)} \tag{14.1.891}$$

the multinomial logistic model, considered the $K-1$ ratios:

$$\frac{P(Y_i=j)}{P(Y_i=K)}=\frac{\pi_i^{(j)}}{\pi_i^{(1)}} \tag{14.1.892}$$

for $j=1,2,\ldots,K-1$.

Now we will consider the $K-1$ cumulative probabilities instead!

$$\gamma_i^{(j)}=P(Y_i\leq j)=\pi_i^{(1)}+\ldots+\pi_i^{(j)} \tag{14.1.893}$$

for $j=1,\ldots,K-1$ and write down a model for each of them.

Remark

Note that $\gamma_i^{(K)}=P(Y_i\leq K)=1$ always, so it need not be modelled!

The following holds:

$$\ln\left(\frac{\gamma_i^{(j)}}{1-\gamma_i^{(j)}}\right)=\ln\left(\frac{P\left(Y_i\leq j\right)}{P\left(Y_i>j\right)}\right)=\text{logit}(P(Y_i\leq j)=\alpha^{(j)}-(\beta_1x_{1i}+\cdots+\beta_nx_{ni}) \tag{14.1.894}$$

In other words, the ordinal logistic model considers as for the multinomial version, a set of dichotomies, one for each possible cutoff of the response categories into two sets, of "high" and "low" responses. But this concept of "high" and "low" at the opposite of multinomial regression is meaningful only if the categories of Y do have an ordering!

Remark

In the software Strata and in the `polr` package of the `R` software the ordinal logistic regression model is parametrized as:

$$\text{logit}(P(Y\leq j))=\alpha^{(j)}-(\eta_1x_{1i}+\cdots+\eta_nx_{ni}) \tag{14.1.895}$$

instead of:

$$\text{logit}(P(Y \leq j)) = \alpha^{(j)} + (\beta_1 x_{1i} + \cdots + \beta_n x_{ni}) \tag{14.1.896}$$

where $\eta_i = -\beta_1$ hence the notation above with the minus signs.

If we consider the ordered labels: Strongly disagree (SD), Disagree (D), Agree (A) and Strongly Agree (SA), the cutoffs are:

- SD vs (D, A or SA)
- (SD or D) vs (A or SA)
- (SD, D or A) vs SA

A binary logistic model is then defined for the log-odds of each of these cuts!

The model for the cumulative probabilities is (we omit the index i without loss of generality but just to simplify the notations!):

$$\gamma^{(j)} = P(Y \leq j) = \frac{\exp\left[\alpha^{(j)} - (\beta_1 x_1 + \cdots + \beta_k x_k)\right]}{1 + \exp\left[\alpha^{(j)} - (\beta_1 x_1 + \cdots + \beta_k x_k)\right]} \tag{14.1.897}$$

The intercept terms must be $\alpha^{(1)} < \alpha^{(2)} < \ldots < \alpha^{(K-1)}$, to guarantee that $\gamma^{(1)} < \gamma^{(2)} < \ldots < \gamma^{(K-1)}$. The $\beta_1, \beta_2, \ldots, \beta_n$ are assumed to be the same for each value of j.

From this the practitioner must remember that:

- There is thus only one set of regression coefficients, not $K-1$ as in a multinomial logistic model
- The curves for $\gamma^{(1)}, \gamma^{(2)}, \ldots, \gamma^{(K-1)}$ are translated (i.e. "proportional") as seen in the plots below
- This is the assumption of "proportional odds". This is why ordinal logistic model is also known as the "proportional odds model" or "parallel regression model"!

This is good for the parsimony of the model, because it means that the effect of an explanatory variable on the ordinal response is described by one parameter! However, it is also a restriction on the flexibility of the model, which may or may not be adequate for the data.

In other words, one of the assumptions underlying ordinal logistic (and ordinal probit) regression is that the relationship between each pair of outcome groups is the same. In other words, ordinal logistic regression assumes that the coefficients that describe the relationship between, say, the lowest versus all higher categories of the response variable are the same as those that describe the relationship between the next lowest category and all higher categories, etc. Because the relationship between all pairs of groups is the same, there is only one set of coefficients! If this was not the case, we would need different sets of coefficients in the model to describe the relationship between each pair of outcome groups.

Thus, in order to assess the appropriateness of our model, we need to evaluate whether the proportional odds assumption is tenable. Statistical tests to do this are available in some software packages. However, it seems that these tests have been criticized for having a tendency to reject the null hypothesis (that the sets of coefficients are the same), and hence, indicate that there the parallel slopes assumption does not hold, in cases where the assumption does hold (see [232] page 335). However, Harrell does recommend a graphical method for assessing the parallel slopes assumption. The values displayed in his proposed graph are essentially (linear) predictions from a logit model, used to model the probability that y is greater than or equal to a given value (for each level of y), using one predictor (x) variable at a time.

✍**Example:**

Suppose the proportions of members of the statistical population who would answer "poor", "fair", "good", "very good", and "excellent" are respectively p_1, p_2, p_3, p_4, p_5. Then the logarithms of the odds (not the logarithms of the probabilities) of answering in certain ways are:

$$\begin{array}{rcc}
\text{poor,} & \ln\left(\dfrac{p_1}{p_2+p_3+p_4+p_5}\right), & 0 \\
\text{poor or fair,} & \ln\left(\dfrac{p_1+p_2}{p_3+p_4+p_5}\right), & 1 \\
\text{poor, fair, or good,} & \ln\left(\dfrac{p_1+p_2+p_3}{p_4+p_5}\right), & 2 \\
\text{poor, fair, good, or very good,} & \ln\left(\dfrac{p_1+p_2+p_3+p_4}{p_5}\right), & 3
\end{array} \tag{14.1.898}$$

The proportional odds assumption is that the number added to each of these logarithms to get the next is the same in every case. In other words, these logarithms form an arithmetic sequence. The model states that the number in the last column of the table - the number of times that the logarithm must be added - is some linear combination of the other observed variables.

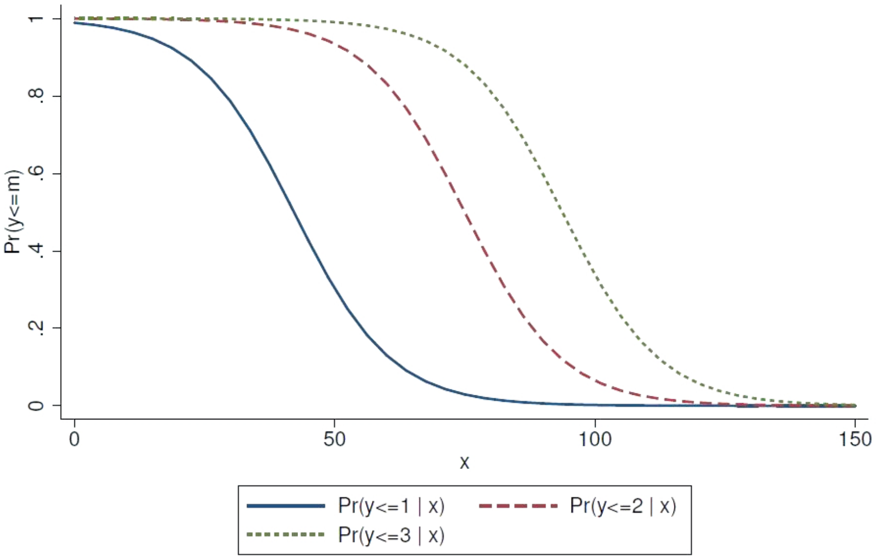
The probabilities of individual categories are:

$$\begin{aligned}
P(Y=1) &= \gamma^{(1)} = \frac{\exp\left[\alpha^{(1)}-(\beta_1 x_1+\cdots+\beta_n x_n)\right]}{1+\exp\left[\alpha^{(1)}-(\beta_1 x_1+\cdots+\beta_n x_n)\right]} \\
P(Y=j) &= \gamma^{(j)}-\gamma^{(j-1)} = \frac{\exp\left[\alpha^{(j)}-(\beta_1 x_1+\cdots+\beta_k x_k)\right]}{1+\exp\left[\alpha^{(j)}-(\beta_1 x_1+\cdots+\beta_n x_n)\right]} \\
&\quad - \frac{\exp\left[\alpha^{(j-1)}-(\beta_1 x_1+\cdots+\beta_n x_n)\right]}{1+\exp\left[\alpha^{(j-1)}-(\beta_1 x_1+\cdots+\beta_n x_n)\right]}
\end{aligned} \tag{14.1.899}$$

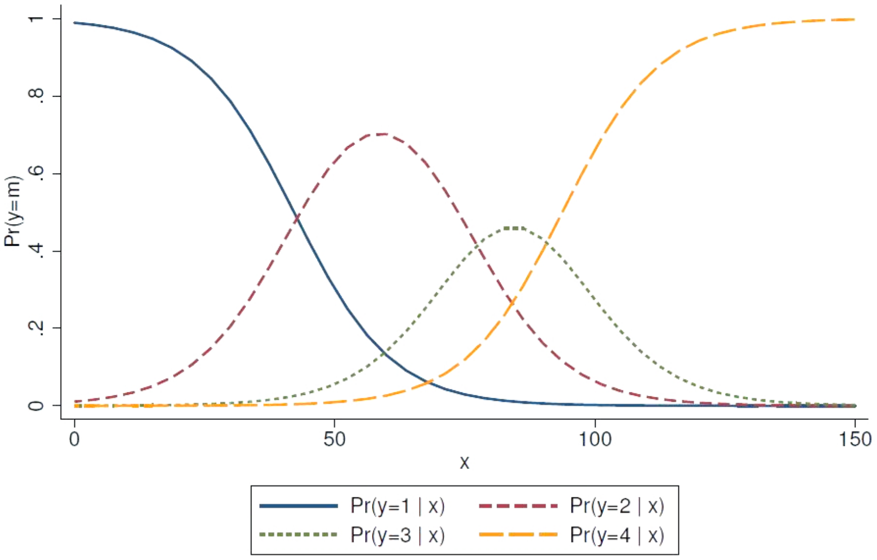
for $j = 2, \ldots, K-1$ and:

$$P(Y=K) = 1-\gamma^{(K-1)} = \frac{\exp\left[\alpha^{(K-1)}-(\beta_1 x_1+\cdots+\beta_n x_n)\right]}{1+\exp\left[\alpha^{(K-1)}-(\beta_1 x_1+\cdots+\beta_n x_n)\right]}$$

Illustrated below with plots for a case with $K = 4$ categories, first the cumulative probabilities:



and the probabilities of individual categories:



Everything here is unchanged from binary logistic models:

- Parameters are estimated using maximum likelihood estimation
- Hypotheses of interest are typically of the form $\beta_j = 0$, for one or more coefficients β_j
- Exponentiated coefficients are interpreted as partial odds ratios for being in the higher rather than the lower half of the dichotomy
- Wald tests, likelihood ratio tests and confidence intervals are the same defined and used as before

✍**Example:**

In Stata and `R` (package `polr`) the ordinal logistic regression model is parametrized a:

$$\text{logit}(P(Y \leq j)) = \beta_{j0} - \eta_1 x_1 - \ldots - \eta_p x_p$$

where for recall $\eta_i = -\beta_i$.

Suppose we want to see whether a binary predictor parental education (*pared*) predicts an ordinal outcome of students who are unlikely, somewhat likely and very likely to apply to a college (*apply*).

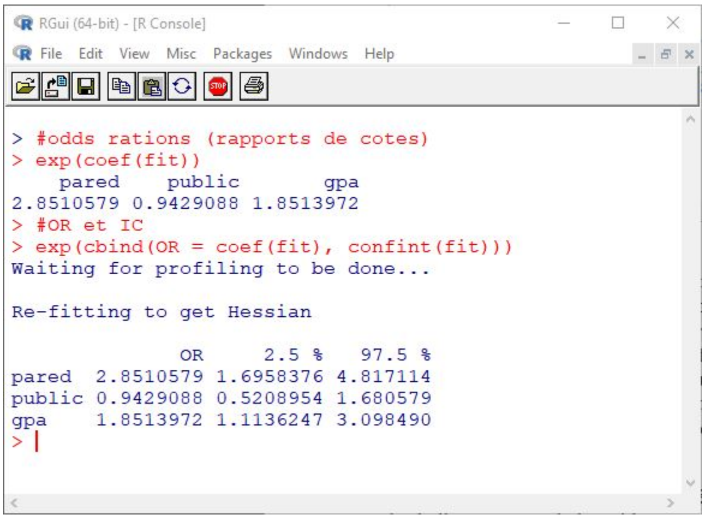
Due to the parallel odds assumption, even though we have categories, the coefficient of parental education (*pared*) stays the same across the two categories. Then the two equations for pared $= 1$ and pared $= 0$ are:

$$\begin{aligned} \text{logit}\left(P(Y \leq j)|x_1 = 1\right) &= \beta_{j0} - \eta_1 \\ \text{logit}\left(P(Y \leq j)|x_1 = 0\right) &= \beta_{j0} \end{aligned}$$

Then:

$$\text{logit}\left(P(Y \leq j)|x_1 = 1\right) - \text{logit}\left(P(Y \leq j)|x_1 = 0\right) = -\eta_1$$

To run an ordinal logistic regression in `R` we run (see our `R` companion book for more details):



```
> #odds rations (rapports de cotes)
> exp(coef(fit))
    pared    public       gpa
2.8510579 0.9429088 1.8513972
> #OR et IC
> exp(cbind(OR = coef(fit), confint(fit)))
Waiting for profiling to be done...

Re-fitting to get Hessian

              OR     2.5 %   97.5 %
pared  2.8510579 1.6958376 4.817114
public 0.9429088 0.5208954 1.680579
gpa    1.8513972 1.1136247 3.098490
> |
```

The output shows that for students whose parents attended college, the log odds of being unlikely to college (versus somewhat or very likely) is actually $-\hat{\eta}_1 = -1.13$ or 1.13 points lower than the students who did not attend college. Recall that $-\eta_i = \beta_i$ for $j = 1, 2$ only since logit $(P(Y \leq 3))$ is undefined. So the formulations for the first and second category becomes:

$$\begin{aligned} \text{logit}(P(Y \leq 1)) &= 0.377 - 1.13x_1 \\ \text{logit}(P(Y \leq 2)) &= 2.452 - 1.13x_1 \end{aligned}$$

To see the connection between the proportional odds assumption, we exponentiate both sides of the equations above and we use the property that $\log(b) - \log(a) = \log(b/a)$ to calculate the odds of *pared* for each level of *apply*:

$$\frac{P\left(Y \leq 1|x_1=1\right)}{P\left(Y > 1|x_1=1\right)} = \frac{e^{0.377}}{e^{1.13}}$$
$$\frac{P\left(Y \leq 1|x_1=0\right)}{P\left(Y > 1|x_1=0\right)} = e^{0.377}$$
$$\frac{P\left(Y \leq 2|x_1=1\right)}{P\left(Y > 2|x_1=1\right)} = \frac{e^{2.45}}{e^{1.13}}$$
$$\frac{P\left(Y \leq 2|x_1=0\right)}{P\left(Y > 2|x_1=0\right)} = e^{2.45}$$

From the odds of each level of pared, we can calculate the odds ratio of *pared* for each level of *apply*:

$$\frac{\frac{P\left(Y \leq 1|x_1=1\right)}{P\left(Y > 1|x_1=1\right)}}{\frac{P\left(Y \leq 1|x_1=0\right)}{P\left(Y > 1|x_1=0\right)}} = \frac{1}{e^{1.13}} = e^{-1.13}$$
$$\frac{\frac{P\left(Y \leq 2|x_1=1\right)}{P\left(Y > 2|x_1=1\right)}}{\frac{P\left(Y \leq 2|x_1=0\right)}{P\left(Y > 2|x_1=0\right)}} = \frac{1}{e^{1.13}} = e^{-1.13}$$

The proportional odds assumption ensures that the odds ratios across all $J-1$ categories are the same. In our example, the proportional odds assumption means that the odds of being unlikely versus somewhat or very likely to apply $(j=1)$ is equal to the odds of being unlikely and somewhat likely versus very likely to apply $(j=2)$.

The proportional odds assumption is not simply that the odds are the same but that the odds ratios are the same across categories. These odds ratios can be derived by exponentiating the coefficients (in the log-odds metric), but the interpretation is a bit unexpected. Recall that the coefficient $-\eta_1$ represents a one unit change in the log odds of applying for students whose parents went to college versus parents who did not:

$$\text{logit}(P(Y \leq j)|x_1=1) - \text{logit}(P(Y \leq j)|x_1=0) = -\eta_1$$

Since the exponent is the inverse function of the log, we can simply exponentiate both sides of this equation, and by using the property that $\log(b) - \log(a) = \log(b/a)$:

$$\frac{\frac{P(Y \leq j|x_1=1)}{P(Y > j|x_1=1)}}{\frac{P(Y \leq j|x_1=0)}{P(Y > j|x_1=0)}} = e^{-\eta_1}$$

For simplicity of notation and by the proportional odds assumption, let:

$$\frac{P(Y \leq j|x_1=1)}{P(Y > j|x_1=1)} = \frac{p_1}{1-p_1} \quad \text{and} \quad \frac{P(Y \leq j|x_1=0)}{P(Y > j|x_1=0)} = \frac{p_0}{1-p_0}$$

Then the odds ratio is defined as:

$$\frac{p_1/(1-p_1)}{p_0/(1-p_0)}=e^{-\eta_1}$$

In our example, $e^{-1.13}=0.323$, which means that students whose parents attended college have a 67.6% lower odds of being less likely to apply to college.

But you won't get this value with `R` and Stata (they retrieve the value 3.087 instead). Let's see why!

Since:

$$e^{-\eta_1}=\frac{1}{e^{\eta_1}}$$

From the output $\eta=1.13$, which means that 3.086 come from actually:

$$e^{\eta_1}=\frac{p_0/(1-p_0)}{p_1/(1-p_1)}=3.086$$

This suggests that students whose parents did not go to college have higher odds of being less likely to apply.

Double negation can be logically confusing. Suppose we wanted to interpret the odds of being more likely to apply to college. We can perform a slight manipulation of our original odds ratio:

$$\begin{aligned}e^{-\eta_1}&=\frac{p_1/\left(1-p_1\right)}{p_0/\left(1-p_0\right)}=\frac{p_1\left(1-p_0\right)}{p_0\left(1-p_1\right)}=\frac{\left(1-p_0\right)/p_0}{\left(1-p_1\right)/p_1}\\&=\frac{P(Y>j|x=0)/P(Y\leq j|x=0)}{P(Y>j|x=1)/P(Y\leq j|x=1)}\end{aligned}$$

Since $e^{-\eta_1}=1/e^{\eta_1}$, then we have:

$$\frac{P(Y>j|x=1)/P(Y\leq j|x=1)}{P(Y>j|x=0)/P(Y\leq j|x=0)}=e^{\eta_1}$$

Instead of interpreting the odds of being in the j th category or less, we can interpret the odds of being greater than the j th category by exponentiating η itself. In our example, $e^{\eta_1}=e^{1.127}=3.086$ means that students whose parents went to college have 3.086 times the odds of being very likely to apply (vs. somewhat or unlikely) compared to students whose parents did not go to college. The results here are consistent with our intuition because it removes double negatives. As a general rule, it is easier to interpret the odds ratios of $x_1=1$ vs. $x_1=0$ by simply exponentiating η itself rather than interpreting the odds ratios of $x_1=0$ vs. $x_1=1$ by exponentiating $-\eta$. However by doing so, we flip the interpretation of the outcome by placing $P(Y>j)$ in the numerator.

Ok so far we have seen the derivation and the most important details of Binary Logistic Regression, Multinomial Logistic Regression and Ordinal Logistic Regression. We will stop here because in this textbook we want to focus only on the basic in the purpose to not be scientifically illiterate. The reader must however keep in mind that there are other logistic models like:

- **Generalized Ordinary Logistic Regression (GOLR):** Is a partial proportional odds model when the proportionality of odds doesn't hold.
- **Alternating Logistic Regression (ALR):** Is suited when we deal with correlated observations, e.g. when we analyse repeated or clustered data. Next to mixed-effect and marginal models fitted via GEE (Generalized Estimating Equations), there's also the ALR, handling the dependency between pairs of observations by using log odds ratios instead of correlations (GEEway). It handles ordinal responses too.
- **Fractional Logistic Regression (FLR):** Is typically used with 0-1 bounded fractions rather than just binary classes. More flexible than beta regression, but not as powerful as simplex regression or 0-1-inflated beta regression.
- **Logistic Quantile Regression (LQR):** Is a robust statistical method used to model the quantiles of an outcome variable that takes on values within a bounded, known interval. This method is particularly useful when dealing with data that is not symmetrically distributed or when the interest lies in understanding the conditional distribution of the outcome variable across different quantiles.
- **Conditional Logistic Regression:** Used if we deal with stratification and matching groups of data, e.g. in observational studies without randomization, to match subjects by a certain characteristics and create a more homogenous "baseline".

+ all the above models can be extended:

- To handle repeated / clustered observations - by employing random effects and GEE (generalized estimating equations).
- To relax linearity in parameters - by using splines or GAM (Generalized Additive Model), invented by Prof. Hastie & Tibshirani.

14.1.12.6.4 Log-Loss

Let us recall the relation that we have introduced just earlier for the binomial logistic regression:

$$\begin{aligned}\ln\left(L(D,w)\right)&=\ln\left(\prod_{i=1}^{n}P(y_i=1|x_i)^{y_i}(1-P(y_i=1|\vec{x}))^{1-y_i}\right)\\&=\sum_{i=1}^{n}y_i\ln(P(y_i=1|\vec{x}))+(1-y_i)\ln((1-P(y_i=1|\vec{x})))\end{aligned}\tag{14.1.900}$$

It is often rewritten as following and defined as the "Log-loss" (often used in Data Mining/Data Science that like to use the log in base 10 instead of the natural logarithm...):

$$\boxed{\text{LL}=-\frac{1}{n}\log\left(L(D,w)\right)=-\frac{1}{n}\sum_{i=1}^{n}\left[y_i\log(\hat{y}_i)+(1-y_i)\log(1-\hat{y}_i)\right]}\tag{14.1.901}$$

with $y_i \in \{0,1\}$ type of data with estimated $\hat{y}_i \in \{0,1\}$, thus $\text{LL} > 0$ (the Log-loss gradually declines as the predicted probability improves as the reader can notice it). In other words, Log-loss is used when we have $\{0,1\}$ response. This is usually because when we have $\{0,1\}$ response, the best models give us values in terms of probabilities.

It is also sometimes written as following:

$$\text{LL} = -\frac{1}{n}\log\left(L(D,w)\right) = -\frac{1}{n}\sum_{i=1}^{n}\left[y_i\log(p_i) + (1-y_i)\log(1-p_i)\right] \tag{14.1.902}$$

In simple words (even if the Log-loss function is simply implicitly the objective function to minimize, in order to fit a log linear probability model to a set of binary labelled examples!), Log-loss measures the uncertainty of the probabilities of your model by comparing them to the true labels. Let us look closely at its formula and see how it measures the uncertainty

Now the question is, your training labels are 0 and 1 but your training predictions are 0.4, 0.6, 0.89, 0.1122, etc. So how do we calculate a measure of the error of our model ? If we directly classify all the observations having values > 0.5 into 1 then we are at a high risk of increasing the misclassification. This is because it may so happen that many values having probabilities 0.4, 0.45, 0.49 can have a true value of 1.

This is where Log-loss comes into picture!

Now let us closely follow the formula of Log-loss. There can be four major cases for the values of y_i and p_i:

C1. $y_i = 1\,,\, p_i = \text{High}\,,\, 1-y_i = 0\,,\, 1-p_i = \text{Low}$

C2. $y_i = 1\,,\, p_i = \text{Low}\,,\, 1-y_i = 0\,,\, 1-p_i = \text{High}$

C3. $y_i = 0\,,\, p_i = \text{Low}\,,\, 1-y_i = 1\,,\, 1-p_i = \text{High}$

C4. $y_i = 0\,,\, p_i = \text{High}\,,\, 1-y_i = 1\,,\, 1-p_i = \text{Low}$

- Case 1:

  In this case $y = 1$ and $p =$ High implies that we have got things right! Because the true value of the response agrees with our high probability. Now look closely! Occurrence of Case 1 will significantly decrease the sum because, $y_i\log(p_i)$ would be small and simultaneously the other term in the summation would be zero since $1-y_i = 1-1 = 0$. So more occurrences of Case 1 would decrease the sum and consequently decrease the mean.

  Also note that this is possible because if:

  $$p_i > 1-p_i \qquad \text{then} \qquad \log(p_i) > \log(1-p_i) \tag{14.1.903}$$

- Case 2:

  In this case $y = 1$ and $p =$ Low. This is a totally undesirable case because our probability of y being 1 is low but still the true value of y is 1. Now again looking at the Log-loss closely, the second term in the summation would be very small since $1-y_i$ would almost equal to zero. And since $p=$ Low, $y_i \log(p_i)$ would inflate the sum at the opposite of Case 1. So Case 2 would ultimately affect the sum a lot.

Similarly the occurrences of Case 3 would not change the sum and occurrences of Case 4 significantly.

Now coming back to the main question, how does Log-loss measure uncertainty of your model? The answer is simple! Suppose we have more of Case 1 and Case 3, then the sum inside the Log-loss relation would be small (would tend to decrease). This would imply that the mean $(/n)$ would also tend to decrease and will be substantially small in comparison to what it would have been if Case 2 and Case 4 got added. So now this value is as small as possible at Case 1 and Case 3 which indicates a good prediction. This is why smaller the value, better is the model i.e. smaller the Log-loss, better is the model i.e. smaller the uncertainty.

14.1.12.6.5 Odds Ratio Confidence Interval

We have seen earlier above during our study of the binomial logistic regression (see page 6456) that the odds ratio was defined by:

$$\boxed{\text{O.R.}=\frac{\dfrac{p}{1-p}}{\dfrac{q}{1-q}}=\frac{p(1-q)}{q(1-p)}} \tag{14.1.904}$$

What we can also write as:

$$\text{O.R.}=\frac{\dfrac{p_1}{q_1}}{\dfrac{p_2}{q_2}}=\frac{p_1q_2}{q_1p_2} \tag{14.1.905}$$

But that many practitioners write it as following:

$$\text{O.R.}=\frac{\dfrac{p_1}{p_2}}{\dfrac{p_3}{p_4}}=\frac{p_1p_4}{p_3p_2}=\frac{\pi_1\pi_4}{\pi_3\pi_2} \tag{14.1.906}$$

Since the ratio of proportions is equivalent to the ratio of the size of the concerned populations, it is customary to write the estimator of the odds ratio as being:

$$\boxed{\widehat{\text{O.R.}}=\frac{n_1n_4}{n_3n_2}} \tag{14.1.907}$$

Which then relates to a table typically of the following kind in the medical field (and other fields obviously!):

	Sick	**Non-Sick**	**Odds**
Treated Group	n_1	n_2	n_1/n_2
Non-Treated Group	n_3	n_4	n_3/n_4
Totals	n_1+n_3	n_2+n_4	$\widehat{\text{O.R.}}=\dfrac{\frac{n_1}{n_2}}{\frac{n_3}{n_4}}$

In the field of survival analysis (see section Statistics page 1271) such a table will be represented as following:

	Observed	**Expected**	**Relative failure rate**
Survival Curve 1	O_1	E_1	O_1/E_1
Survival Curve 2	O_2	E_2	O_2/E_2
Totals	O_1+O_2	E_2+E_4	$\widehat{\text{O.R.}}=\dfrac{\frac{O_1}{E_1}}{\frac{O_2}{E_2}}$

Remark

An O.R. of 1.00 means that the two groups were equally likely to remain sick. An O.R. higher than 1.00 means that a group is more likely to experience the event than the second group. An O.R. of less than 1.00 means that a group was less likely to experience the event. However, an O.R. value below 1.00 is not directly interpretable. It is important to put the group expected to have higher odds of the event in the first row.

Now, let us consider that the n_i follow an asymptotically Normal law such as according to what we had seen in our study of the construction of the Normal Law:

$$Z_i \underset{n\rightarrow+\infty}{\cong} \frac{n_i-np_i}{\sqrt{np_iq_i}} \tag{14.1.908}$$

Now the idea will be to make an additional approximation ... otherwise we will not find anything simple. We will put that:

$$Z_i \underset{n\rightarrow+\infty}{\cong} \frac{n_i-np_i}{\sqrt{np_iq_i}} \cong \frac{n_i-np_i}{\sqrt{n}} \tag{14.1.909}$$

It is very very approximate as approach .... since rigorously:

$$\frac{n_i-np_i}{\sqrt{n}} \underset{n\rightarrow+\infty}{\cong} \mathcal{N}(0,\sigma^2) \tag{14.1.910}$$

Simulations show that we have a Normal law beyond n equating 30, but although it is a Normal centered law ... it is hardly reduced (therefore not of unit variance...).

Regarding the last choice established, we have:

$$\begin{aligned}
&\mathrm{E}(Z_i)\cong 0\\
&\mathrm{V}(Z_i)\cong V\left(\frac{n_i-np_i}{\sqrt{n}}\right)=\mathrm{V}\left(\frac{n_i}{\sqrt{n}}\right)+\underbrace{\mathrm{V}\left(\frac{np_i}{\sqrt{n}}\right)}_{=0}=\frac{1}{n}\mathrm{V}(n_i)=\frac{1}{n}np_iq_i=p_iq_i=p_i(1-p_i)
\end{aligned} \tag{14.1.911}$$

This last approximation then allows us to write (we detail the steps a maximum on the request of one of our reader):

$$\begin{aligned}
&Z_i\cong\frac{n_i-np_i}{\sqrt{n}}\Rightarrow n_i\cong np_i+\sqrt{n}Z_i\Rightarrow n_i=np_i+\frac{n}{n}\sqrt{n}Z_i\\
&\Rightarrow\frac{n_i}{n}\cong p_i+\frac{\sqrt{n}Z_i}{n}=p_i+\frac{\sqrt{n}}{\sqrt{n}}\frac{\sqrt{n}Z_i}{n}=p_i+\frac{nZ_i}{n\sqrt{n}}=p_i+\frac{Z_i}{\sqrt{n}}\\
&=p_i\left(1+\frac{Z_i}{p_i\sqrt{n}}\right)
\end{aligned} \tag{14.1.912}$$

Now let us take the logarithm (it is customary to take the natural logarithm):

$$\ln\left(\frac{n_i}{n}\right) \cong \ln(p_i) + \ln\left(1 + \frac{Z_i}{p_i\sqrt{n}}\right) \tag{14.1.913}$$

The second term can be developed in Taylor series of the first order (see section Sequences and Series page 1703):

$$\ln(1+x) \underset{x\rightarrow +0}{\cong} x \tag{14.1.914}$$

It comes then after many approximations ...:

$$\ln\left(\frac{n_i}{n}\right) \cong \ln(p_i) + \frac{Z_i}{p_i\sqrt{n}} \tag{14.1.915}$$

We then have:

$$\begin{aligned}\ln(\text{O.R.}) &= \ln\left(\frac{n_1 n_4}{n_3 n_2}\right) = \ln\left(\frac{\frac{n_1}{n}\frac{n_4}{n}}{\frac{n_3}{n}\frac{n_2}{n}}\right) = \ln\left(\frac{n_1}{n}\right) + \ln\left(\frac{n_4}{n}\right) - \ln\left(\frac{n_2}{n}\right) - \ln\left(\frac{n_3}{n}\right)\\ &\cong \ln(p_1) + \frac{Z_1}{p_1\sqrt{n}} + \ln(p_4) + \frac{Z_4}{p_4\sqrt{n}} - \ln(p_2) - \frac{Z_2}{p_2\sqrt{n}} - \ln(p_4) - \frac{Z_3}{p_3\sqrt{n}}\\ &= \ln\left(\frac{p_1 p_4}{p_3 p_2}\right) + \frac{1}{\sqrt{n}}\left(\frac{Z_1}{p_1} + \frac{Z_4}{p_4} - \frac{Z_2}{p_2} - \frac{Z_3}{p_3}\right) \cong \ln(\widehat{\text{O.R.}}) + \frac{1}{\sqrt{n}}\left(\frac{Z_1}{p_1} + \frac{Z_4}{p_4} - \frac{Z_2}{p_2} - \frac{Z_3}{p_3}\right)\end{aligned} \tag{14.1.916}$$

However, we observe that (do not forget that the variance of a random variable multiplied by a constant puts the constant squared):

$$\ln(\text{O.R.}) \cong \underbrace{\ln(\widehat{\text{O.R.}})}_{=c^{te}} + \underbrace{\frac{1}{\sqrt{n}}\left(\frac{Z_1}{p_1} + \frac{Z_4}{p_4} - \frac{Z_2}{p_2} - \frac{Z_3}{p_3}\right)}_{=\mathcal{N}(0,\sigma)} = \mathcal{N}\left(\ln(\widehat{\text{O.R.}}), \frac{\sigma^2}{n}\right) \tag{14.1.917}$$

We then first consider that the variance part of the random variables as independent (we will take into account the covariance just after):

$$\begin{aligned}\text{V}(\ln(\text{O.R.})) &\cong \frac{1}{n}\left[\frac{\text{V}(Z_1)}{p_1^2} + \frac{\text{V}(Z_4)}{p_4^2} + \frac{\text{V}(Z_2)}{p_2^2} + \frac{\text{V}(Z_3)}{p_3^2}\right]\\ &= \frac{1}{n}\left[\frac{p_1 q_1}{p_1^2} + \frac{p_4 q_4}{p_4^2} + \frac{p_2 q_2}{p_2^2} + \frac{p_3 q_3}{p_3^2}\right] = \frac{1}{n}\left[\frac{1-p_1}{p_1} + \frac{1-p_4}{p_4} + \frac{1-p_2}{p_2} + \frac{1-p_3}{p_3}\right]\\ &= \sum_{i=1}^{4}\frac{1-p_i}{np_i} = \frac{1}{n}\left(-4 + \sum_{i=1}^{4}\frac{1}{p_i}\right)\end{aligned} \tag{14.1.918}$$

We now have to take into account the following six covariances (refer to the section Statistics for the proof that when we sum n random variables there are as many covariances to compute as possible pairs of possible variables):

$$\begin{gathered}\text{cov}(Z_1, Z_4)\\ \text{cov}(Z_1, Z_2)\\ \text{cov}(Z_1, Z_3)\\ \text{cov}(Z_4, Z_2)\\ \text{cov}(Z_4, Z_3)\\ \text{cov}(Z_2, Z_3)\end{gathered} \tag{14.1.919}$$

Recall that during our study of the multinomial law and as part of an application for the McNemar test (page 1264), we proved that:

$$\text{cov}(n_{11},n_{22})=-np_{11}p_{22} \tag{14.1.920}$$

which in our context with a more general notation is written:

$$\text{cov}(n_r,n_s)=-np_rp_s \tag{14.1.921}$$

If we center these two random variables (as is the case in our developments so far), the covariance does not change:

$$\text{cov}(n_r-np_r,n_s-np_s)=\text{cov}(n_r,n_s) \tag{14.1.922}$$

If we reduce the random variables by $\sqrt{n}$, then we have:

$$\text{cov}(Z_r,Z_s)=\text{cov}\left(\frac{n_r-np_r}{\sqrt{n}},\frac{n_s-np_s}{\sqrt{n}}\right)=\text{cov}\left(\frac{n_r}{\sqrt{n}},\frac{n_s}{\sqrt{n}}\right)=\frac{1}{n}\text{cov}(n_r,n_s)=-p_rp_s \tag{14.1.923}$$

and therefore:

$$\text{cov}\left(\frac{Z_r}{p_r},\frac{Z_s}{p_s}\right)=\frac{\text{cov}\left(Z_r,Z_s\right)}{p_rp_s}=\frac{-p_rp_s}{p_rp_s}=-1 \tag{14.1.924}$$

Among the six covariances that we need to calculate we have therefore:

$$\begin{aligned}\text{cov}\left(Z_1,Z_4\right)&=+1\\ \text{cov}\left(Z_1,Z_2\right)&=-1\\ \text{cov}\left(Z_1,Z_3\right)&=-1\\ \text{cov}\left(Z_4,Z_2\right)&=-1\\ \text{cov}\left(Z_4,Z_3\right)&=-1\\ \text{cov}\left(Z_2,Z_3\right)&=+1\end{aligned} \tag{14.1.925}$$

So the sum is worth -2. It is necessary to multiply by 2 the whole (reminder of the proof of the general case which makes a factor 2 appear before each term of the covariance) to obtain the global value of the covariance terms. So in the end we have a value of -4 for the sum of the pure covariances:

$$2\sum_{r<s}^{4}\text{cov}\left(Z_r,Z_s\right)=-4 \tag{14.1.926}$$

The total variance is ultimately given by:

$$\text{V}(\ln(\widehat{\text{O.R.}}))=\frac{1}{n}\left[\left(-4+\sum_{i=1}^{4}\frac{1}{p_i}\right)-4\right]=\frac{1}{n}\sum_{i=1}^{4}\frac{1}{p_i}=\sum_{i=1}^{4}\frac{1}{np_i}=\sum_{i=1}^{4}\frac{1}{n_i} \tag{14.1.927}$$

And finally we have the approximation sometimes named "Woolf method":

$$\ln(\widehat{\text{O.R.}})-Z_{\alpha/2}\frac{\hat{\sigma}}{\sqrt{n}}\leq\ln(\text{O.R.})\leq\ln(\widehat{\text{O.R.}})+Z_{1-\alpha/2}\frac{\hat{\sigma}}{\sqrt{n}} \tag{14.1.928}$$

More explicitly (notice that the lower and upper bound are symmetrical):

$$\boxed{\ln(\widehat{\text{O.R.}})-Z_{\alpha/2}\sqrt{\sum_{i=1}^{4}\frac{1}{n_i}}\leq\ln(\text{O.R.})\leq\ln(\widehat{\text{O.R.}})+Z_{1-\alpha/2}\sqrt{\sum_{i=1}^{4}\frac{1}{n_i}}} \tag{14.1.929}$$

Relationship that is often written as:

$$\ln(\widehat{\text{O.R.}})\pm Z_{\alpha/2}\hat{\sigma}_{\text{O.R.}}\leq\ln(\text{O.R.}) \tag{14.1.930}$$

Some softwares calculate the upper and lower bound by using the exponential (especially softwares plotting the famous "Four-fold plot"), and therefore the upper and lower bound are no longer symmetrical:

$$\widehat{\text{O.R.}}.e^{-Z_{\alpha/2}\sqrt{\sum_{i=1}^{4}\frac{1}{n_i}}}\leq\text{O.R.}\leq\widehat{\text{O.R.}}.e^{+Z_{1-\alpha/2}\sqrt{\sum_{i=1}^{4}\frac{1}{n_i}}} \tag{14.1.931}$$

✍**Example:**

Let us consider the following data:

Group / Heart Attack	**Yes**	**No**
Placebo	53	58
Treated Group	11	40

The odds ratio is then:

$$\text{O.R.}=\frac{\dfrac{n_1}{n_2}}{\dfrac{n_3}{n_4}}=\frac{\dfrac{53}{58}}{\dfrac{11}{40}}\cong 3.32 \tag{14.1.932}$$

So the Placebo group is almost three times more likely to experience the event of interest (Heart Attack).

You must keep in mind the three following scenarios (refresh!):

- The odds ratio is almost or equal to 1.0. means that the odds of exposure among cases is the same as the odds of exposure among controls. In other words, the exposure is not associated with the disease.
- The odds ratio is greater than 1.0 means that the odds of exposure among cases is greater than the odds of exposure among controls. In other words, the exposure may be a risk factor for the disease.
- The odds ratio is less than 1.0 means that the odds of exposure among cases is lower than the odds of exposure among controls. In other words, the exposure may be protective against the disease.

The confidence interval of $\ln(\text{O.R.})$ at a confidence level of 95% is then approximately given by:

$$3.32-1.96\sqrt{\frac{1}{53}+\frac{1}{58}+\frac{1}{11}+\frac{1}{4}}\leq \ln(\text{O.R.})\leq 3.32+1.96\sqrt{\frac{1}{53}+\frac{1}{58}+\frac{1}{11}+\frac{1}{40}} \tag{14.1.933}$$

Thus:

$$3.32-1.96\cdot 0.39\leq \ln(\text{O.R.})\leq 3.32+1.96\cdot 0.39 \tag{14.1.934}$$

Hence:

$$0.44\leq \ln(\text{O.R.})\leq 1.97 \tag{14.1.935}$$

and so taking the exponential we finally have the interval that interests us (read further below the text on the corresponding four-fold plot!):

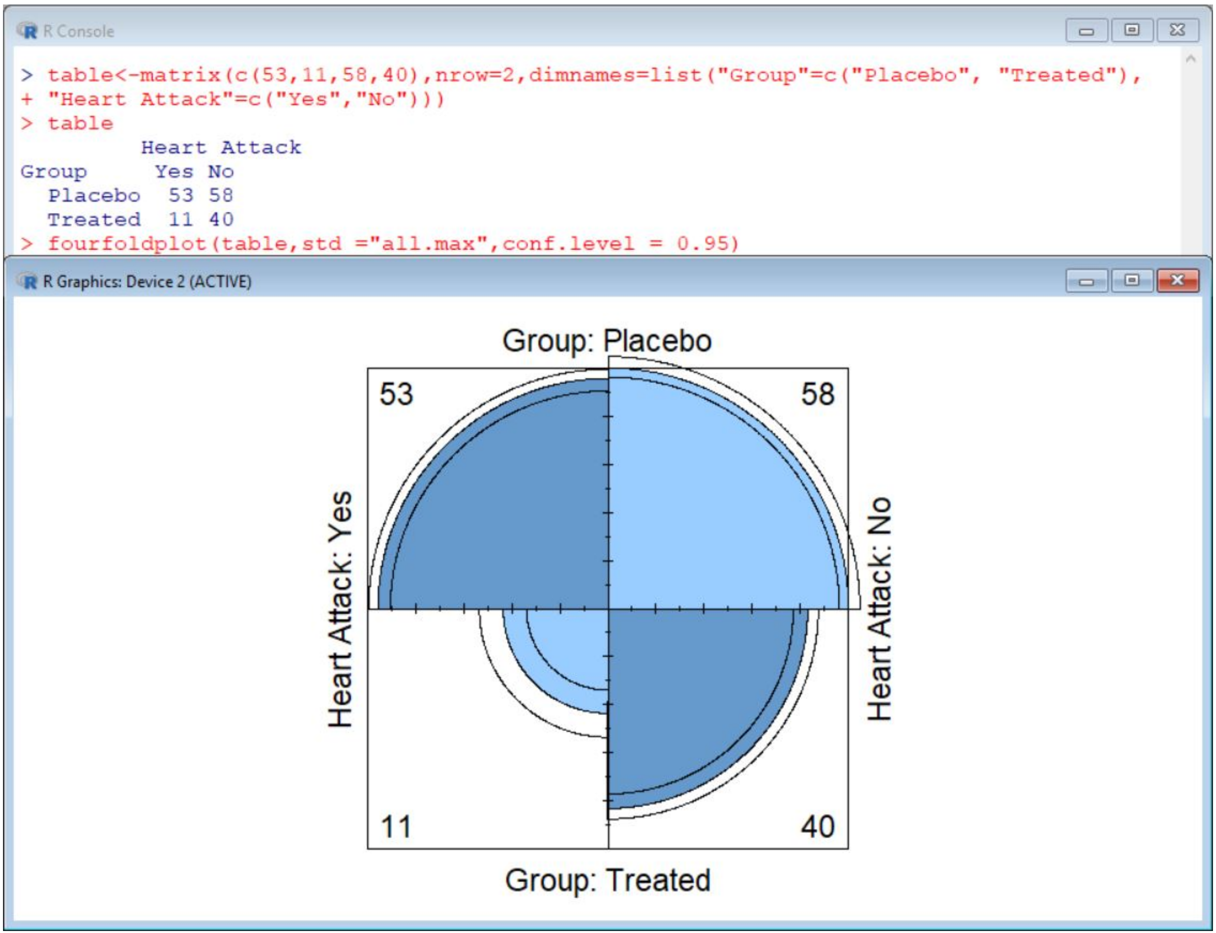
$$1.55\leq \text{O.R.}\leq 7.14 \tag{14.1.936}$$

Caution!!! While the estimator of the natural logarithm of the odds ratio is in the middle of the confidence interval, this is obviously not the case with the standard odds ratio!

14.1.12.6.5.1 Four-fold plot

The "four-fold plot", or "fourfold plot, is a graphic designed to display the frequencies in a 2×2 contingency table. In this display the frequency in each cell is shown by a quarter circle, whose area is proportional to the cell count in a given 2×2 layer, in a way that depicts the odds ratios for 1 strata. Confidence rings for the odds ratio can be superimposed to provide a visual test of the hypothesis of no association in each stratum.

Before we deal with the maths let us look with the R 3.4.2 software how to generate a four-fold plot for the previous example:



```
> table<-matrix(c(53,11,58,40),nrow=2,dimnames=list("Group"=c("Placebo", "Treated"),
+ "Heart Attack"=c("Yes","No")))
> table
         Heart Attack
Group      Yes No
  Placebo   53 58
  Treated   11 40
> fourfoldplot(table,std ="all.max",conf.level = 0.95)
```

Figure 14.25: **Four-fold plot with R 3.4.2**

In this display the frequency n_i in each cell of a four-fold table is shown by a quarter circle (on a vertical and horizontal axis of range $[-1,+1]$ with major ticks each 0.2 and minor ticks each 0.1), whose radius is proportional to $\sqrt{n_i}$ so that they are is proportional to the cell count (otherwise it would be proportional to the square of the cell count as $S=\pi R^2$).

The four-fold display is constructed so that the four quadrants will align vertically and horizontally when the odds ratio is 1. Confidence rings for the observed odds ratio provide a visual test of the hypothesis of no association. They have the property that rings for adjacent quadrants overlap if and only if the observed counts are consistent with this null hypothesis. In the above figure the confidence intervals do not overlap, indicating a significant association between *Heart attack* and *Group*.

The radius of the circles are given by:

Group / Heart Attack	**Yes**	**No**
Placebo	$\sqrt{\dfrac{n_1}{\max n_i}}$	$\sqrt{\dfrac{n_2}{\max n_i}}$
Treated Group	$\sqrt{\dfrac{n_3}{\max n_i}}$	$\sqrt{\dfrac{n_4}{\max n_i}}$

Explicitly:

Group / Heart Attack	**Yes**	**No**
Placebo	$\sqrt{\frac{53}{58}}=0.955$	$\sqrt{\frac{58}{58}}=1.000$
Treated Group	$\sqrt{\frac{11}{58}}=0.435$	$\sqrt{\frac{40}{58}}=0.830$

14.1.12.6.6 Risk Ratio and its Confidence Interval

The "risk ratio" or "relative risk" is defined quite naturally by:

$$\text{R.R.}=\frac{\text{Probability of event 1}}{\text{Probability of event 2}} \tag{14.1.937}$$

Consider the typical case in the medical field:

	Sick	**Non-Sick**	**Total**
Treated Group	n_1	n_2	n_A
Non-Treated Group	n_3	n_4	n_B

Thus the risk of illness for the treated group (TG), also named "Experimental Event Rate" (EER), is:

$$\hat{R}_{\text{TG}}=\text{EER}=\frac{n_1}{n_1+n_2}=p_1 \tag{14.1.938}$$

and for the non-treated group (NTG) (or "control group"), also named "Control Event Rate" (CER):

$$\hat{R}_{\text{NTG}}=\text{CER}=\frac{n_3}{n_3+n_4}=p_2 \tag{14.1.939}$$

and hence the risk ratio is defined by:

$$\boxed{\text{R.R.}=\frac{\dfrac{n_1}{n_1+n_2}}{\dfrac{n_3}{n_3+n_4}}=\frac{p_1}{p_2}=\frac{\text{EER}}{\text{CER}}=\frac{\text{Risk treated group}}{\text{Risk control group}}=\text{O.R.}\frac{\dfrac{n_2}{n_1+n_2}}{\dfrac{n_4}{n_3+n_4}}} \tag{14.1.940}$$

remembering that:

$$\text{O.R.}=\frac{\dfrac{n_1}{n_2}}{\dfrac{n_3}{n_4}} \tag{14.1.941}$$

Risk Ratios (RR) and Odds Ratios (OR) are both used to analyse factors associated with increased risk of disease. They are different in that a risk ratio is the ratio of two risks and an odds ratio is the ratio of two odds. Risks and odds are calculated differently. For example, with one toss of a fair die, the risk of rolling a 1 is $1/6=0.167$. The odds of rolling a 1 are $1/5=0.200$. In textbook terms, risk is successes divided by total trials and odds are successes divided by failures. In this example rolling a 1 is a success and rolling 2 through 5 is a failure.

✍**Example:**

Let us consider a R.R of 1.50. That means obviously an increase of the risk of 50% in the treatment group in comparison of the control group. So if the control group has a risk of 20%, then the treatment group has a risk of $20\% + 1.5 \cdot 20\% = 30\%$.

Remark

If n_1 is small relatively to n_2 and n_3 is small relatively to n_4 we fall back on the odds ratio:

$$\widehat{\text{R.R.}} \cong \widehat{\text{O.R.}} = \frac{\dfrac{n_1}{n_2}}{\dfrac{n_3}{n_4}} = \frac{n_1 n_4}{n_3 n_2} \tag{14.1.942}$$

we then better understand why the odds ratio is sometimes named "approximate relative risk".

So in the medical field, we say that if the disease is rare in treated and non-treated groups the interpretation of relative risk (i.e. risk ratio) and odds ratio is the same.

Let us take the log of the relative risk (i.e. risk ratio):

$$\ln(\widehat{\text{R.R.}}) = \ln(p_1) - \ln(p_2) \tag{14.1.943}$$

It then comes for the variance since p_1 and p_2 are assumed to be independent:

$$\text{V}(\ln(\text{R.R.})) = \text{V}(\ln(p_1) - \ln(p_2)) = \text{V}(\ln(p_1)) + \text{V}(\ln(p_2)) \tag{14.1.944}$$

To determine the variance of the natural logarithm of the proportions we will have to use a technique that we name the "univariate delta method" (indeed, because of the presence of a sum at the denominator, we will not be able to take the same approach as the one used for the odds ratio) which consists of approximating the exact variance by the corresponding asymptotically normal variance.

To see what the univariate delta method is, let's remember that we have proved in the section Statistics (see page 696) that:

$$\frac{\bar{X} - \mu}{\sigma / \sqrt{n}} \underset{n \to +\infty}{\cong} Z \Leftrightarrow \sqrt{n}(\bar{X} - \mu) \underset{n \to +\infty}{\cong} \sigma Z \tag{14.1.945}$$

Now, let us consider the following linear function:

$$g(t) = at + b \tag{14.1.946}$$

where a and b are any two constants. From then on, using the linearity property of the mean, we immediately have:

$$\text{E}(g(X)) = \text{E}(aX + b) = a\text{E}(X) + b = a\mu + b = g(\mu) \tag{14.1.947}$$

Now, let us ask ourselves the question, what is the limit of:

$$\lim_{n\rightarrow+\infty}\sqrt{n}\left(g(\bar{X})-g(\mu)\right) \tag{14.1.948}$$

We then have:

$$\sqrt{n}\left(g(\bar{X})-g(\mu)\right)=\sqrt{n}\left(a\bar{X}+b-(a\mu+b)\right)=a\sqrt{n}(\bar{X}-\mu) \tag{14.1.949}$$

We immediately deduce that:

$$\sqrt{n}\left(g(\bar{X})-g(\mu)\right)\underset{n\rightarrow+\infty}{\cong}a\sigma Z=N(0,a^2\sigma^2) \tag{14.1.950}$$

Now, let us develop in series of Taylor in the first order around μ the function $g(t)$, which would not necessarily be linear, then we have:

$$g(t)\cong g(\mu)+g'(\mu)(t-\mu)=g'(\mu)t-g'(\mu)\mu+g(\mu) \tag{14.1.951}$$

By identification with the simple linear case, we then have:

$$g(t)\cong\underbrace{g'(\mu)}_{a}t+\underbrace{g(\mu)-g'(\mu)\mu}_{b} \tag{14.1.952}$$

It then comes in the case of a function $g(t)$ that is not necessarily linear, but approximated as such by a series development of Taylor and under the assumption that the variable is continuous that:

$$\sqrt{n}\left(g(\bar{X})-g(\mu)\right)\underset{n\rightarrow+\infty}{\cong}g'(\mu)\sigma Z=\mathcal{N}(0,g'(\mu)^2\sigma^2) \tag{14.1.953}$$

So don't forget what this method means (!!): If X_n is (asymptotically) Normal with mean 0 and variance σ^2, g is differentiable and $g'(\mu)\neq 0$, then $g(X_n)$ is approximately given by:

$$\boxed{g(X_n)\underset{n\rightarrow+\infty}{\cong}\mathcal{N}\left(0,g'(\mu)^2\sigma^2\right)} \tag{14.1.954}$$

For the purpose of demonstrating the confidence interval of the risk ratio, let us apply that to the binomial distribution with:

$$g(t)=\ln(t) \tag{14.1.955}$$

It then comes from the previous results that the approximation of the variance by a Normal law and from the knowledge that the variance and the mean of the binomial law are given for recall by (see section Statistics page 658):

$$\mu=np \tag{14.1.956}$$
$$\sigma^2=npq \tag{14.1.957}$$

that the univariate delta method gives:

$$\begin{aligned}\mathcal{N}(0,g'(\mu)^2\sigma^2)&=\mathcal{N}\left(0,\left(\frac{\mathrm{d}\ln(np)}{\mathrm{d}np}\right)^2npq\right)=\mathcal{N}\left(0,\left(\frac{1}{np}\right)^2npq\right)=\mathcal{N}\left(0,\frac{q}{np}\right)\\&=\mathcal{N}\left(0,\frac{1-p}{np}\right)\end{aligned} \tag{14.1.958}$$

So the variance corresponding to $\ln(p_i)$ is given asymptotically by:

$$\text{V}(\ln(p_i))=\frac{1-p_i}{n_ip_i} \tag{14.1.959}$$

Therefore:

$$\text{V}\left(\ln(\widehat{\text{R.R.}})\right)=\text{V}(\ln(p_1))+\text{V}(\ln(p_2))\cong\frac{1-p_1}{n_Ap_1}+\frac{1-p_2}{n_Bp_2} \tag{14.1.960}$$

Hence:

$$\hat{\sigma}_{\widehat{\text{R.R.}}}\cong\sqrt{\frac{1-p_1}{n_Ap_1}+\frac{1-p_2}{n_Bp_2}} \tag{14.1.961}$$

Thus, we have asymptotically the following interval for the risk ratio if the assumptions are satisfied (independence and underlying Normal distribution):

$$\boxed{\ln(\widehat{\text{R.R.}})-Z_{\alpha/2}\sqrt{\frac{1-p_1}{n_Ap_1}+\frac{1-p_2}{n_Bp_2}}\leq\ln(\widehat{\text{R.R.}})\leq\ln(\widehat{\text{R.R.}})+Z_{\alpha/2}\sqrt{\frac{1-p_1}{n_Ap_1}+\frac{1-p_2}{n_Bp_2}}} \tag{14.1.962}$$

or in condensed form:

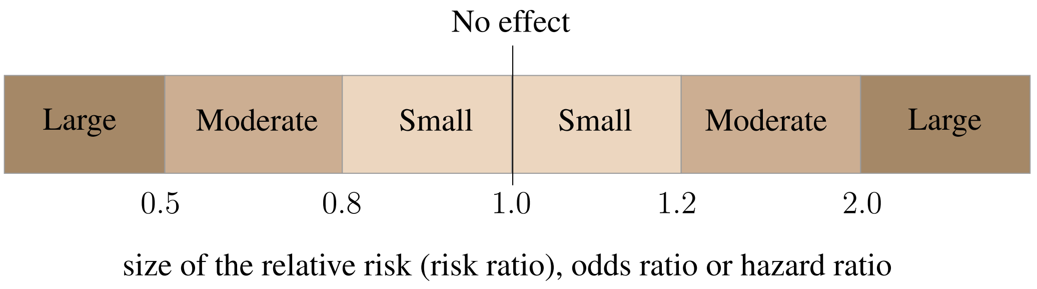
$$\ln(\widehat{\text{R.R.}})-Z_{\alpha/2}\hat{\sigma}_{\widehat{\text{R.R.}}}\leq\ln(\widehat{\text{R.R.}})\leq\ln(\widehat{\text{R.R.}})+Z_{\alpha/2}\hat{\sigma}_{\widehat{\text{R.R.}}} \tag{14.1.963}$$

Note that in the medical literature, the reader will also find the standard deviation of the risk ratio in many other forms that are here (which are of course all equivalent):

$$\begin{aligned}\hat{\sigma}_{\widehat{\text{R.R.}}}&=\sqrt{\frac{1-p_1}{n_Ap_1}+\frac{1-p_2}{n_Bp_2}}=\sqrt{\frac{1-p_1}{(n_1+n_2)p_1}+\frac{1-p_2}{(n_3+n_4)p_2}}\\&=\sqrt{\frac{1-\dfrac{n_1}{n_1+n_2}}{(n_1+n_2)\dfrac{n_1}{n_1+n_2}}+\frac{1-\dfrac{n_3}{n_3+n_4}}{(n_3+n_4)\dfrac{n_3}{n_3+n_4}}}=\sqrt{\frac{1-\dfrac{n_1}{n_1+n_2}}{n_1}+\frac{1-\dfrac{n_3}{n_3+n_4}}{n_3}}\\&=\sqrt{\frac{1}{n_1}-\frac{1}{n_1+n_2}+\frac{1}{n_3}-\frac{1}{n_3+n_4}}=\sqrt{\frac{n_2}{n_1(n_1+n_2)}+\frac{n_4}{n_3(n_3+n_4)}}\end{aligned} \tag{14.1.964}$$

If the risk ratio is the same for both target groups, the Risk Ratio will obviously be equal to 100% (i.e. equal to 1). If it is less than 100% (i.e. less than 1), it simply means that the risk of illness in the treated group is lower than that of the non-treated group, etc.

The typical range of values of the odds ratio and risk ratio are designated (wrongly!) traditionally as following in scientific publications:



No effect
Large
Moderate
Small
Small
Moderate
Large
0.5
0.8
1.0
1.2
2.0
size of the relative risk (risk ratio), odds ratio or hazard ratio

Figure 14.26: **Odds Ratio and Risk Ratio range values subjective qualifications**

Caution!!! While the natural logarithm Risk Ratio estimator is in the middle of the confidence interval, this is obviously not the case for the standard Risk Ratio!

✍**Example:**

Let us consider the following data:

Group/Heart attack	**Yes**	**No**
Placebo	53	58
Aspirin	11	40

The relative risk is then (which corresponds to what the MedCalc software returns):

$$\widehat{\text{R.R}}=\frac{\text{EER}}{\text{CER}}=\frac{\dfrac{n_1}{n_1+n_2}}{\dfrac{n_3}{n_3+n_4}}=\frac{\dfrac{53}{53+58}}{\dfrac{11}{11+40}}=\frac{0.477}{0.215}=\frac{p_1}{p_2}\cong 2.21 \tag{14.1.965}$$

The confidence interval of $\ln(\widehat{\text{R.R.}})$ at a confidence level of 95% is then approximately given by:

$$\ln(2.21)-Z_{\alpha/2}\sqrt{\frac{1-0.477}{(53+58)\cdot 0.477}}\leq\ln(\widehat{\text{RR}})\leq\ln(2.21)+Z_{\alpha/2}\sqrt{\frac{1-0.477}{(53+58)\cdot 0.477}} \tag{14.1.966}$$

Hence:

$$0.794-1.96\cdot 0.284\leq\ln(\widehat{\text{RR}})\leq 0.794+1.96\cdot 0.284 \tag{14.1.967}$$

So finally:

$$0.236\cdot 0.284\leq\ln(\widehat{\text{RR}})\leq 1.353 \tag{14.1.968}$$

and so taking the exponential we finally have the interval that interests us:

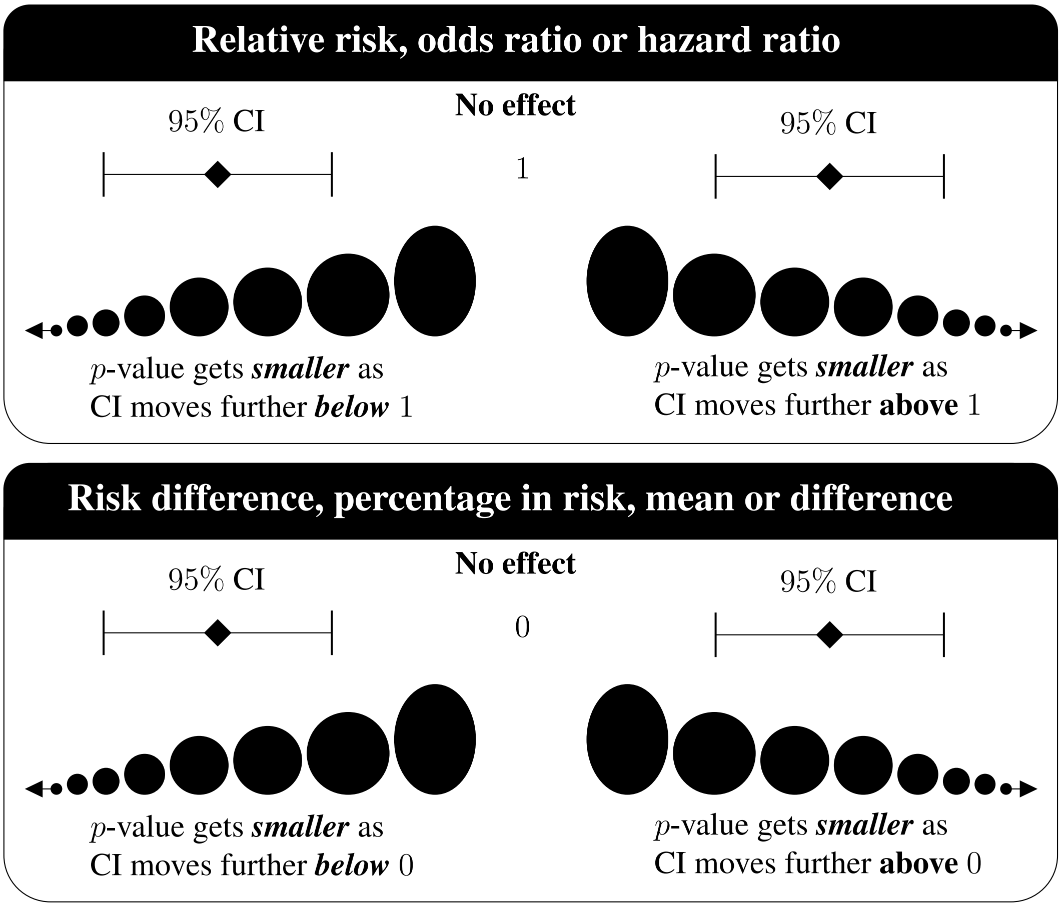
$$1.266\leq\ln(\widehat{\text{RR}})\leq 3.869 \tag{14.1.969}$$

This perfectly matches the data returned by the MedCalc software! The Absolute Risk Increase is given by:

$$\text{A.R.I.}=\text{E.E.R.}-\text{C.E.R.}=0.447-0.215=26.2\% \tag{14.1.970}$$

The reader or practitioner must keep in mind that the odds ratio, as the risk ratio, are tools as we have just seen, used to make null hypothesis statistical testing (NHST) as they involve confidence intervals. So don't forget that what we are seeking is to reject the null hypothesis H_0 ! Because of this, a lot of people read medical studies wrongly as they have forgotten how NHST works (or they just don't know...)!

So for recall:



Relative risk, odds ratio or hazard ratio
95% CI

CI moves further ***below*** 0
p-value gets ***smaller*** as
CI moves further **above** 0

Figure 14.27: Risk Ratio (relative risk), Odds Ratio or Hazard Ratio rules

So far we have seen that in calculation of patient risks there are two indicators. But that's quite wrong in practice... Indeed, it is quite common to find the following indicators in many scientific papers:

- Odds ratio:

$$\widehat{\text{O.R}}=\frac{n_1n_4}{n_2n_3} \tag{14.1.971}$$

- Relative risk (risk ratio):

$$\widehat{\text{R.R.}}=\frac{\dfrac{n_1}{n_1+n_2}}{\dfrac{n_3}{n_3+n_4}} \tag{14.1.972}$$

- Experimental event rate (EER):

$$\widehat{\text{E.E.R.}}=\frac{n_1}{n_1+n_2} \tag{14.1.973}$$

- Control event rate (CER):

$$\widehat{\text{C.E.R.}}=\frac{n_3}{n_3+n_4} \tag{14.1.974}$$

- Absolute risk increase (also named "attributable risk"):

$$\widehat{\text{A.R.I.}}=\frac{n_1}{n_1+n_2}-\frac{n_3}{n_3+n_4}=\widehat{\text{E.E.R.}}-\widehat{\text{C.E.R.}} \tag{14.1.975}$$

- Absolute risk reduction:

$$\widehat{\text{A.R.R.}}=\frac{n_3}{n_3+n_4}-\frac{n_1}{n_1+n_2}=\widehat{\text{C.E.R.}}-\widehat{\text{E.E.R.}} \tag{14.1.976}$$

- Number needed to harm:

$$\widehat{\text{N.N.H.}}=\frac{1}{\dfrac{n_1}{n_1+n_2}-\dfrac{n_3}{n_3+n_4}}=\frac{1}{\widehat{\text{A.R.I.}}} \tag{14.1.977}$$

It should be noticed that any scientific paper in clinical research should communicate at least the Risk Ratio (RR), the Odds Ratio (OR) the Absolute Risk Reduction (ARR) and their respective confidence intervals at a given threshold! We have already derived how to compute the confidence interval for the RR and OR. But we didn't for ARR. So let's do it!

✍**Example:**

- Cancer risk for smokers:

$$\frac{10}{30}=0.3\bar{3}$$

- Cancer risk for non-smokers:

$$\frac{1}{30}=0.03\bar{3}$$

- Risk difference:

$$\widehat{\text{R.D.}}=\frac{10}{30}-\frac{1}{30}=0.3$$

- Relative risk (risk ratio) for the smokers:

$$\widehat{\text{R.R}}=\frac{10/30}{1/30}=10$$

- Relative risk (risk ratio) for the non-smokers:

$$\widehat{\text{R.R}}=\frac{1/30}{10/30}=0.1$$

- Relative risk (risk ratio) reduction for the non-smokers ($\widehat{\text{R.R}}=0.1$):

$$\widehat{\text{R.R.R}}=100\cdot(1-\widehat{\text{R.R}})=100\cdot(1-0.1)=90\%$$

- Number need to treat (number of people who must be treated to avoid a case of bad outcome):

$$\widehat{\text{N.D.T.}}=\frac{1}{0.3}=3.\bar{3}$$

It is obvious that C.E.R and E.E.R. are binomial random variables that belong to the range $[0,1]$ and furthermore independent (i.e. without correlation) by construction of the experimental design. Therefore the variance of A.R.R. is the sum of the variance of two independent binomial variables. Sadly there are eleven methods to calculate such an interval (...). The most common and naive one for two binomial independent random variable is given by (see section Statistics page 880):

$$(\widehat{\text{CER}}-\widehat{\text{EER}})-Z_{\alpha/2}\sqrt{\frac{\widehat{\text{CER}}(1-\widehat{\text{CER}})}{n_3+n_4}+\frac{\widehat{\text{EER}}(1-\widehat{\text{EER}})}{n_1+n_2}}\leq \text{ARR}\leq(\widehat{\text{CER}}-\widehat{\text{EER}})+Z_{\alpha/2}\sqrt{\frac{\widehat{\text{CER}}(1-\widehat{\text{CER}})}{n_3+n_4}+\frac{\widehat{\text{EER}}(1-\widehat{\text{EER}})}{n_1+n_2}} \tag{14.1.978}$$

And keep always in mind what we already mentioned during our study of Chemistry:

quote
14.1:6510.#76

> *All things are poisons, for there is nothing without poisonous qualities. It is only the dose which makes a thing poison*[28]*!*
>
> Paracelsus

Remark

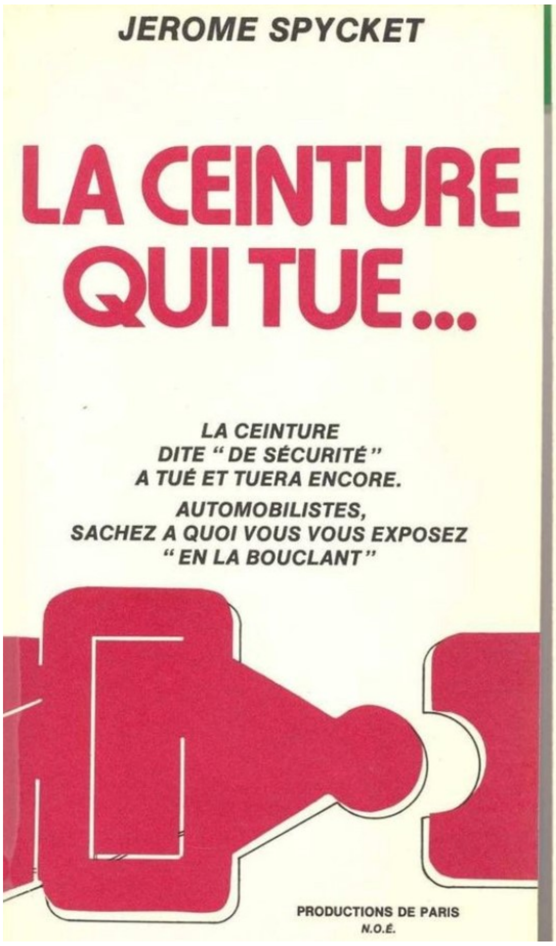
A famous example of personal patient risk appreciation is about industrial drugs or medicines usage risk! Indeed, it seems that on the $18,000$ drugs commercially released this last century around the World only approximately 177 of them (source: `https://en.wikipedia.org/wiki/List_of_withdrawn_drugs`) were withdrawn because of risks for patients, but also because of commercial reasons (e.g. lack of demand and relatively high production costs).

Let us take an example taken during the COVID-19 pandemic published the 2021-04-03 by FranceInfo (french news channel): According to the numbers that the EMA unveiled on Wednesday, there were at this stage 62 cases of cerebral venous thrombosis in the world, including 44 in the 30 countries of the European Economic Area (EU, Iceland, Norway, Liechtenstein) for 9.2 million doses of vaccine administered. 9 deaths have been recorded in Germany out of 2.8 millions AstraZeneca vaccine injected. In France 4 death have been reported out of 1.9 million injections, 3 death cases in Norway out of $120,000$ injections in the Netherlands. But as with any drug, knowing the risk is not enough, it must be compared with the benefits provided by the product. The Risk Ratio of the AstraZeneca vaccine in preventing COVID-19, which leads to hospitalizations and much more deaths, obviously outweigh the risks of side effects.

The fact that a fraction of the population doesn't know and doesn't understand (or don't want because they have a political or economic agenda) the concept of risk benefit ratio in the case of vaccines, medicines or any activity/action in daily life isn't something new as we can see it from the screenshot below of a 11975 (holocene calendar) french book where the author (which was an artist and evidence show us that we can't expect obviously any scientific literacy from the huge majority of people working in the artistic field) argue because some people died in their car because they had put their security belt is the proof that there shouldn't be any law to oblige people to put the security belt (...):

---

[28] A famous scientific experiment has provided evidence that at the contrary to the intuition that increasing dose makes something more poisonous, there exist sometimes non-monotonic (see section Functional Analysis page 2203) dose response curves (NMDRCs) demonstrated for natural hormones and endocrine disrupting chemicals (EDCs) like Bisphenonal A!



JEROME SPYCKET

LA CEINTURE QUI TUE...

L'AURORE - 2/9/75

EN PLEIN PARIS

La ceinture de sécurité a tué

UN automobiliste est mort carbonisé en plein Paris, devant les passants impuissants. Sanglé sur son siège par sa ceinture de sécurité, M. [redacted], 51 ans, a fait des efforts désespérés pour tenter de se détacher, alors que les flammes gagnaient peu à peu l'intérieur de la voiture. C'est en vain qu'il a lutté jusqu'au bout avec le système d'ouverture avant d'être dévoré par le brasier.

Il roulait vers 2 heures du matin sur la voie sur berge pour regagner son domicile, [redacted] rue Oberkampf (11e), quand, à la hauteur du pont d'Austerlitz, il a remarqué qu'une fumée sortait de son tableau de bord.

Pas de remède miracle

M. [redacted] a alors garé sa voiture, pensant ouvrir son capot et trouver l'origine de la fumée. C'est alors que les premières flammes ont jailli. Ne le voyant pas descendre de voiture, des automobilistes et des passants ont tenté de lui porter secours, mais, déjà, les flammes léchaient le véhicule, interdisant toute approche. Ils ont vu le malheureux se débattre en vain avec sa ceinture et, finalement, se recroqueviller dans le feu.

Ainsi donc, la ceinture a tué, mais il n'est pourtant pas question de rouvrir une polémique où partisans et adversaires resteront inconditionnellement sur leurs bases. A la délégation à la Sécurité routière, on reconnait pourtant qu'il n'y a pas de remède miracle : « Il est certain que, dans quelques cas, la ceinture peut être un handicap. Ces affaires sont toujours tragiques mais, si l'on veut regarder les chiffres avec lucidité, on s'aperçoit que le nombre de vies humaines sauvées grâce à la ceinture est infiniment plus grand que celui des accidents qu'elle a pu provoquer. »

Mais si le principe même de la ceinture — malgré la gêne ou l'impression de frustration qu'elle peut causer — n'est pas remis en cause, sa conception laisse souvent à désirer. Certaines boucles, trop compliquées ou trop dures à déclencher, peuvent devenir des cadenas mortels, surtout pour un passager déjà paniqué par l'accident et qui n'a plus tout son sang-froid.

C. D.

Cette victime de la ceinture, comme toutes celles qui l'ont précédée, ne figurera dans aucune statistique. La Délégation à la Sécurité Routière les ignore. C'est ce qu'elle appelle « regarder les chiffres avec lucidité » — ces chiffres extravagants qu'elle fabrique pour les besoins de sa cause, et que le Président du Syndicat des Journalistes de la Presse Automobile a qualifié de « véritable escroquerie ».

La vérité — que les Pouvoirs publics essaient à tout prix de cacher — est que la ceinture tue. Et qu'elle tuera de plus en plus avec l'extension de son port. Personne n'est aujourd'hui en mesure de dire de bonne foi si l'obligation sauvera plus qu'elle ne tuera. Mais du moment qu'elle tue, cette obligation est injustifiable puisque la ceinture ne concernera jamais que celui qui la porte, sans aucune répercussion possible sur la sécurité d'autrui. Tant que l'obligation ne sera pas rapportée, chaque mort due à la ceinture pourra être considérée comme la victime d'un véritable assassinat légal. Il faut rendre à chacun la liberté de boucler ou non sa ceinture.

7509 ISBN 2.7267.9127.1

14.1.12.6.7 ROC and Lift curves

ROC (Receiver Operating Characteristic) curve and Lift chart are techniques for visualizing, organizing, improving and selecting classifiers based on their performance. They facilitate our conception of classifiers and are therefore useful in research and in result presentation.

ROC curve is a plot of the true positive rate (TPR) against the false positive rate (FPR) at various threshold settings. It is used to evaluate the performance of a binary classifier.

Lift chart is a measure of the effectiveness of a predictive model. It compares the results of the model against a random guess and tells us how much better we are doing than random guessing.

14.1.12.6.7.1 ROC curve

Classifier performance evaluation should consider all the score range instead of a single point, unless specified by the application domain requirements. That is probably the reason why the area under the curve (AUC) of the Receiver Operating Characteristics (ROC) became so popular among scientists for binary classification quality assessment, instead of confusion matrix, error rates, maximum vertical distance of the ROC curve, maximum Kolmogorov-Smirnov vertical difference and all other single point specific metrics that are useful for the human brain but not very reliable.

The "ROC curve", that stands for "Receiver Operating Characteristic curve", is a measure of the performance of a binary classifier, that is to say a system that aims to categorize entities in two distinct groups on the basis of one or more of their characteristics.

Graphically, we often represents the ROC measurement in the form of a curve which gives the true positive rate (sensitivity: fraction of positives that are correctly detected) according to the rate of false positive rate (proportion of negatives which are incorrectly detected) for the same group. ROC curves are often used in statistics to show the progress realized with a binary classifier when "discrimination threshold" (cutoff) varies.

Remark

We present this tool because many statistical software return automatically a ROC curve as output but the interest of this tool is in my personal opinion very questionable. However, we will show a more useful tool right after.

Let us see practical case by taking our previous example (the Bank and its subsidiaries) with the spreadsheet software Microsoft® Excel® 14.0.7106. First to build the ROC curve we must obtain the confusion matrix C that we presented just a little higher with Minitab. For this with a spreadsheet software and without doing code, here is a simple solution (but this is not the more condensed solution for pedagogical reasons).

The goal will be first to build the following table (this is only a part of the table of the previous example since in reality there are 136 rows of data) whose columns `B` and `C` comes from the three small tables of Credits used just before, column `A` is just the cumulative frequency of individuals $1/136$ ... $2/136$ ... $3/136$ ... and so on):

	A	B	C	D	E	F	G	H	I	J	K
1	%	Amount	Status	Model	1-Model (Score)	Output	True Positive	False Positive	True Negative	False Negative

Figure 14.28: **List to obtain in Microsoft® Excel® the ROC curve**

Now let us see what is in columns `D`, `E` and `F` and that are directly related to the result obtained above, which was for recall:

$$P(Y)=\frac{1}{1-e^{-(-15.1116+0.001837x)}} \tag{14.1.979}$$

but that we have refined with a specialized statistical software to obtain:

$$P(Y)=\frac{1}{1-e^{-(-61.3183+0.002211x)}} \tag{14.1.980}$$

which then allows us to build the three previous mentioned columns (here we have only a few of the first rows because it is sufficient to just increment the formulas to the bottom of the list):

	D	E	F
1	**Model**	**1-Model (Score)**	**Output**
2	=1/(1+EXP(61.3183-0.002211*B2))	=1-D2	=IF(D2>$M$3,1,0)
3	=1/(1+EXP(61.3183-0.002211*B3))	=1-D3	=IF(D3>$M$3,1,0)
4	=1/(1+EXP(61.3183-0.002211*B4))	=1-D4	=IF(D4>$M$3,1,0)
5	=1/(1+EXP(61.3183-0.002211*B5))	=1-D5	=IF(D5>$M$3,1,0)
6	=1/(1+EXP(61.3183-0.002211*B6))	=1-D6	=IF(D6>$M$3,1,0)
7	=1/(1+EXP(61.3183-0.002211*B7))	=1-D7	=IF(D7>$M$3,1,0)
8	=1/(1+EXP(61.3183-0.002211*B8))	=1-D8	=IF(D8>$M$3,1,0)
9	=1/(1+EXP(61.3183-0.002211*B9))	=1-D9	=IF(D9>$M$3,1,0)
10	=1/(1+EXP(61.3183-0.002211*B10))	=1-D10	=IF(D10>$M$3,1,0)
11	=1/(1+EXP(61.3183-0.002211*B11))	=1-D11	=IF(D11>$M$3,1,0)

13	=1/(1+EXP(61.3183-0.002211*B13))	=1-D13	=IF(D13>$M$3,1,0)
14	=1/(1+EXP(61.3183-0.002211*B14))	=1-D14	=IF(D14>$M$3,1,0)
15	=1/(1+EXP(61.3183-0.002211*B15))	=1-D15	=IF(D15>$M$3,1,0)
16	=1/(1+EXP(61.3183-0.002211*B16))	=1-D16	=IF(D16>$M$3,1,0)
17	=1/(1+EXP(61.3183-0.002211*B17))	=1-D17	=IF(D17>$M$3,1,0)
18	=1/(1+EXP(61.3183-0.002211*B18))	=1-D18	=IF(D18>$M$3,1,0)
19	=1/(1+EXP(61.3183-0.002211*B19))	=1-D19	=IF(D19>$M$3,1,0)
20	=1/(1+EXP(61.3183-0.002211*B20))	=1-D20	=IF(D20>$M$3,1,0)
21	=1/(1+EXP(61.3183-0.002211*B21))	=1-D21	=IF(D21>$M$3,1,0)
22	=1/(1+EXP(61.3183-0.002211*B22))	=1-D22	=IF(D22>$M$3,1,0)
23	=1/(1+EXP(61.3183-0.002211*B23))	=1-D23	=IF(D23>$M$3,1,0)
24	=1/(1+EXP(61.3183-0.002211*B24))	=1-D24	=IF(D24>$M$3,1,0)
25	=1/(1+EXP(61.3183-0.002211*B25))	=1-D25	=IF(D25>$M$3,1,0)
26	=1/(1+EXP(61.3183-0.002211*B26))	=1-D26	=IF(D26>$M$3,1,0)
27	=1/(1+EXP(61.3183-0.002211*B27))	=1-D27	=IF(D27>$M$3,1,0)
28	=1/(1+EXP(61.3183-0.002211*B28))	=1-D28	=IF(D28>$M$3,1,0)

Figure 14.29: **Spreadsheet formulas for the probability of the model and the score**

The formula in column `F` refers to the cell `M3` which as we shall see a little further contains the empirical choice of the value of the cutoff we had mentioned during the presentation of the theoretical model of the logistics regression (by default we defined it at 50%).

Then we must build the columns of true positive, false positive, true negative, false negatives using basic spreadsheet formulas:

	G	H	I	J
1	True Positive	False Positive	True Negative	False Negative
2	=IF(AND(C2=F2,C2=1),1,0)	=IF(AND(C2<>F2,C2=1),1,0)	=IF(AND(C2=F2,C2=0),1,0)	=IF(AND(C2<>F2,C2=0),1,0)
3	=IF(AND(C3=F3,C3=1),1,0)	=IF(AND(C3<>F3,C3=1),1,0)	=IF(AND(C3=F3,C3=0),1,0)	=IF(AND(C3<>F3,C3=0),1,0)
4	=IF(AND(C4=F4,C4=1),1,0)	=IF(AND(C4<>F4,C4=1),1,0)	=IF(AND(C4=F4,C4=0),1,0)	=IF(AND(C4<>F4,C4=0),1,0)
5	=IF(AND(C5=F5,C5=1),1,0)	=IF(AND(C5<>F5,C5=1),1,0)	=IF(AND(C5=F5,C5=0),1,0)	=IF(AND(C5<>F5,C5=0),1,0)
6	=IF(AND(C6=F6,C6=1),1,0)	=IF(AND(C6<>F6,C6=1),1,0)	=IF(AND(C6=F6,C6=0),1,0)	=IF(AND(C6<>F6,C6=0),1,0)
7	=IF(AND(C7=F7,C7=1),1,0)	=IF(AND(C7<>F7,C7=1),1,0)	=IF(AND(C7=F7,C7=0),1,0)	=IF(AND(C7<>F7,C7=0),1,0)
8	=IF(AND(C8=F8,C8=1),1,0)	=IF(AND(C8<>F8,C8=1),1,0)	=IF(AND(C8=F8,C8=0),1,0)	=IF(AND(C8<>F8,C8=0),1,0)
9	=IF(AND(C9=F9,C9=1),1,0)	=IF(AND(C9<>F9,C9=1),1,0)	=IF(AND(C9=F9,C9=0),1,0)	=IF(AND(C9<>F9,C9=0),1,0)
10	=IF(AND(C10=F10,C10=1),1,0)	=IF(AND(C10<>F10,C10=1),1,0)	=IF(AND(C10=F10,C10=0),1,0)	=IF(AND(C10<>F10,C10=0),1,0)
11	=IF(AND(C11=F11,C11=1),1,0)	=IF(AND(C11<>F11,C11=1),1,0)	=IF(AND(C11=F11,C11=0),1,0)	=IF(AND(C11<>F11,C11=0),1,0)
12	=IF(AND(C12=F12,C12=1),1,0)	=IF(AND(C12<>F12,C12=1),1,0)	=IF(AND(C12=F12,C12=0),1,0)	=IF(AND(C12<>F12,C12=0),1,0)
13	=IF(AND(C13=F13,C13=1),1,0)	=IF(AND(C13<>F13,C13=1),1,0)	=IF(AND(C13=F13,C13=0),1,0)	=IF(AND(C13<>F13,C13=0),1,0)
14	=IF(AND(C14=F14,C14=1),1,0)	=IF(AND(C14<>F14,C14=1),1,0)	=IF(AND(C14=F14,C14=0),1,0)	=IF(AND(C14<>F14,C14=0),1,0)
15	=IF(AND(C15=F15,C15=1),1,0)	=IF(AND(C15<>F15,C15=1),1,0)	=IF(AND(C15=F15,C15=0),1,0)	=IF(AND(C15<>F15,C15=0),1,0)
16	=IF(AND(C16=F16,C16=1),1,0)	=IF(AND(C16<>F16,C16=1),1,0)	=IF(AND(C16=F16,C16=0),1,0)	=IF(AND(C16<>F16,C16=0),1,0)
17	=IF(AND(C17=F17,C17=1),1,0)	=IF(AND(C17<>F17,C17=1),1,0)	=IF(AND(C17=F17,C17=0),1,0)	=IF(AND(C17<>F17,C17=0),1,0)
18	=IF(AND(C18=F18,C18=1),1,0)	=IF(AND(C18<>F18,C18=1),1,0)	=IF(AND(C18=F18,C18=0),1,0)	=IF(AND(C18<>F18,C18=0),1,0)
19	=IF(AND(C19=F19,C19=1),1,0)	=IF(AND(C19<>F19,C19=1),1,0)	=IF(AND(C19=F19,C19=0),1,0)	=IF(AND(C19<>F19,C19=0),1,0)
20	=IF(AND(C20=F20,C20=1),1,0)	=IF(AND(C20<>F20,C20=1),1,0)	=IF(AND(C20=F20,C20=0),1,0)	=IF(AND(C20<>F20,C20=0),1,0)
21	=IF(AND(C21=F21,C21=1),1,0)	=IF(AND(C21<>F21,C21=1),1,0)	=IF(AND(C21=F21,C21=0),1,0)	=IF(AND(C21<>F21,C21=0),1,0)
22	=IF(AND(C22=F22,C22=1),1,0)	=IF(AND(C22<>F22,C22=1),1,0)	=IF(AND(C22=F22,C22=0),1,0)	=IF(AND(C22<>F22,C22=0),1,0)

28	=IF(AND(C28=F28,C28=1),1,0)	=IF(AND(C28<>F28,C28=1),1,0)	=IF(AND(C28=F28,C28=0),1,0)	=IF(AND(C28<>F28,C28=0),1,0)
29	=IF(AND(C29=F29,C29=1),1,0)	=IF(AND(C29<>F29,C29=1),1,0)	=IF(AND(C29=F29,C29=0),1,0)	=IF(AND(C29<>F29,C29=0),1,0)

Figure 14.30: Spreadsheet formulas for true / false positives and negatives

Once we have this data, we can rebuild the confusion matrix $\mathcal{C}$ that was given to us by Minitab and we will need to develop the ROC curve:

	K	L	M	N	O
1					
2					
3		Cutt-Off value	0.5	(normaly we choose the value of the score)	
4		True positives	=SUM(G2:G137)	True negatives	=SUM(I2:I137)
5		False positives	=SUM(H2:H137)	False negatives	=SUM(J2:J137)
6		Total:	=SUM(M4:M5)		=SUM(O4:O5)
7					
8		TP-Rate:	=M4/M6	TN-Rate:	=O4/O6
9		FP-Rate:	=O4/O6	Sum: TP/TN rate:	=SUM(O8,M8)
10					
11		Coordonnée Y:	=M8		
12		Coordonnée X:	=1-M9		

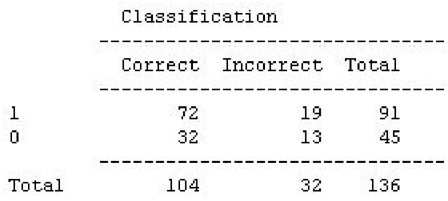
Figure 14.31: Spreadsheet formulas to build the confusion matrix

which explicitly gives:

	K	L	M	N	O
1					
2					
3		Cutt-Off value	50.00%	(normaly we choose the value of the score)	
4		True positives	72	True negatives	32
5		False positives	19	False negatives	13
6		Total:	91		45
7					
8		TP-Rate:	0.791	TN-Rate:	0.711
9		FP-Rate:	0.711	Sum: TP/TN rate:	1.502
10					
11		Coordonnée Y:	0.791		
12		Coordonnée X:	0.289		

Figure 14.32: Corresponding values of the construction of the confusion matrix

compared with the confusion matrix that we gave and coming from Minitab:



```
                 Classification
               ------------------------------
                 Correct  Incorrect  Total
               ------------------------------
1                    72         19      91
0                    32         13      45
               ------------------------------
Total               104         32     136
```

Figure 14.33: **Confusion matrix with Minitab 16.1.1**

Now observe the ROC curve given by Minitab:

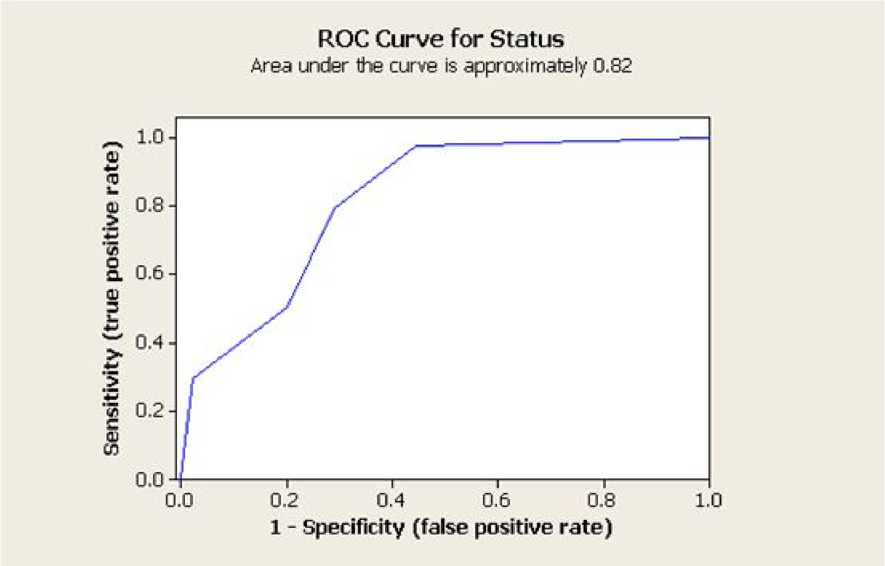


Figure 14.34: **ROC curve with Minitab 16.1.1**

Why the abscissa-represents:

$$1-\%\text{false positives}$$

you will probably ask yourself when the interpretation would have been easier if we had just the:

$$\%\text{false positives}$$

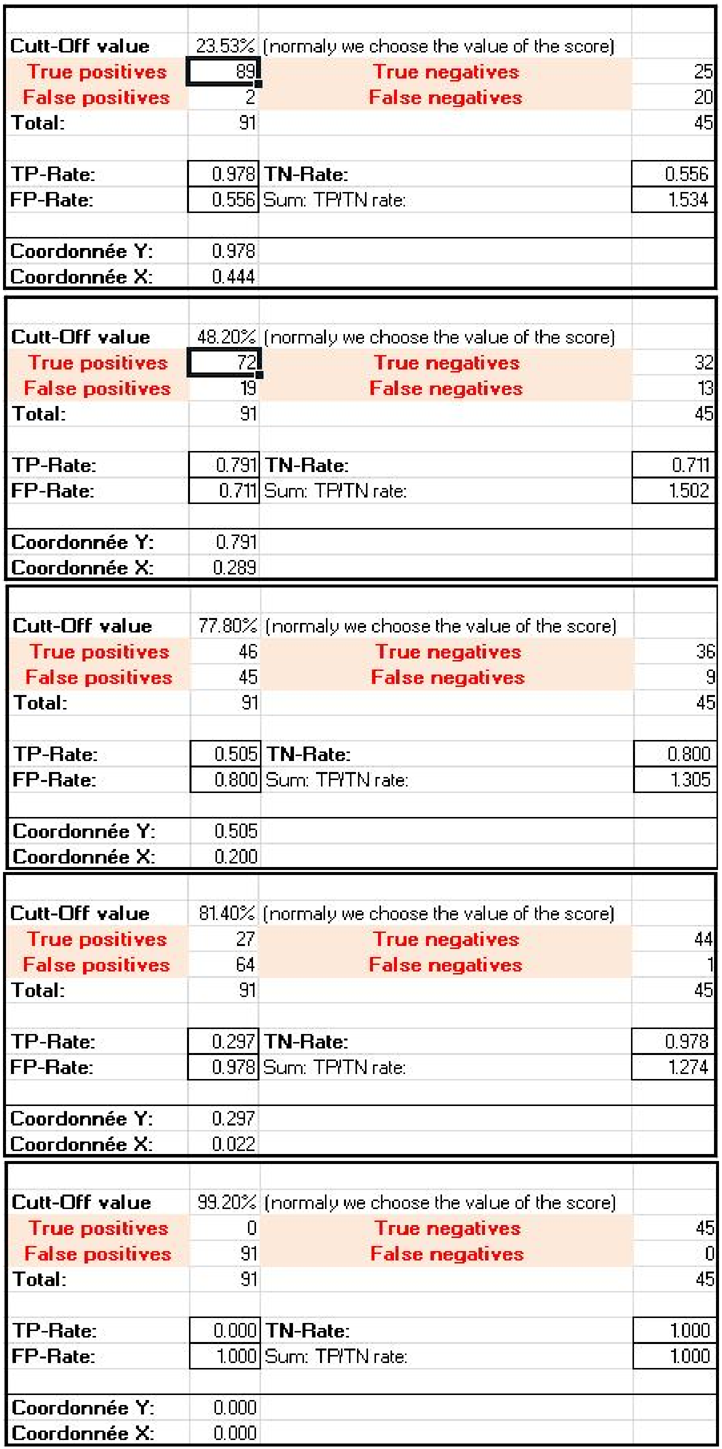
Well for two reasons: the first is that practitioners like strictly increasing functions... and the second reason, the most important, is that if the binary classifier is fully effective, the surface is then equal to 1(that is to say, 100%). Which admittedly is nicer than to say that a null surface corresponds to a 100% efficiency. Well that being said ... let us continue.

Before learning how to interpret this chart, how to get the same curve in a spreadsheet software? Well just simply observe our column `D` of our Microsoft® Excel® list. Logically we have there

5 different cumulative probabilities (as there were only 5 credits values) which are respectively:

$$0.235214057$$
$$0.481608302$$
$$0.777818743$$
$$0.813679766$$
$$0.991760974$$

Therefore the idea of the construction of the ROC curve is to take each of the accumulated probabilities as cutt-off values. This gives respectively:



Cutt-Off value	23.53%	(normaly we choose the value of the score)	
True positives	89	**True negatives**	25
False positives	2	**False negatives**	20
Total:	91		45
TP-Rate:	0.978	**TN-Rate:**	0.556
FP-Rate:	0.556	Sum: TP/TN rate:	1.534
Coordonnée Y:	0.978		
Coordonnée X:	0.444		

Cutt-Off value	48.20%	(normaly we choose the value of the score)	
True positives	72	**True negatives**	32
False positives	19	**False negatives**	13
Total:	91		45
TP-Rate:	0.791	**TN-Rate:**	0.711
FP-Rate:	0.711	Sum: TP/TN rate:	1.502
Coordonnée Y:	0.791		
Coordonnée X:	0.289		

Cutt-Off value	77.80%	(normaly we choose the value of the score)	
True positives	46	**True negatives**	36
False positives	45	**False negatives**	9
Total:	91		45
TP-Rate:	0.505	**TN-Rate:**	0.800
FP-Rate:	0.800	Sum: TP/TN rate:	1.305
Coordonnée Y:	0.505		
Coordonnée X:	0.200		

Cutt-Off value	81.40%	(normaly we choose the value of the score)	
True positives	27	**True negatives**	44
False positives	64	**False negatives**	1
Total:	91		45
TP-Rate:	0.297	**TN-Rate:**	0.978
FP-Rate:	0.978	Sum: TP/TN rate:	1.274
Coordonnée Y:	0.297		
Coordonnée X:	0.022		

Cutt-Off value	99.20%	(normaly we choose the value of the score)	
True positives	0	**True negatives**	45
False positives	91	**False negatives**	0
Total:	91		45
TP-Rate:	0.000	**TN-Rate:**	1.000
FP-Rate:	1.000	Sum: TP/TN rate:	1.000
Coordonnée Y:	0.000		
Coordonnée X:	0.000		

Figure 14.35: Values of the confusion matrix for various cutoff values

So we get each time the coordinates of points of the ROC curve in function of cutoff values. Well this done, now let us turn to the interpretation by taking the below manually completed graph:

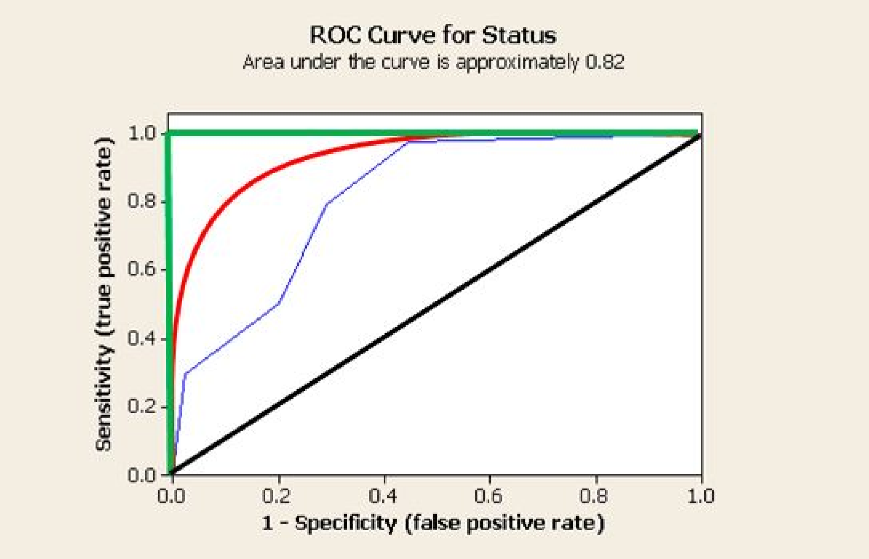


Figure 14.36: **ROC curves**
(blue: average classifier, red: good classifier, green: perfect classifier, black: poor classifier)

Credit Amount	Proportion P	Cutt-Off Value	x Coordinate of ROC Curve point	y Coordinate of ROC Curve point
			0	0
$27,200$	0.0741	23.53%	0	0
$27,700$	0.7083	48.20%	0.022	0.297
$28,300$	0.8667	77.80%	0.200	0.505
$28,400$	0.7037	81.40%	0.289	0.791
$29,900$	0.9643	99.2%	0.444	0.978
			1	1

Then as shown in the graph above and the intuition, a perfect binary classifier is one whose true positive rate is constant and always equal to 100%. So the binary classifier in our example is moderately good.

Remark

The biggest vertical distance between the black line in the figure above and the blue ROC curved is sometimes used as a quality metric for classification named the "maximum vertical distance" and abbreviated MVD.

But from my personal point of view a good binary classifier is one that for a given value of the cutoff maximizes the sum of the rate of true positives and true negatives. Thus, with a spreadsheet software such as Microsoft® Excel® in "evolutionary mode" it is very easy to find this cutoff value that maximizes this objective. But however be careful to the trap: the value may not be unique, it can also be an interval (which is the case in our example!).

Finally, if we denote by TP the true positive, TN the true negative, FP the false positives or Type I error (in terms of decision theory or tests theory), and FN false negative or Type II error we can then define a set of indicators to judge the quality of our predictor/classifier (or rather of our score):

- $\text{TPR} = \dfrac{\text{TP}}{\text{P}} = \dfrac{\text{TP}}{\text{TP+FN}}$ named "sensitivity", corresponding to the rate of true positives.
- $\text{RPF} = \dfrac{\text{FP}}{\text{N}} = \dfrac{\text{FP}}{\text{FP+TN}}$ corresponding to the rate of false positives.
- $\text{ACC} = \dfrac{\text{TP+TN}}{\text{P+N}}$ named "accuracy" (fraction of instances that are correctly classified).
- $\text{SPC} = \dfrac{\text{TN}}{\text{N}} = \dfrac{\text{TN}}{\text{FP+TN}} = 1 - \text{FPR}$ named "specificity" or true negative rate.
- $\text{PPV} = \dfrac{\text{TP}}{\text{TP+TP}}$ the "positive predictive value".
- $\text{NPV} = \dfrac{\text{TN}}{\text{TN+FN}}$ the "negative predictive value".
- $\text{FDR} = \dfrac{\text{FP}}{\text{FP+TP}}$ corresponding to the "false discovery rate".

And we can build many quality metrics like (for the most famous one!) the Matthews correlation coefficient (see section Statistics page 1254), the F_1 score (see page 6482) or the "Rand Index" (also sometimes named "model accuracy") defined by:

$$\text{RI} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{FP} + \text{TN} + \text{FN}} \tag{14.1.981}$$

Remark

In practice, the sensitivity and specificity of a test give an assessment of its intrinsic validity. It is considered in practice that taken separately, they do not mean anything. For example, it should be obvious for the reader a test with 95% sensitivity has no value if its specificity is only 5%. It is considered in practice that if the sum of sensitivity and specificity is equal to 100% the test is as good a random.

✍**Example:**

Consider a disease test sensibility and sensitivity analysis with the following values:

		Patients with bowel cancer (as confirmed by endoscopy)		
		Positive	**Negative**	
Disease Test	**Positive**	TP$=2$	FP$=18$	$\frac{\text{TP}}{\text{TP}+\text{FP}}$ $=\frac{2}{2+18}$ $=10\%$
	Negative	FN$=1$	TN$=182$	$\frac{\text{TN}}{\text{TN}+\text{FN}}$ $=\frac{182}{1+182}$ $=99.5\%$
		Sensitivity $=\frac{\text{TP}}{\text{TP}+\text{FN}}$ $=\frac{2}{2+1}=66.\bar{6}\%$	Specificity $=\frac{\text{TN}}{\text{FP}+\text{TN}}$ $=\frac{182}{18+182}=91\%$	

Table 14.15: **Example of sensibility and specificity analysis**

There are some cases where sensitivity is important and need to be near to 1. There are business cases where specificity is important and need to be near to 1 (ideally we want to maximize both sensitivity & specificity, but this is not always possible always). We need to understand the business problem and decide the importance of sensitivity and specificity.

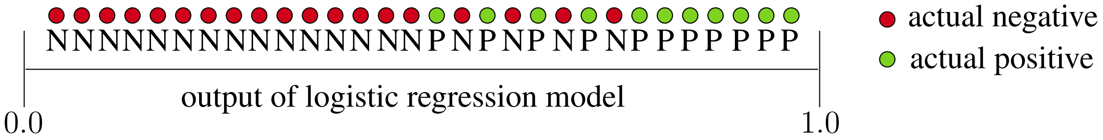
Remark

Current generation HIV tests are considered extremely accurate. The blood-based HIV ELISA has a demonstrated sensitivity of between 99.3% to 99.7 percent, with a specificity of between 99.91% and 99.97%. When combined with a Western blot, this translates to approximately one false positive out of every $250,000$ tests in the general U.S. population. Newer, fourth generation combination tests, which test for both HIV antibodies and antigens, are reported to have a clinical sensitivity of 99.9%.

As you may have notice in the previous chart above. Below the title of the chart there was a mention of something named "Area Under the Curve" and that is well known under the abbreviation AUC.

Obviously, the names mean what it is: It measures the entire two-dimensional area underneath the entire ROC curve (think integral calculus) from $[0,0]$ to $[1,1]$.

AUC provides an aggregate measure of performance across all possible classification thresholds. One way of interpreting AUC is as the probability that the model ranks a random positive example more highly than a random negative example. For example, given the following examples, which are arranged from left to right in ascending order of logistic regression predictions:



N N N N N N N N N N N N N N N P N P N P N P N P P P P P P P
output of logistic regression model
0.0
1.0
● actual negative
● actual positive

AUC represents the probability that a random positive (green) example is positioned to the right of a random negative (red) example.

Example:

If we have a model with an AUC of 80%, it means that if we choose randomly two individuals in the population, one negative and the other positive, the model will classify correctly these two individuals in their respective groups 8 times on 10.

The corresponding mathematical expression is quite obviously given by:

$$\text{AUC} = P\left(X_{(p)} > X_{(n)}\right) = \frac{1}{mn}\sum_{i=1}^{m}\sum_{j=1}^{n} 1_{p_i > p_j} \tag{14.1.982}$$

Here i runs over all m data points with true label 1, and j runs over all n data points with true label 0; p_i and p_j denote the probability score assigned by the classifier to data point i and j, respectively. 1 is always the indicator function: it outputs 1 if and only if the condition $(p_i > p_j)$ is satisfied!

AUC ranges in value from 0 to 1. A model whose predictions are 100% wrong has an AUC of 0.0; one whose predictions are 100% correct has an AUC of 1.0. A model that doesn't better than chance will have an AUC of less than 50%.

Testing the fact evidence that the AUC is significantly different of 0.5 is like the null hypothesis H_0: *The distribution of the ranks in the two groups are equal*. It's then the equivalent of running a Wilcoxon rank sum test (see section Statistics page 1160).

Remark

In logistic regression if we consider then probabilities $\left\{\left(\hat{\pi}(\hat{\vec{\beta}}|\vec{x}_i\right), \hat{\pi}\left(\hat{\vec{\beta}}, \vec{x}_j\right)\right\}$, the C-index can be defined as:

$$C = P\left[\hat{\pi}\left(\hat{\vec{\beta}}|\vec{x}_i\right) > \hat{\pi}\left(\hat{\vec{\beta}}|\vec{x}_i\right)\middle| Y_i = 1 \& Y_j = 0\right] \tag{14.1.983}$$

Which is equivalent to:

$$C = P\left[\hat{\vec{\beta}} \circ \vec{x}_i > \hat{\vec{\beta}} \circ \vec{x}_j \middle| Y_i = 1 \& Y_j = 0\right] \tag{14.1.984}$$

AUC is desirable for the following two reasons:

- AUC is scale-invariant. It measures how well predictions are ranked, independently of their absolute values.
- AUC is classification-threshold-invariant. It measures the quality of the model's predictions irrespective of what classification threshold is chosen.

Notice that there is a simple relation between the AUC and the Gini index. Indeed, as we have proved it in the section of Quantitative Management (see page 8099), we have:

$$G=2A \tag{14.1.985}$$

But as:

$$\text{AUC}=A+\frac{1}{2} \tag{14.1.986}$$

We then have:

$$G=2\cdot\text{AUC}-1 \tag{14.1.987}$$

Remark

In multi-class models, we can plot N number of AUC ROC curves for N number classes using the "One vs All methodology". So for example, if you have three classes named A, B and C, you will have one ROC for A classified against B and C, another ROC for B classified against A and B, and a third one C classified against A and B.

Having done this, let us move to the second curve.

14.1.12.6.7.2 Lift curve

The principle of the "lift curve" is very simple but is based on a questionable assumption (which fortunately has not however a great importance) that is that without the theoretical model (logistic model in this case) we will absolutely know nothing of the real behaviour that will have the customers (debtors). The hypothesis is to consider that if we took 50% of the individuals in our sample, we would have 50% of true positives (real bad debtors), if we took 25% of our sample, we would have 25% of true positives (true bad debtors) and so on. This initial hypothesis (considered by practitioners as the worst case) will be represented graphically by the following straight line:

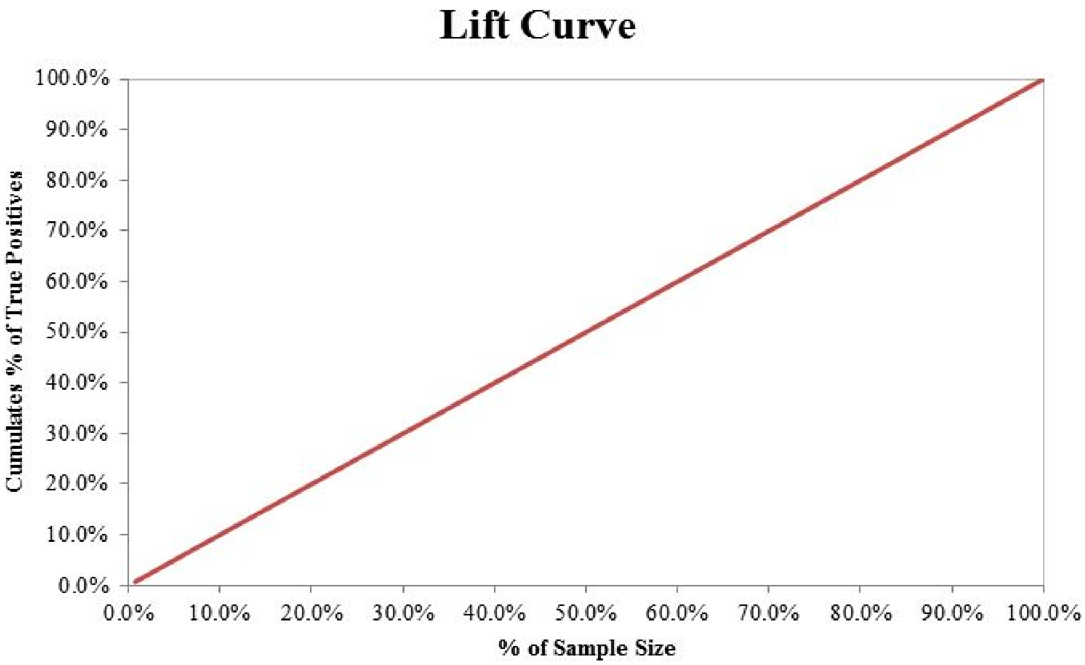


Figure 14.37: Lift curve at worst (as assumption)

But that's just to have an empirical reference when working with a single model of statistical clustering. In fact, given the multiplicity of statistical modelling methods, where almost each has its own empirical indicators of quality, statisticians have sought general criteria for the performance of a model (this obviously in the idea to be able to compare the accuracy of various models between them).

Thus, an empirical and intuitive enough choice is to say that a statistical method is better than another if for a given subset of the sample, its predictive power (the cumulative number of true positives for example) is better or not. This is the purpose of the lift curve.

The lift curve is therefore a variation of the ROC curve. The lift curve classify the individuals by descending score (again for reasons of simplification of interpretation of the surface under the curve and especially to have in first the target group of interest to monitor), by grouping them by percentiles for example, determining the percentage of events of interest in each percentile (normally the true positives) and then by plotting the cumulative curve of these percentages, so that a point of the coordinates (n, m) on the curve means that the $n\%$ of individuals with the highest score concentrate $m\%$ of events. This is the way to build this curve which makes we speak of "predictive performance of targeted marketing".

Let's see how to build such a curve, always with the same spreadsheet software and always the same data. The start of construction is to take some columns that we had used for the ROC curve (first 31 rows out of 136):

	B	C	D	E	F
1	Amount	Status	Model	Output	True Positives
2	27200	0	=1/(1+EXP(61.3183-0.002211*B2))	=IF(D2>50%,1,0)	=IF(AND(C2=E2,C2=1),1,0)
3	27200	0	=1/(1+EXP(61.3183-0.002211*B3))	=IF(D3>50%,1,0)	=IF(AND(C3=E3,C3=1),1,0)
4	27200	0	=1/(1+EXP(61.3183-0.002211*B4))	=IF(D4>50%,1,0)	=IF(AND(C4=E4,C4=1),1,0)
5	27200	0	=1/(1+EXP(61.3183-0.002211*B5))	=IF(D5>50%,1,0)	=IF(AND(C5=E5,C5=1),1,0)
6	27200	0	=1/(1+EXP(61.3183-0.002211*B6))	=IF(D6>50%,1,0)	=IF(AND(C6=E6,C6=1),1,0)
7	27200	0	=1/(1+EXP(61.3183-0.002211*B7))	=IF(D7>50%,1,0)	=IF(AND(C7=E7,C7=1),1,0)
8	27200	0	=1/(1+EXP(61.3183-0.002211*B8))	=IF(D8>50%,1,0)	=IF(AND(C8=E8,C8=1),1,0)
9	27200	0	=1/(1+EXP(61.3183-0.002211*B9))	=IF(D9>50%,1,0)	=IF(AND(C9=E9,C9=1),1,0)
10	27200	0	=1/(1+EXP(61.3183-0.002211*B10))	=IF(D10>50%,1,0)	=IF(AND(C10=E10,C10=1),1,0)
11	27200	1	=1/(1+EXP(61.3183-0.002211*B11))	=IF(D11>50%,1,0)	=IF(AND(C11=E11,C11=1),1,0)
12	27200	0	=1/(1+EXP(61.3183-0.002211*B12))	=IF(D12>50%,1,0)	=IF(AND(C12=E12,C12=1),1,0)
13	27200	0	=1/(1+EXP(61.3183-0.002211*B13))	=IF(D13>50%,1,0)	=IF(AND(C13=E13,C13=1),1,0)
14	27200	0	=1/(1+EXP(61.3183-0.002211*B14))	=IF(D14>50%,1,0)	=IF(AND(C14=E14,C14=1),1,0)
15	27200	0	=1/(1+EXP(61.3183-0.002211*B15))	=IF(D15>50%,1,0)	=IF(AND(C15=E15,C15=1),1,0)
16	27200	0	=1/(1+EXP(61.3183-0.002211*B16))	=IF(D16>50%,1,0)	=IF(AND(C16=E16,C16=1),1,0)
17	27200	0	=1/(1+EXP(61.3183-0.002211*B17))	=IF(D17>50%,1,0)	=IF(AND(C17=E17,C17=1),1,0)
18	27200	0	=1/(1+EXP(61.3183-0.002211*B18))	=IF(D18>50%,1,0)	=IF(AND(C18=E18,C18=1),1,0)
19	27200	0	=1/(1+EXP(61.3183-0.002211*B19))	=IF(D19>50%,1,0)	=IF(AND(C19=E19,C19=1),1,0)
20	27200	0	=1/(1+EXP(61.3183-0.002211*B20))	=IF(D20>50%,1,0)	=IF(AND(C20=E20,C20=1),1,0)
21	27200	0	=1/(1+EXP(61.3183-0.002211*B21))	=IF(D21>50%,1,0)	=IF(AND(C21=E21,C21=1),1,0)
22	27200	0	=1/(1+EXP(61.3183-0.002211*B22))	=IF(D22>50%,1,0)	=IF(AND(C22=E22,C22=1),1,0)
23	27200	0	=1/(1+EXP(61.3183-0.002211*B23))	=IF(D23>50%,1,0)	=IF(AND(C23=E23,C23=1),1,0)
24	27200	0	=1/(1+EXP(61.3183-0.002211*B24))	=IF(D24>50%,1,0)	=IF(AND(C24=E24,C24=1),1,0)
25	27200	0	=1/(1+EXP(61.3183-0.002211*B25))	=IF(D25>50%,1,0)	=IF(AND(C25=E25,C25=1),1,0)
26	27200	0	=1/(1+EXP(61.3183-0.002211*B26))	=IF(D26>50%,1,0)	=IF(AND(C26=E26,C26=1),1,0)
27	27200	0	=1/(1+EXP(61.3183-0.002211*B27))	=IF(D27>50%,1,0)	=IF(AND(C27=E27,C27=1),1,0)
28	27200	1	=1/(1+EXP(61.3183-0.002211*B28))	=IF(D28>50%,1,0)	=IF(AND(C28=E28,C28=1),1,0)
29	27700	0	=1/(1+EXP(61.3183-0.002211*B29))	=IF(D29>50%,1,0)	=IF(AND(C29=E29,C29=1),1,0)

30	21.3%	27700	0	0.48161	0	0
31	22.1%	27700	0	0.48161	0	0
32	22.8%	27700	1	0.48161	0	0

Figure 14.39: **Explicit value in Microsoft® Excel® to obtain for the lift curve**

One difference now compared to the ROC curve is that we want the events of interest first (the bad debtors). Then we must sort the column Model (that is to say the: Score) in descending order. This will give:

	A	B	C	D	E	F
1	**%**	**Amount**	**Status**	**Model**	**Output**	**True Positives**
2	0.7%	29900	0	0.99176	1	0
3	1.5%	29900	1	0.99176	1	1
4	2.2%	29900	1	0.99176	1	1
5	2.9%	29900	1	0.99176	1	1
6	3.7%	29900	1	0.99176	1	1
7	4.4%	29900	1	0.99176	1	1
8	5.1%	29900	1	0.99176	1	1
9	5.9%	29900	1	0.99176	1	1
10	6.6%	29900	1	0.99176	1	1
11	7.4%	29900	1	0.99176	1	1
12	8.1%	29900	1	0.99176	1	1
13	8.8%	29900	1	0.99176	1	1
14	9.6%	29900	1	0.99176	1	1
15	10.3%	29900	1	0.99176	1	1
16	11.0%	29900	1	0.99176	1	1
17	11.8%	29900	1	0.99176	1	1
18	12.5%	29900	1	0.99176	1	1
19	13.2%	29900	1	0.99176	1	1
20	14.0%	29900	1	0.99176	1	1
21	14.7%	29900	1	0.99176	1	1
22	15.4%	29900	1	0.99176	1	1
23	16.2%	29900	1	0.99176	1	1
24	16.9%	29900	1	0.99176	1	1
25	17.6%	29900	1	0.99176	1	1
26	18.4%	29900	1	0.99176	1	1
27	19.1%	29900	1	0.99176	1	1
28	19.9%	29900	1	0.99176	1	1
29	20.6%	29900	1	0.99176	1	1
30	21.3%	28400	0	0.81368	1	0
31	22.1%	28400	0	0.81368	1	0
32	22.8%	28400	0	0.81368	1	0

Figure 14.40: **Explicit sorted value in Microsoft® Excel® to obtain for the lift curve**

Then we add the column of %Cumulative of true positives:

	G
1	**%Cumulated of True Positives**
2	=COUNTIF($F$2:F2,"=1")/COUNTIF($F$2:$F$137,"=1")
3	=COUNTIF($F$2:F3,"=1")/COUNTIF($F$2:$F$137,"=1")
4	=COUNTIF($F$2:F4,"=1")/COUNTIF($F$2:$F$137,"=1")
5	=COUNTIF($F$2:F5,"=1")/COUNTIF($F$2:$F$137,"=1")
6	=COUNTIF($F$2:F6,"=1")/COUNTIF($F$2:$F$137,"=1")
7	=COUNTIF($F$2:F7,"=1")/COUNTIF($F$2:$F$137,"=1")
8	=COUNTIF($F$2:F8,"=1")/COUNTIF($F$2:$F$137,"=1")
9	=COUNTIF($F$2:F9,"=1")/COUNTIF($F$2:$F$137,"=1")
10	=COUNTIF($F$2:F10,"=1")/COUNTIF($F$2:$F$137,"=1")
11	=COUNTIF($F$2:F11,"=1")/COUNTIF($F$2:$F$137,"=1")

29	20.6%	29900	1	0.99176	1	1	37.50%
30	21.3%	28400	0	0.81368	1	0	37.50%
31	22.1%	28400	0	0.81368	1	0	37.50%
32	22.8%	28400	0	0.81368	1	0	37.50%

Figure 14.42: **Overview of all constructed columns for the lift curve**

The last step is now simply to build a graph of %cumulative number of true positive (column G) relative to the %cumulative of the sample size (column `A`) to get:

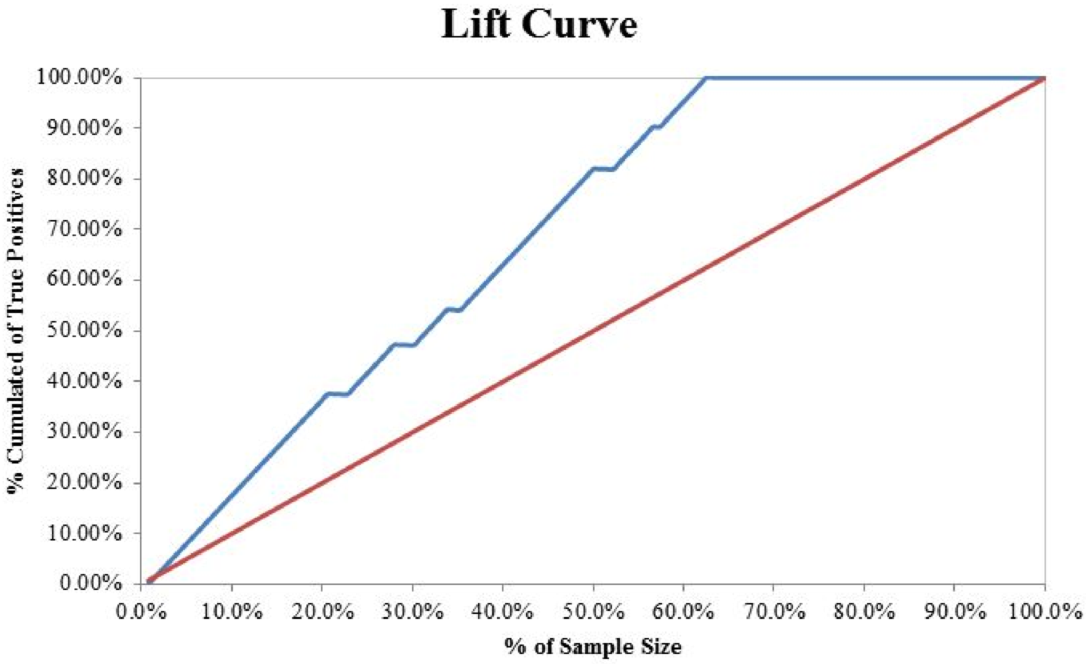

Figure 14.43: **Lift curve (in red at worst, in blue our model)**

So obviously we can not do in this case an interpretation of the predictive power in terms of "lift" in comparison to another statistical model. By cons we can compare the predictive power of the logistic model used in this case in terms of lift compared to the case considered at worst (the diagonal for reminder ...). So in this case, if we take the 20% of customers (debtors) having the highest score, that's what we have:

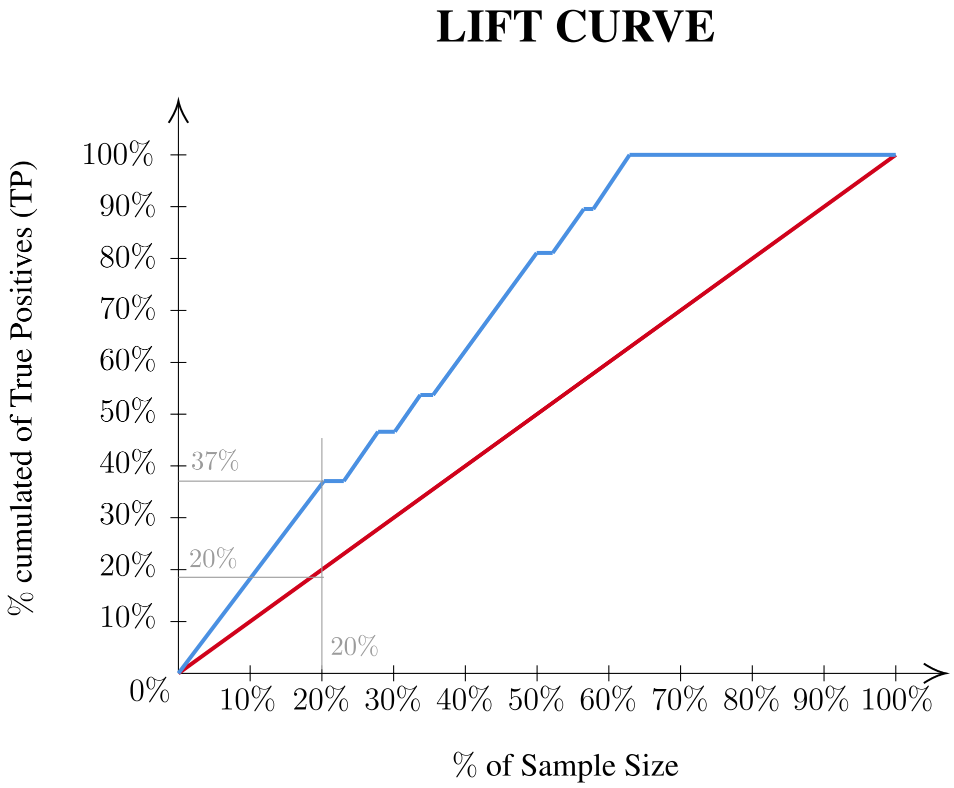

Figure 14.44: **Lift Analysis**

So in this particular example, this means that if we focus our analysis / research / target marketing or other... than on the 20% of the sample being the best score (for example ... for cost reasons), we have an overperformance of $37\%/20\% = 1.85$. Then we say that the model has a lift of 1.85. The idea then when we compare several models is to keep the one with the greatest lift (leverage).

14.1.12.7 General Linear Models (GLM)

So far we have seen multiple linear regression techniques (simple, multiple linear regression, Gaussian linear model, linearisation of non-linear regressions, logistic regressions, etc.).

There are, however, still other types of regressions named "general linear models" (not to be confused with "generalized linear models") which are intended for cases where the regression of the variable to be explained (and therefore the residuals) takes values whose range is not necessarily in $]-\infty,+\infty[$ as it is the case for the Gaussian linear model, but only takes integer positive values in $\mathbb{N}$, or that takes real values in the interval $[0,1]$, etc.

Remark

We will focus here on the essential concepts of the generalized linear regression models because for each of the submodels that we will see below it is possible to find textbooks of 300 to 500 pages which are dedicated to it! In the same way as for classical linear regression (Gaussian model) we one can find textbooks of almost 1,000 pages.

To introduce this type of model, recall what characterizes a general regression model (think by reading the following lines to the particular case of Gaussian linear model as it may help for the understanding):

C1. The response variable Y is a random component with a probability distribution: Normal (the most frequent case for continuous data), Binomial (positive integer successes in n trials), Poisson (positive integer successes for rare events), Bernoulli (whole positive success with one unique try), Binomial-Negative (positive integer success in a sequence of independent and identically distributed Bernoulli trials before a specified (non-random) number of failures occurs). We notice that these are laws belonging to the exponential family (the underlying idea being to linearise it with logarithm) as we will see later.

For example, for the linear Gaussian model seen earlier above, we have shown that for the case with a unique explanatory variable:

$$Y_i=\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{1}{2}\left(\frac{\alpha x_i+\beta-\mu_i}{\sigma}\right)^2} \tag{14.1.988}$$

was a model with which we relied on the least squares method via the log-likelihood maximum.

C2. The explanatory variables $x_1,x_2,\ldots,x_k$ with the intercept constant used as predictors in the model define as a linear (or non-linear by multiplying the variables by pairs) the deterministic components.

C3. The link describing the functional relationship between the linear combination of the explanatory variables and the expectation of the response variable Y is named the "link function" or "canonical parameter" and is traditionally denoted $g(\text{E}(Y_i))$.

In general, when the relation between $\text{E}(Y_i)$ and the explanatory variables is linear we speak of "linear model", when the relation between a function $g(\text{E}(Y_i))$ and the parameters is linear, we speak then of "general linear model".

For example, in the case of the linear Gaussian model with an explanatory variable, we have (it is immediate by the property of the underlying distribution):

$$\text{E}(Y_i)=\mu_i=\alpha x_i+\beta \tag{14.1.989}$$

Thus, in the case of the Gaussian linear model, the expectation is modelled directly. Thus, the link function for the Normal distribution is the mean itself! We talk then about an "identity link relation".

We will obviously not be able to use the linear Gaussian model given the definition domain taken by the variable to be explained when that latter is defined only on integers. On the other hand we could try an approach by saying that each count:

$$Y_i=n_i \tag{14.1.990}$$

Follows a Poisson distribution:

$$Y_i=e^{-\lambda_i}\frac{\lambda_i^{k_i}}{k_i!} \tag{14.1.991}$$

of mean (still in the special case with a unique explanatory variable!):

$$\mu_i=\lambda_i=N_i e^{\alpha x_i+\beta} \tag{14.1.992}$$

The studied model is then written:

$$Y_i=\text{Poisson}(\mu_i) \tag{14.1.993}$$

and we deduce from it:

$$\ln(\mu_i)=\ln(N_i)+\alpha x_i+\beta=\alpha x_i+B \tag{14.1.994}$$

We say that $\log(N_i)$ is an "offset variable" (in the industry it is often a value representing the time spent until the event of interest) and that the "link function" is then the logarithm for the Poisson regression. We speak more generally of "log-linear Poisson model" which is associated with a "logarithmic link".

Obviously the above approach is very far-fetched but a little further we will see the rigorous approach to get this link function.

Let us recall some important things in this model which are that the hypothesis are similar to the Gaussian linear model: the Y_i are all supposed to follow a Poisson distribution, to have all the same variance and to be independent, and so on...

Note that since we have:

$$\ln(\mu_i)=\alpha x_i+B\Leftrightarrow\mu_i=e^{\alpha x_i}e^B \tag{14.1.995}$$

The mean is therefore exponential, influenced by the sign of α (it is logical but it can always be useful to specify it). In the general case, we will see that the law of probability density associated with can be written in the general form:

$$\boxed{f(y_i,\theta_i,\varphi_i,\omega_i)=\exp\left(\frac{y_i\theta_i-b(\theta_i)}{a_i(\varphi)}+c(y_i,\alpha)\right)} \tag{14.1.996}$$

and we say then that the law belongs to the "exponential family" (the Normal, Poisson, Bernoulli and Gamma laws are part of it for example).

Remark

Very few specialists designate by the abbreviation "GLZM" the GLM other than those based on the Normal law.

14.1.12.7.1 Normal GLM

Let's see this with the Normal law by analogy (the homoscedastic case to simplify...):

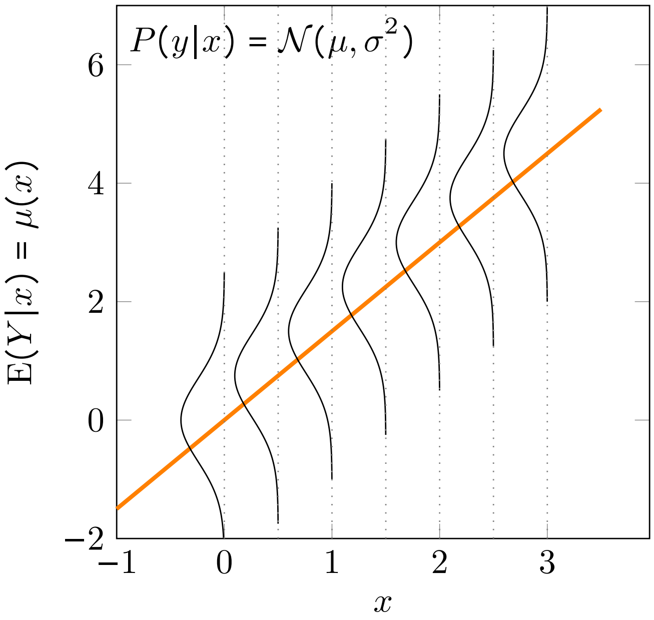

Figure 14.45: **Underlying idea of the Normal GLM (author: Walmes Zeviani)**

We therefore start from:

$$\begin{aligned}Y_i &= \frac{1}{\sigma\sqrt{2\pi}}\exp\left(-\frac{1}{2}\left(\frac{\alpha x_i+\beta-\mu_i}{\sigma}\right)^2\right) = \frac{1}{\sqrt{2\pi\sigma^2}}\exp\left(-\frac{1}{2}\left(\frac{y_i-\mu_i}{\sigma}\right)^2\right)\\ &= \exp\left(-\frac{1}{2\sigma^2}(y_i-\mu_i)^2+\ln\left(\frac{1}{\sqrt{2\pi\sigma^2}}\right)\right) = \exp\left(-\frac{1}{2\sigma^2}(y_i^2-2y_i\mu_i+\mu_i^2)-\ln(\sqrt{2\pi\sigma^2})\right)\\ &= \exp\left(\frac{y_i\mu_i-\mu_i^2/2}{\sigma^2}-\frac{y_i^2}{2\sigma^2}-\ln\left((2\pi\sigma^2)^{1/2}\right)\right) = \exp\left(\frac{y_i\mu_i-\mu_i^2/2}{\sigma^2}-\frac{1}{2}\left(\frac{y_i^2}{\sigma^2}-\ln\left(2\pi\sigma^2\right)\right)\right)\end{aligned} \tag{14.1.997}$$

So it comes by identification with:

$$f(y_i,\theta_i,\varphi,\omega_i) = \exp\left(\frac{y_i\theta_i-b(\theta_i)}{a_i(\varphi)}+c(y_i,\varphi)\right) \tag{14.1.998}$$

that:

$$\begin{aligned}
&\theta_i=\mu_i\\
&b(\theta_i)=\frac{1}{2}\theta_i^2=\frac{1}{2}\mu_i^2\\
&a_i(\varphi)=\sigma^2\\
&c(y_i,\varphi)=-\frac{1}{2}\left(\frac{y_i^2}{\varphi}-\ln(2\pi\varphi)\right)=-\frac{1}{2}\left(\frac{y_i^2}{\sigma^2}-\ln(2\pi\sigma^2)\right)\\
&\varphi=\sigma^2
\end{aligned} \tag{14.1.999}$$

Note also that (this is very important for what will follow!):

$$\begin{aligned}
&\frac{\mathrm{d}b(\theta_i)}{\mathrm{d}\theta_i}=\frac{\mathrm{d}b(\mu_i)}{\mathrm{d}(\mu_i)}=\frac{\mathrm{d}\left(\dfrac{1}{2}\mu_i^2\right)}{\mathrm{d}(\mu_i)}=\mu\\
&\frac{\mathrm{d}^2b(\theta_i)}{\mathrm{d}\theta_i^2}a_i(\varphi)=\frac{\mathrm{d}^2b(\mu_i)}{\mathrm{d}(\mu_i^2)}\sigma^2=\frac{\mathrm{d}^2\left(\dfrac{1}{2}\mu_i^2\right)}{\mathrm{d}(\mu_i^2)}\sigma^2=1\cdot\sigma^2=\sigma^2
\end{aligned} \tag{14.1.1000}$$

So we fall back on the expected mean and the variance of the Normal law. It would be interesting to check if we have the same kind of property for another law of the exponential family to see if it is generalizable or not ???

Let us also indicate that compared to the famous "canonical parameter" (since mean and variance ultimately depend on it), we have in this case:

$$\theta_i=\mu_i \tag{14.1.1001}$$

so the canonical function is then (without too much surprise in this case...):

$$g(\mathrm{E}(Y))=1\cdot\mathrm{E}(Y)=\mu_i=\alpha x_i+\beta \tag{14.1.1002}$$

that it is customary to write in a relatively general case as we already know in vector notation (see the study of multiple linear regression for the notation):

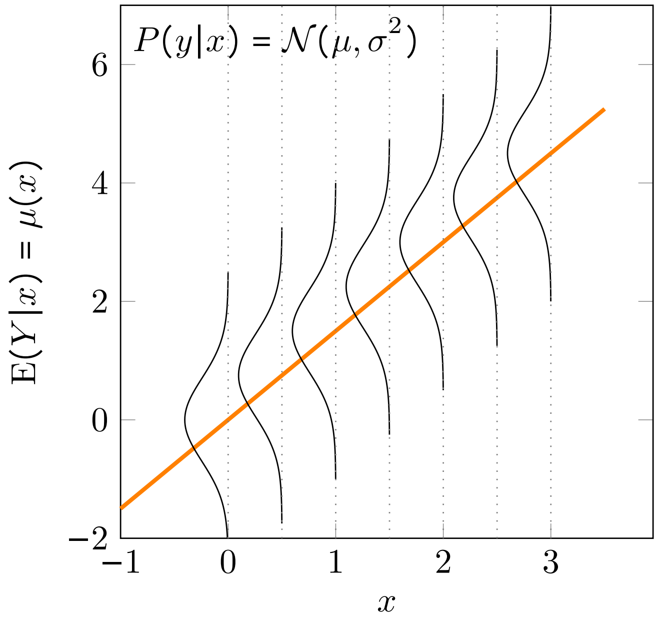
$$g(\mathrm{E}(Y))=\theta_i=\mu_i=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j \tag{14.1.1003}$$

In this case the canonical function is the unitary application. We speak then of "canonical identity link" and it is the only case where the method of ordinary least squares is confused (to understand: is an identical approach) to the use of the GLM.

We notice that the assumptions of use of the Normal GLM trivially remain the independence of the explanatory variables, the homoscedasticity, the linearity of the model and the linearity of the expected mean.

14.1.12.7.2 Poisson GLM

Let's do the same as before but with the Poisson's law. The idea is therefore that the variable to be explained is discrete and whereas in the same order of idea of the Normal regression we have:



then with the Poisson regression, the idea is to have (notice that as the mean increase, the variance seems also to increase and we will prove this further below even if it's quite obvious regarding to the moment of the Poisson distribution):

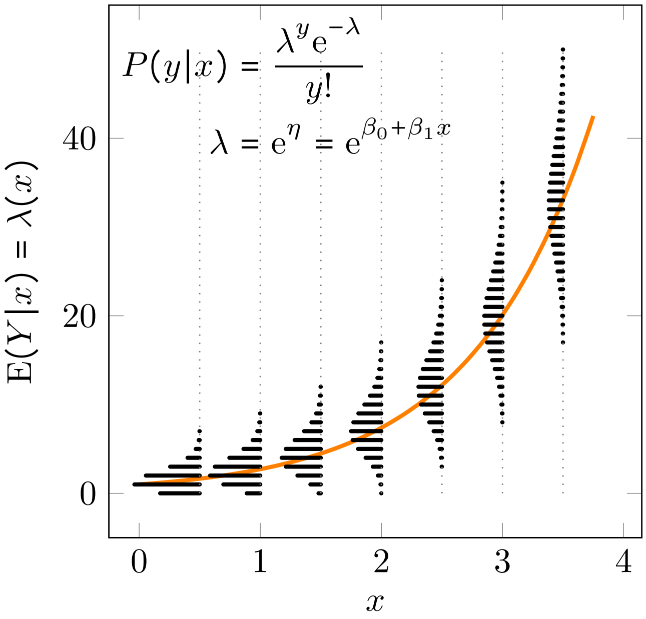


Figure 14.46: Underlying idea of the Poisson GLM (author: Walmes Zeviani)

However, the reader must be keep in mind that even a continuous variable can have an excellent fit to a Poisson's law, which is why Poisson's regression is also sometimes used for variables to be explained that are continuous (typically for heteroscedastic regressions where weighted regression is to difficult to apply or fails).

We will therefore look for a regression model which, like Gaussian GLM regression, gives the slip of the expected mean of the Gaussian law as a function of explanatory variables but this time with a model that gives the slip of the expected mean of the Poisson's law (yes indeed as a reminder ... the two moments of the Poisson's law are directly connected to each other). We start from:

$$\begin{aligned}Y_i &= \frac{\mu_i^{\alpha x_i+\beta}}{(\alpha x_i+\beta)!}e^{-\mu_i}=\frac{\mu_i^{y_i}}{y_i!}e^{-\mu_i}=\exp\left(\ln\left(\frac{\mu_i^{y_i}}{y_i!}e^{-\mu_i}\right)\right)\\ &=\exp\left(\ln(\mu_i^{y_i})-\ln(y_i!)+\ln(e^{-\mu_i})\right)=\exp\left(y_i\mu_i-\ln(y_i!)-\mu_i\right)\\ &=\exp\left(\left(\frac{y_i\ln(\mu_i)-\mu_i}{1}\right)-\ln(y_i!)\right)\end{aligned}\tag{14.1.1004}$$

Last arrangement that we had to guess ... to make an identification with:

$$f(y_i,\theta_i,\varphi,\omega_i)=\exp\left(\frac{y_i\theta_i-b(\theta_i)}{a_i(\varphi)}+c(y_i,\varphi)\right)\tag{14.1.1005}$$

Therefore it comes:

$$\begin{aligned}&\theta_i=\ln(\mu_i)\\ &b(\theta_i)=b(\ln(\mu_i))=\mu_i\Rightarrow b(\theta_i)=e^{\ln(\mu_i)}\\ &a_i(\varphi)=1\\ &c(y_i,\varphi)=-\ln(y_i!)\\ &\varphi=1\end{aligned}\tag{14.1.1006}$$

Let us indicate for the small parenthesis that some authors use the Euler Gamma function (see section Differential and Integral Calculus page 1574) and write:

$$\ln(y_i!)=\Gamma(y_i+1)\tag{14.1.1007}$$

Now, let's have a look at what gives the derivatives used above:

$$\begin{aligned}&\frac{\mathrm{d}b(\theta_i)}{\mathrm{d}\theta_i}=\frac{\mathrm{d}(e^{\ln(\mu_i)})}{\mathrm{d}(\ln(\mu_i))}=e^{\ln(\mu_i)}=\mu_i\\ &\frac{\mathrm{d}^2b(\theta_i)}{\mathrm{d}\theta_i^2}a_i(\varphi)=\frac{\mathrm{d}(e^{\ln(\mu_i)})}{\mathrm{d}(\ln(\mu_i))}\cdot 1=e^{\ln(\mu_i)}=\mu_i=\sigma^2\end{aligned}\tag{14.1.1008}$$

So we can once again find the expected mean and variance but this time of the Poisson's law. It would be interesting to check again if we have the same kind of property for another law of the exponential family in order to see if it is generalizable or not ???

So we notice a second time that the parameter θ controls the mean and the variance through its first and second derivative. The variance is therefore a function of the mean for all the laws of the family of exponential laws.

Let us also indicate that relatively to the famous "canonical parameter" (since mean and variance ultimately depend on it), we have in this case:

$$\theta_i = \ln(\mu_i) \tag{14.1.1009}$$

The canonical function for the Poisson's law is then:

$$g(\mathrm{E}(Y)) = \theta_i = \ln(\mathrm{E}(Y)) = \ln(\mu_i) \tag{14.1.1010}$$

So the canonical function is the logarithmic application. We then talk about "canonical logarithmic link".

Before going further let us compare, the generalized form of the Normal law of the regression with that of Poisson:

$$\begin{aligned} Y_{i,\mathcal{N}} &= \exp\left(\frac{y_i\mu_i - \mu_i^2/2}{\sigma^2} - \frac{1}{2}\left(\frac{y_i^2}{\sigma^2} - \ln\left(2\pi\sigma^2\right)\right)\right) \\ Y_{i,\mathcal{P}} &= \exp\left(\frac{y_i \ln(\mu_i) - \mu_i}{1} - \ln\left(y_i!\right)\right) \end{aligned} \tag{14.1.1011}$$

Remark

We will not go too much further with the Poisson's law for regression because according to the experience feedback of the senior practitioners it seems that it suffers from the major problem that as the expected mean is equal to the variance whereas in reality the variance tends to be higher than the expected mean. The negative binomial model (see below) should be preferred to that of Poisson.

For the parameters to be estimated, it is customary to also use the maximum log-likelihood as we have done for many previous regression models. Then the likelihood is given in this case by:

$$L(\mu_i, y_i) = \prod_{i=1}^{n} \frac{\mu_i^{y_i}}{y_i!} e^{-\mu_i} \tag{14.1.1012}$$

The log-likelihood becomes:

$$\ln[L(\mu_i, y_i)] = \ln\left(\prod_{i=1}^{n} \frac{\mu_i^{y_i}}{y_i!} e^{-\mu_i}\right) = \sum_{i=1}^{n} (-\mu_i + y_i \ln(\mu_i) - \ln(y_i!)) \tag{14.1.1013}$$

Now to proceed as we did with the Gaussian linear regression, let us recall that the y_i are given by the experiment. We will write then:

$$\ln[L(\mu_i, y_i)] = \sum_{i=1}^{n} (-\mu_i + Y_i \ln(\mu_i) - \ln(Y_i!)) \tag{14.1.1014}$$

and that, as for Gaussian linear regression, the explicit expression of the μ_i must allow us to determine the expression of parameters β_j of the regression.

However we have seen earlier above that the link function for the Poisson regression was the natural logarithm which in the general case is written as follows:

$$g(\mathrm{E}(Y)) = \ln(\mathrm{E}(Y)) = \ln(\mu_i) = \vec{x}_i^T \vec{\beta} = \sum_{j=0}^{p-1} x_{j,i}\beta_j \tag{14.1.1015}$$

So we have so far:

$$\begin{gathered} g_{\mathcal{N}}(\mu_i)=\theta_i=\mu_i=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j \\ g_{\mathcal{P}}(\mu_i)=\theta_i=\ln(\mu_i)=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j \end{gathered} \tag{14.1.1016}$$

Therefore for the Poisson logarithm link:

$$\ln(\mu_i)=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j \Leftrightarrow \mu_i=\exp\left(\sum_{j=0}^{p-1}x_{j,i}\beta_j\right) \tag{14.1.1017}$$

Hence the log-likelihood will be written:

$$\begin{aligned} \ln[L(\mu_i,y_i)]&=\sum_{i=1}^{n}(-\mu_i+Y_i\ln(\mu_i)-\ln(Y_i!)) \\ &=\sum_{i=1}^{n}\left(-\exp\left(\sum_{j=0}^{p-1}x_{j,n}\beta_j\right)+Y_i\left(\sum_{j=0}^{p-1}x_{j,n}\beta_j\right)-\ln(Y_i!)\right) \end{aligned} \tag{14.1.1018}$$

To solve this kind of log-likelihood, we then use Newton-Raphson type algorithms (see further below in this section page 6673).

We notice that the hypotheses of use of the GLM Poisson remain trivially the independence of the explanatory variables, the homoscedasticity is on the other hand no more assumed since the variance depends on the expected mean, the linearity of the model is always a hypothesis and the expected mean is linear only under a logarithmic transformation.

Finally, let us say that, just as for the Gaussian regression, we can use the result of the Poisson regression to make the probabilistic inference. Indeed, since the density probability function of the Poisson distribution is given by:

$$P_k=\frac{\mu^k}{k!}e^{-\mu} \tag{14.1.1019}$$

and since we have:

$$\ln(\mu_i)=\alpha x_i+B\Leftrightarrow\mu_i=e^{\alpha x_i}e^{B} \tag{14.1.1020}$$

Then:

$$P_k=\frac{\mu^k}{k!}e^{-\mu}=\frac{\left(e^{\alpha x_i+B}\right)^k}{k!}e^{-\left(e^{\alpha x_i+B}\right)} \tag{14.1.1021}$$

and in this case you have to change the notation so that it makes sense:

$$P_k=\frac{\left(e^{\alpha x_i+\beta}\right)^{y_i}}{y_i!}e^{-\left(e^{\alpha x_i+\beta}\right)} \tag{14.1.1022}$$

Thus, for any abscissa value x_i of our model (which in the present case is univariate), we can calculate the prior probability of the realization of an event of interest for an ordinate value $y_i\in\mathbb{N}$.

Remark

The response variable of a Poisson GLM is obviously a count as we have seen it. For example, the response variable can model the number of customers who enter a grocery store. It turns out that this is NOT the only way to perform Poisson GLM! We can also divide the response variable by a time period or distance, which sets the response variable as a rate or a proportion instead. Extending our earlier example, we can therefore model the number of customers who enter a grocery store per hour. In Poisson GLM, this is named an "offset".

14.1.12.7.3 Binomial GLM

Let's do the same with the binomial law!

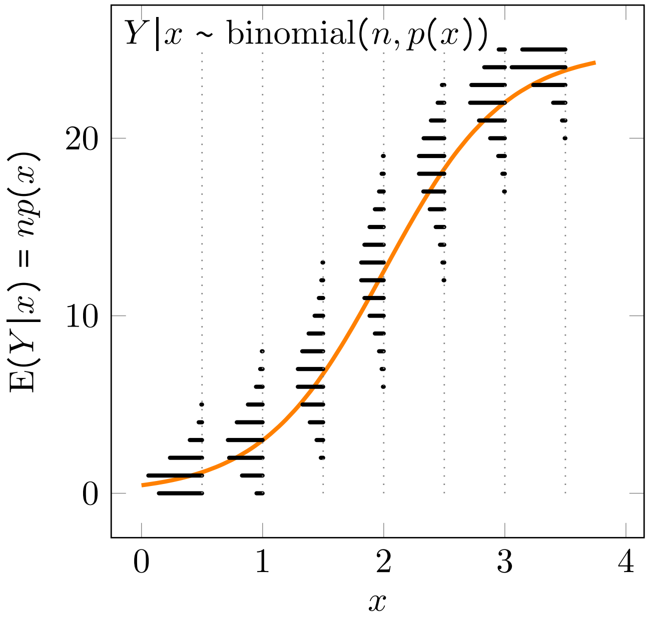

Figure 14.47: **Underlying idea of the binomial GLM (author: Walmes Zeviani)**

We start from:

$$\begin{aligned}
Y_i &= \frac{N!}{(\alpha x_i+\beta)!(N-(\alpha x_i+\beta))!}p^{\alpha x_i+\beta}q^{N-(\alpha x_i+\beta)}\\
&= \frac{N!}{y_i!(N-y_i)!}p^{y_i}(1-p)^{N-y_i} = C_{y_i}^{N}p^{y_i}(1-p)^{N-y_i}\\
&= \exp\left(\ln\left(C_{y_i}^{N}p^{y_i}(1-p)^{N-y_i}\right)\right)\\
&= \exp\left(\ln(p^{y_i})+\ln\left((1-p)^{N-y_i}\right)+\ln(C_{y_i}^{N})\right)\\
&= \exp\left(y_i\ln(p)+(N-y_i)\ln(1-p)+\ln(C_{y_i}^{N})\right)\\
&= \exp\left(y_i\ln(p)+N\ln(1-p)-y_i\ln(1-p)+\ln(C_{y_i}^{N})\right)\\
&= \exp\left(y_i\ln\left(\frac{p}{1-p}\right)+N\ln(1-p)+\ln(C_{y_i}^{N})\right)\\
&= \exp\left(\left(\frac{y_i\ln\left(\dfrac{p}{1-p}\right)+N\ln(1-p)}{1}\right)+\ln(C_{y_i}^{N})\right)
\end{aligned}\tag{14.1.1023}$$

Now, let's do the identification with:

$$f(y_i,\theta_i,\varphi,\omega_i)=\exp\left(\frac{y_i\theta_i-b(\theta_i)}{a_i(\varphi)}+c(y_i,\varphi)\right)\tag{14.1.1024}$$

Therefore we get (take a particular care at how looks like the first parameter...):

$$\begin{aligned}
\theta_i &= \ln\left(\frac{p}{1-p}\right)\\
b(\theta_i) &= b\left(\ln\left(\frac{p}{1-p}\right)\right) = -N\ln(1-p)\Rightarrow b(\theta_i)=N\ln\left(1+e^{\theta_i}\right)\\
a_i(\varphi) &= 1\\
c(y_i,\varphi) &= -\ln(C_{y_i}^{N})\\
\varphi &= 1
\end{aligned}\tag{14.1.1025}$$

Now, let's have a look at what gives the derivatives used earlier above:

$$\begin{aligned}
\frac{\mathrm{d}b(\theta_i)}{\mathrm{d}\theta_i} &= \frac{\mathrm{d}(N\ln(1+e^{\theta_i}))}{\mathrm{d}\theta_i} = N\frac{\mathrm{d}(\ln(1+e^{\theta_i}))}{\mathrm{d}\theta_i} = N\frac{e^{\theta_i}}{1+e^{\theta_i}}\\
&= N\frac{e^{\ln\left(\frac{p}{1-p}\right)}}{1+e^{\ln\left(\frac{p}{1-p}\right)}} = N\frac{\dfrac{p}{1-p}}{1+\dfrac{p}{1-p}} = N\frac{p}{1-p+p} = Np = \mu
\end{aligned}\tag{14.1.1026}$$

and:

$$\begin{aligned}\frac{\mathrm{d}^2b(\theta_i)}{\mathrm{d}\theta_i^2}a_i(\varphi)&=\frac{\mathrm{d}\left(N\dfrac{e^{\theta_i}}{1+e^{\theta_i}}\right)}{\mathrm{d}\theta_i}\cdot 1=N\frac{\mathrm{d}\left(e^{\theta_i}\dfrac{1}{1+e^{\theta_i}}\right)}{\mathrm{d}\theta_i}\\&=N\left(e^{\theta_i}\frac{1}{1+e^{\theta_i}}-e^{\theta_i}\frac{e^{\theta_i}}{(1+e^{\theta_i})^2}\right)=N\left(\frac{e^{\theta_i}(1+e^{\theta_i})}{(1+e^{\theta_i})^2}-\frac{e^{\theta_i}e^{\theta_i}}{(1+e^{\theta_i})^2}\right)\\&=N\left(\frac{e^{\theta_i}(1+e^{\theta_i})-e^{\theta_i}e^{\theta_i}}{(1+e^{\theta_i})^2}\right)=N\frac{e^{\theta_i}}{(1+e^{\theta_i})^2}=N\left(\frac{e^{\theta_i}}{1+e^{\theta_i}}\right)\left(\frac{1}{1+e^{\theta_i}}\right)\\&=N\left(\frac{e^{\ln\left(\frac{p}{1-p}\right)}}{1+e^{\ln\left(\frac{p}{1-p}\right)}}\right)\left(\frac{1}{1+e^{\ln\left(\frac{p}{1-p}\right)}}\right)=Np\left(\frac{1}{1+\dfrac{p}{1-p}}\right)=Np(1-p)=\sigma^2\end{aligned}\tag{14.1.1027}$$

So we can once again fall back on the expected mean and variance but this time the of the binomial law!

Let us also indicate that relatively to the famous "canonical parameter" (since expected mean and variance ultimately depend on it), we have in this case:

$$\theta_i=\ln\left(\frac{p}{1-p}\right)\tag{14.1.1028}$$

So the canonical function is:

$$g(\mathrm{E}(Y))=\theta_i=\ln\left(\frac{p}{1-p}\right)=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j\tag{14.1.1029}$$

in this case the canonical function is named, as we already know, the "logit link" or simply the "logit" (which we had already discovered otherwise in our study of logistic regression).

Let us compare now the generalized form of the Normal law of the regression with that of Poisson and the Binomial law:

$$\begin{aligned}Y_{i,\mathcal{N}}&=\exp\left(\frac{y_i\mu_i-\mu_i^2/2}{\sigma^2}-\frac{1}{2}\left(\frac{y_i^2}{\sigma^2}-\ln\left(2\pi\sigma^2\right)\right)\right)\\Y_{i,\mathcal{P}}&=\exp\left(\frac{y_i\ln(\mu_i)-\mu_i}{1}-\ln\left(y_i!\right)\right)\\Y_{i,\mathcal{B}}&=\exp\left(\left(\frac{y_i\ln\left(\dfrac{p}{1-p}\right)+N\ln\left(1-p\right)}{1}\right)+\ln\left(C_{y_i}^N\right)\right)\end{aligned}\tag{14.1.1030}$$

and also the link functions:

$$\begin{aligned}
g_N(\mu_i)&=\theta_i=\mu_i=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j\\
g_P(\mu_i)&=\theta_i=\ln(\mu_i)=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j\\
g_B(\mu_i)&=\theta_i=\ln\left(\frac{p}{1-p}\right)=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j
\end{aligned}\tag{14.1.1031}$$

We notice that the assumptions of use of the Binomial GLM remain trivially the independence of the explanatory variables, the homoscedasticity is on the other hand no more assumed, the linearity of the model is always a hypothesis and the expected mean is linear under a logit transformation .

We will not develop here the likelihood model of the binomial regression as we already did it during our study of the binomial logistic regression on page 6363.

14.1.12.7.4 Binomial Negative GLM

Negative binomial regression (sometimes abbreviated in general as N.B.R.M. for Negative Binomial Regression Model) is probably the most widely used in practice outside binomial logistic regression or Gaussian regression. However it suffers from a major problem ... Indeed there are about twenty derived models such as: NB-C (the simplest that we will study here), NB-1, NB-2 (generalization of GLM Poisson), truncated NB / NB-1 / NB-C, NB with zero inflation (ZINB), censored NB, NB with obstacle, NB-P, heterogeneous-NB (NBH), finite mixed model, conditional fixed effects model, random effects model, NB endogenous stratification, NB sampling, NB latent class, NB bivariate, etc. In short enough to write several thousand pages and study for several years ...

Well this being said, let's take a look at the case of canonical negative binomial regression.

We thus start from one of the possible expressions of the density function of the negative binomial law (see the section Statistics page 667 for the demonstration of its origin):

$$\begin{aligned}
P(E,N,p)&=\binom{E+R-1}{E-1}q^Rp^E=\frac{(E+R-1)!}{(E-1)!(E+R-1-(E-1))!}q^Rp^E\\
&=\binom{E+R-1}{E-1}q^Rp^E
\end{aligned}\tag{14.1.1032}$$

We then adapt this notation to the GLM sauce, admitting that we are interested in failures E:

$$\begin{aligned}
Y_i&=\frac{(y_i+R-1)!}{(y_i-1)!R!}q_i^R(1-q_i)^{y_i}=\frac{((\alpha x_i+\beta)+R-1)!}{((\alpha x_i+\beta)-1)!R!}q_i^R(1-q_i)^{\alpha x_i+\beta}\\
&=C_{y_i-1}^{y_i+R-1}q_i^R(1-q_i)^{y_i}=\exp\left(\ln\left(C_{y_i-1}^{y_i+R-1}q_i^R(1-q_i)^{y_i}\right)\right)\\
&=\exp\left(\ln\left((1-q_i)^{y_i}\right)+\ln\left(q_i^R\right)+\ln\left(C_{y_i-1}^{y_i+R-1}\right)\right)\\
&=\exp\left(\frac{y_i\ln(1-q_i)+R\ln(q_i)}{1}+\ln\left(C_{y_i-1}^{y_i+R-1}\right)\right)
\end{aligned}\tag{14.1.1033}$$

Now, let's do the identification with:

$$f(y_i,\theta_i,\varphi,\omega_i)=\exp\left(\frac{y_i\theta_i-b(\theta_i)}{a_i(\varphi)}+c(y_i,\varphi)\right) \tag{14.1.1034}$$

Therefore:

$$\begin{aligned}\theta_i&=\ln(1-q_i)\Rightarrow q_i=1-e^{\theta_i}\\ b(\theta_i)&=b\left(\ln(1-q_i)\right)=-R\ln(q_i)=-R\ln\left(1-e^{\theta_i}\right)\\ a_i(\varphi)&=1\\ c(y_i,\varphi)&=\ln\left(C_{y_{i-1}}^{y_i+R-1}\right)\\ \varphi&=1\end{aligned} \tag{14.1.1035}$$

Now, let's have a look at what gives the derivatives used earlier above:

$$\begin{aligned}\frac{\mathrm{d}b(\theta_i)}{\mathrm{d}\theta_i}&=\frac{\mathrm{d}(-R\ln(q_i))}{\mathrm{d}\theta_i}=-R\frac{\mathrm{d}(-R\ln(1-e^{\theta_i}))}{\mathrm{d}\theta_i}=R\frac{e^{\theta_i}}{1-\theta_i}\\ &=R\frac{e^{\ln(1-q_i)}}{1-e^{\ln(1-q_i)}}=R\frac{1-q_i}{1-(1-q_i)}=\frac{R(1-q_i)}{q_i}=\mu_i\end{aligned} \tag{14.1.1036}$$

Which corresponds well to the expected mean of the number of failures before the R-th success (result to be compared with the expected mean of the number of successes of the negative binomial law as demonstrated in the section Statistics) since it is this that we seek to model by linear regression. Do not forget that we can reverse the roles failures / successes.

And:

$$\begin{aligned}\frac{\mathrm{d}^2b(\theta_i)}{\mathrm{d}\theta_i^2}a_i(\varphi)&=\frac{\mathrm{d}\left(R\dfrac{e^{\theta_i}}{1-e^{\theta_i}}\right)}{\mathrm{d}\theta_i}\cdot 1=R\frac{\mathrm{d}\left(e^{\theta_i}\dfrac{1}{1-e^{\theta_i}}\right)}{\mathrm{d}\theta_i}\\ &=R\left(e^{\theta_i}\frac{1}{1-e^{\theta_i}}+e^{\theta_i}\frac{e^{\theta_i}}{(1-e^{\theta_i})^2}\right)=R\left(\frac{e^{\theta_i}(1-e^{\theta_i})}{(1-e^{\theta_i})^2}+\frac{e^{\theta_i}e^{\theta_i}}{(1-e^{\theta_i})^2}\right)\\ &=R\left(\frac{e^{\theta_i}(1-e^{\theta_i})+e^{\theta_i}e^{\theta_i}}{(1-e^{\theta_i})^2}\right)=R\frac{e^{\theta_i}}{(1-e^{\theta_i})^2}=R\left(\frac{e^{\theta_i}}{1-e^{\theta_i}}\right)\left(\frac{1}{1-e^{\theta_i}}\right)\\ &=R\left(\frac{e^{\ln(1-q_i)}}{1-e^{\ln(1-q_i)}}\right)\left(\frac{1}{1-e^{\ln(1-q_i)}}\right)=R\left(\frac{1-q_i}{1-(1+q_i)}\right)\left(\frac{1}{1-(1+q_i)}\right)\\ &=R\left(\frac{1-q_i}{-q_i}\right)\left(\frac{1}{-q_i}\right)=\frac{R(1-q_i)}{q_i^2}=\sigma^2\end{aligned} \tag{14.1.1037}$$

Which corresponds well to the variance of the number of failures (result to be compared with the variance of the number of successes of the negative binomial law as demonstrated in the section Statistics) since this is what we seek to model by the regression.

We then have:

$$\frac{\mathrm{d}b(\theta_i)}{\mathrm{d}\theta_i}=\frac{R(1-q_i)}{q_i}=\mu_i \tag{14.1.1038}$$

Let's now make a usual change of notation:

$$\frac{\mathrm{d}b(\theta_i)}{\mathrm{d}\theta_i}=\frac{(1-q_i)}{\alpha q_i}=\mu_i\Leftrightarrow\alpha\mu_i=\frac{(1-q_i)}{q_i}=\frac{1}{q_i}-1\Leftrightarrow q_i=\frac{1}{\alpha\mu_i+1}\tag{14.1.1039}$$

Which is also sometimes denoted:

$$q_i=\frac{1}{\beta_i+1}\tag{14.1.1040}$$

In this form, we can rewrite:

$$\begin{aligned}P(E,N,p)&=\binom{y_i+R-1}{y_i-1}q^Rp^{y_i}=\binom{y_i+\dfrac{1}{\alpha}-1}{y_i-1}\left(\frac{1}{\alpha\mu_i+1}\right)^{\frac{1}{\alpha}}\left(1-\frac{1}{\alpha\mu_i+1}\right)^{y_i}\\&=\binom{y_i+\frac{1}{\alpha}-1}{y_i-1}\left(\frac{1}{\alpha\mu_i+1}\right)^{\frac{1}{\alpha}}\left(\frac{\alpha\mu_i}{\alpha\mu_i+1}\right)^{y_i}=\binom{y_i+\frac{1}{\alpha}-1}{y_i-1}\left(\frac{1}{\alpha\mu_i+1}\right)^{\frac{1}{\alpha}}\left(\frac{\alpha\mu_i}{\alpha\mu_i+1}\right)^{y_i}\end{aligned}\tag{14.1.1041}$$

If we were more interested in successes rather than failures we would have (this is the case most often chosen in the specialized literature):

$$\begin{aligned}P(E,N,p)&=\binom{E+y_i-1}{E-1}q^{y_i}p^E=\binom{\frac{1}{\alpha}+y_i-1}{\frac{1}{\alpha}-1}q^{y_i}p^{\frac{1}{\alpha}}\\&=\binom{\frac{1}{\alpha}+y_i-1}{\frac{1}{\alpha}-1}\left(\frac{\alpha\mu_i}{\alpha\mu_i+1}\right)^{y_i}\left(\frac{1}{\alpha\mu_i+1}\right)^{\frac{1}{\alpha}}\end{aligned}\tag{14.1.1042}$$

Then, it is customary to write this with the Gamma Euler function (see section page 1574). What then gives (with different common notations):

$$\begin{aligned}P(E,N,p)&=\binom{\frac{1}{\alpha}+y_i-1}{\frac{1}{\alpha}-1}\left(\frac{\alpha\mu_i}{\alpha\mu_i+1}\right)^{y_i}\left(\frac{1}{\alpha\mu_i+1}\right)^{\frac{1}{\alpha}}\\&=\frac{\left(\frac{1}{\alpha}+y_i-1\right)!}{\left(\frac{1}{\alpha}-1\right)!(y_i)!}\left(\frac{1}{\alpha\mu_i+1}\right)^{\frac{1}{\alpha}}\left(\frac{\alpha\mu_i}{\alpha\mu_i+1}\right)^{y_i}\\&=\frac{\Gamma\left(\frac{1}{\alpha}+y_i\right)}{\Gamma\left(\frac{1}{\alpha}\right)\Gamma(y_i+1)}\left(\frac{1}{\alpha\mu_i+1}\right)^{\frac{1}{\alpha}}\left(\frac{\alpha\mu_i}{\alpha\mu_i+1}\right)^{y_i}=\frac{\Gamma(r+k)}{\Gamma(r)\Gamma(k+1)}\left(\frac{1}{\theta+1}\right)^r\left(\frac{\theta}{\theta+1}\right)^k\\&=\frac{\Gamma(R+k)}{\Gamma(R)k!}\left(\frac{1}{\theta+1}\right)^R\left(\frac{\theta}{\theta+1}\right)^k=\frac{\Gamma(R+k)}{\Gamma(R)k!\theta^r}\left(\frac{\theta}{\theta+1}\right)^{k+R}\\&=\left(\frac{\theta}{\theta+1}\right)^{k+R}\frac{1}{\Gamma(R)k!\theta^R}\Gamma(R+k)\end{aligned}\tag{14.1.1043}$$

In this form, we immediately see that expected mean is written then:

$$\mu=R\cdot\theta\tag{14.1.1044}$$

Now, to return to our previous development, let us recall that we have proved in the section of Differential and Integral Calculus during our study of the Euler's Gamma function (see section

Differential and Integral Calculus page 1574) that:

$$\Gamma(x+1)=\int\limits_{0}^{+\infty} t^x e^{-t}\mathrm{d}t \tag{14.1.1045}$$

We then have by extension:

$$\Gamma(x+1)=\Gamma((k+R-1)+1)=\int\limits_{0}^{+\infty} t^{k+R-1}e^{-t}\mathrm{d}t \tag{14.1.1046}$$

It then comes in this case:

$$\begin{aligned}P(X=k,R,\theta)&=\left(\frac{\theta}{\theta+1}\right)^{k+R}\frac{1}{\Gamma(R)k!\theta^r}\int\limits_{0}^{+\infty} t^{k+R-1}e^{-t}\mathrm{d}t\\&=\left(\frac{\theta}{\theta+1}\right)^{k+R}\int\limits_{0}^{+\infty}\frac{t^{k+R-1}e^{-t}}{\Gamma(R)k!\theta^R}\mathrm{d}t\end{aligned} \tag{14.1.1047}$$

Let us integrate with the following variable change:

$$t=\lambda\frac{\theta+1}{\theta} \tag{14.1.1048}$$

We then have:

$$\begin{aligned}P(X=k,R,\theta)&=\left(\frac{\theta}{\theta+1}\right)^{k+R}\int\limits_{0}^{+\infty}\frac{t^{k+R-1}e^{-t}}{\Gamma(R)k!\theta^R}\mathrm{d}t\\&=\left(\frac{\theta}{\theta+1}\right)^{k+R}\int\limits_{0}^{+\infty}\frac{\left(\lambda\frac{\theta+1}{\theta}\right)^{k+R-1}e^{-\lambda\frac{\theta+1}{\theta}}}{\Gamma(R)k!\theta^R}\frac{\theta+1}{\theta}\mathrm{d}\lambda\\&=\left(\frac{\theta}{\theta+1}\right)^{k+R-1}\left(\frac{\theta+1}{\theta}\right)^{k+R-1}\int\limits_{0}^{+\infty}\frac{\lambda^{k+R-1}e^{-\lambda\frac{\theta+1}{\theta}}}{\Gamma(R)k!\theta^R}\mathrm{d}\lambda\\&=\int\limits_{0}^{+\infty}\frac{\lambda^{k+R-1}e^{-\lambda\frac{\theta+1}{\theta}}}{\Gamma(R)k!\theta^R}\mathrm{d}\lambda=\int\limits_{0}^{+\infty}\frac{\lambda^k e^{-\lambda}}{k!}\frac{\lambda^{R-1}e^{-\frac{\lambda}{\theta}}}{\Gamma(R)\theta^R}\mathrm{d}\lambda\end{aligned} \tag{14.1.1049}$$

We find under the integral two density functions which are respectively the Poisson density function and the Gamma density function (see section Statistics page 686 and page 767):

$$P(X=k,R,\theta)=\int\limits_{0}^{+\infty}\underbrace{\frac{\lambda^k e^{-\lambda}}{k!}}_{\text{Poisson law}}\underbrace{\frac{\lambda^{R-1}e^{-\frac{\lambda}{\theta}}}{\Gamma(R)\theta^R}}_{\text{Gamma law}}\mathrm{d}\lambda \tag{14.1.1050}$$

We have a result that it is customary to associate with a generalization of the Poisson's law and which we name "Poisson-Gamma density law" or "mixed Poisson-Gamma law".

Remark

Thus, the negative binomial distribution can be considered as a generalization of the Poisson distribution. Indeed, the negative binomial law can be seen as a Poisson distribution where the Poisson parameter is itself a random variable, distributed according to a Gamma distribution !!!

An important application is in the area of risk insurance where k the number of undesirable events is modelled by a Poisson law of parameter λ which itself is therefore tainted by an uncertainty that is characteristic of the risk category of the insured. Thus, the parameter λ can itself be seen as a random variable traditionally denoted Θ in the field of actuarial science and following a gamma law such that the density function of Θ is then given by (with the traditional notation in actuarial science):

$$\Theta=\int\limits_0^{+\infty}\underbrace{\frac{\theta^k e^{-\theta}}{n!}}_{\text{Poisson law}}\underbrace{\frac{\alpha^{\beta-1}e^{-\frac{\theta}{\alpha}}}{\Gamma(\beta)\alpha^\beta}}_{\text{Gamma law}}\mathrm{d}\lambda \tag{14.1.1051}$$

For the parameters to be estimated, it is customary to also use the maximum log-likelihood as we did for all previous regressions. Then, in order to determine the maximum of the log-likelihood, it is traditional in the case of the negative binomial law to start from the following form demonstrated above:

$$P(\alpha,y_i,\mu_i)=\frac{\Gamma\left(\frac{1}{\alpha}+y_i\right)}{\Gamma\left(\frac{1}{\alpha}\right)\Gamma(y_i+1)}\left(\frac{1}{\alpha\mu_i+1}\right)^{\frac{1}{\alpha}}\left(\frac{\alpha\mu_i}{\alpha\mu_i+1}\right)^{y_i} \tag{14.1.1052}$$

We then have:

$$\ln[L(\alpha,y_i,\mu_i)]=\sum_{i=1}^n\ln\left[\frac{\Gamma\left(\frac{1}{\alpha}+y_i\right)}{\Gamma\left(\frac{1}{\alpha}\right)\Gamma(y_i+1)}\left(\frac{1}{\alpha\mu_i+1}\right)^{\frac{1}{\alpha}}\left(\frac{\alpha\mu_i}{\alpha\mu_i+1}\right)^{y_i}\right] \tag{14.1.1053}$$

The log-likelihood then becomes:

$$\begin{aligned}
&\ln[L(\alpha,y_i,\mu_i)]\\
&=\sum_{i=1}^n\left(\ln\left(\Gamma\left(\frac{1}{\alpha}+y_i\right)\right)-\ln\left(\Gamma\left(\frac{1}{\alpha}\right)\right)-\ln\left(\Gamma(y_i+1)\right)+\frac{1}{\alpha}\ln\left(\frac{1}{\alpha\mu_i+1}\right)+y_i\ln\left(\frac{\alpha\mu_i}{\alpha\mu_i+1}\right)\right)\\
&=\sum_{i=1}^n\left(\ln\left(\Gamma\left(\frac{1}{\alpha}+y_i\right)\right)-\ln\left(\Gamma\left(\frac{1}{\alpha}\right)\right)-\ln\left(\Gamma(y_i+1)\right)-\frac{1}{\alpha}\ln\left(\alpha\mu_i+1\right)+y_i\ln(\alpha\mu_i)-y_i(\alpha\mu_i+1)\right)\\
&=\sum_{i=1}^n\left(\ln\left(\Gamma\left(\frac{1}{\alpha}+y_i\right)\right)-\ln\left(\Gamma\left(\frac{1}{\alpha}\right)\right)-\ln\left(\Gamma(y_i+1)\right)-\left(\frac{1}{\alpha}+y_i\right)\ln\left(\alpha\mu_i+1\right)+y_i\ln(\alpha\mu_i)\right)
\end{aligned} \tag{14.1.1054}$$

Now to proceed as we did with the Gaussian linear regression, let us recall that the y_i are given by the experience. We will write then:

$$\begin{aligned}
&\ln[L(\alpha,Y_i,\mu_i)]\\
&=\sum_{i=1}^n\left(\ln\left(\Gamma\left(\frac{1}{\alpha}+Y_i\right)\right)-\ln\left(\Gamma\left(\frac{1}{\alpha}\right)\right)-\ln\left(\Gamma(Y_i+1)\right)+\left(\frac{1}{\alpha}+Y_i\right)\ln\left(\alpha\mu_i+1\right)+Y_i\ln(\alpha\mu_i)\right)
\end{aligned} \tag{14.1.1055}$$

and that, as for the Gaussian linear regression, the explicit expression of the μ_i must allow us to determine the expression of the parameter α of the regression.

Now, let us recall that:

$$P(k,R,p)=\frac{\Gamma(R+k)}{\Gamma(R)\Gamma(k+1)}(1-p)^Rp^k=\frac{\Gamma(R+k)}{\Gamma(R)k!}(1-p)^Rp^k \tag{14.1.1056}$$

and that:

$$\mu=\frac{R(1-q)}{q}=\frac{Rp}{1-p} \tag{14.1.1057}$$

and let us denoted this λ. Then we get:

$$\lambda=R\frac{p}{1-p}\Leftrightarrow p=\frac{\lambda}{R+\lambda} \tag{14.1.1058}$$

Therefore:

$$\begin{aligned}P(k,R,p)&=\frac{\Gamma(R+k)}{\Gamma(R)k!}(1-p)^Rp^k=\frac{\Gamma(R+k)}{\Gamma(R)k!}\left(1-\frac{\lambda}{R+\lambda}\right)^R\frac{\lambda^k}{(R+\lambda)^k}\\&=\frac{\lambda^k}{k!}\frac{\Gamma(R+k)}{\Gamma(R)(R+\lambda)^k}\left(\frac{R}{R+\lambda}\right)^R=\frac{\lambda^k}{k!}\frac{\Gamma(R+k)}{\Gamma(R)(R+\lambda)^k}\frac{1}{\left(1+\frac{\lambda}{R}\right)^R}\\&=\frac{\lambda^k}{k!}\frac{\Gamma(R+k+1)!}{\Gamma(R)(R+\lambda)^k}\frac{1}{\left(1+\frac{\lambda}{R}\right)^R}\end{aligned} \tag{14.1.1059}$$

Now let us put that $R\rightarrow+\infty$. It comes then:

$$\begin{aligned}\frac{\Gamma(R+k)}{\Gamma(R)(R+\lambda)^k}&=\frac{(R+k)!}{R!(R+\lambda)^k}=\frac{R!(R+k)\cdot\ldots\cdot(R+k)}{R!(R+\lambda)^k}\\&=\frac{R+1}{R+\lambda}\cdot\frac{R+2}{R+\lambda}\cdot\ldots\cdot\frac{R+k}{R+\lambda}\underset{\substack{R\rightarrow+\infty\\\lambda\in\mathbb{R}^+}}{=}1\end{aligned} \tag{14.1.1060}$$

since each term of the product tends to 1 and since there is a constant number of terms in the product (that is, k terms) the whole tends to 1.

And as we saw in the section of Functional Analysis (see page 2291):

$$\left(1+\frac{\lambda}{R}\right)^R\underset{\substack{R\rightarrow+\infty\\\lambda\in\mathbb{R}^+}}{=}e^{\lambda} \tag{14.1.1061}$$

Therefore:

$$P(k,R,p)=\frac{\lambda^k}{k!}\frac{\Gamma(R+k+1)!}{\Gamma(R)(R+\lambda)^k}\frac{1}{\left(1+\frac{\lambda}{R}\right)^R}\underset{\substack{R\rightarrow+\infty\\\lambda\in\mathbb{R}^+}}{=}\frac{\lambda^k}{k!}\cdot1\cdot\frac{1}{e^{\lambda}}=\frac{\lambda^k}{k!}e^{-\lambda} \tag{14.1.1062}$$

We thus fall back in this limit case on the Poisson law!

Therefore, as the Poisson law is a special case of the Negative Binomial law, a possible model for the link function of the Negative Binomial Law is to take up the logarithm (hence the Poisson regression link function).

The canonical function is then that of the Poisson function:

$$g(\mathrm{E}(Y))=\theta_i=\ln(\mathrm{E}(Y))=\ln(\mu_i)=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j\Rightarrow\mu_i=e^{\vec{x}_i^T\vec{\beta}}=e^{\theta_i} \tag{14.1.1063}$$

From then on, the log-likelihood will be written:

$$\begin{aligned}&\ln[L(\alpha,Y_i,\mu_i)]\\&=\sum_{i=1}^{n}\left(\ln\left(\Gamma\left(\frac{1}{\alpha}+Y_i\right)\right)-\ln\left(\Gamma\left(\frac{1}{\alpha}\right)\right)-\ln\left(\Gamma(Y_i+1)\right)-\left(Y_i+\frac{1}{\alpha}\right)\ln\left(\alpha\mu_i+1\right)+Y_i\ln(\alpha\mu_i)\right)\\&=\sum_{i=1}^{n}\left(\ln\left(\Gamma\left(\frac{1}{\alpha}+Y_i\right)\right)-\ln\left(\Gamma\left(\frac{1}{\alpha}\right)\right)-\ln\left(\Gamma(Y_i+1)\right)-\left(Y_i+\frac{1}{\alpha}\right)\ln\left(\alpha e^{\vec{x}_i^T\vec{\beta}}+1\right)\right.\\&\qquad\left.+Y_i\ln(\alpha e^{\vec{x}_i^T\vec{\beta}})\right)=\ln[L(\alpha,Y_i,\vec{x},\vec{\beta})]\end{aligned} \tag{14.1.1064}$$

that it is customary to name the "NB2 log-likelihood" (which is the one used in the majority of statistical softwares).

But there is another version of log-likelihood that uses a combination of approximation and exact value. Indeed, remember that we had obtained:

$$g(\mathrm{E}(Y))=\theta_i=\ln(1-q_i)=\ln\left(1-\frac{1}{\alpha\mu_i+1}\right)=\ln\left(\frac{\alpha\mu_i}{\alpha\mu_i+1}\right)=-\ln\left(\frac{1}{\alpha\mu_i}+1\right) \tag{14.1.1065}$$

Therefore, using:

$$\theta_i=-\ln\left(\frac{1}{\alpha\mu_i}+1\right)\Leftrightarrow\mu_i=\frac{1}{\alpha\left(e^{-\theta_i}-1\right)} \tag{14.1.1066}$$

and by mixing (rather dubious mix...) with the approximation approach using Poisson link function:

$$\theta_i=\ln(\mu_i)=\vec{x}_i^T\vec{\beta} \tag{14.1.1067}$$

We have (happy mix ...):

$$\mu_i=\frac{1}{\alpha\left(e^{-\theta_i}-1\right)}=\frac{1}{e^{-\vec{x}_i^T\vec{\beta}}-1} \tag{14.1.1068}$$

The log-likelihood is written then:

$$\begin{aligned}&\ln[L(\alpha,Y_i,\mu_i)]\\&=\sum_{i=1}^{n}\left(\ln\left(\Gamma\left(\frac{1}{\alpha}+Y_i\right)\right)-\ln\left(\Gamma\left(\frac{1}{\alpha}\right)\right)-\ln\left(\Gamma(Y_i+1)\right)-\left(Y_i+\frac{1}{\alpha}\right)\ln\left(\alpha\mu_i+1\right)+Y_i\ln(\alpha\mu_i)\right)\\&=\sum_{i=1}^{n}\left(\ln\left(\Gamma\left(\frac{1}{\alpha}+Y_i\right)\right)-\ln\left(\Gamma\left(\frac{1}{\alpha}\right)\right)-\ln\left(\Gamma(Y_i+1)\right)-\left(Y_i+\frac{1}{\alpha}\right)\ln\left(\frac{1}{e^{-\vec{x}_i^T\vec{\beta}}-1}+1\right)\right.\\&\qquad\left.+Y_i\ln\left(\frac{1}{e^{-\vec{x}_i^T\vec{\beta}}-1}\right)\right)\end{aligned} \tag{14.1.1069}$$

that is customary named the "NB-C log-likelihood".

To solve this kind of log-likelihood, we then use again Newton-Raphson type algorithms (see further below in this section page 6673).

Let us compare, the generalized form of the Normal law of regression with that of Poisson, of the Binomial and Negative Binomial law:

$$\begin{aligned}
Y_{i,\mathcal{N}} &= \exp\left(\frac{y_i\mu_i-\mu_i^2/2}{\sigma^2}-\frac{1}{2}\left(\frac{y_i^2}{\sigma^2}-\ln\left(2\pi\sigma^2\right)\right)\right)\\
Y_{i,\mathcal{P}} &= \exp\left(\left(\frac{y_i\ln(\mu_i)-\mu_i}{1}\right)-\ln\left(y_i!\right)\right)\\
Y_{i,\mathcal{B}} &= \exp\left(\left(\frac{y_i\ln\left(\dfrac{p}{1-p}\right)+N\ln\left(1-p\right)}{1}\right)+\ln\left(C_{y_i}^N\right)\right)\\
Y_{i,\text{NB-C}} &= \exp\left(\frac{y_i\ln\left(1-q_i\right)+R\ln\left(q_i\right)}{1}+\ln\left(C_{y_i-1}^{y_i+R-1}\right)\right)\\
Y_{i,\text{NB}} &= \exp\left(\frac{y_i\ln\left(1-q_i\right)+R\ln\left(q_i\right)}{1}+\ln\left(C_{y_i-1}^{y_i+R-1}\right)\right)
\end{aligned} \tag{14.1.1070}$$

and also the link functions:

$$\begin{aligned}
g_{\mathcal{N}}(\mu_i) &= \theta_i=\mu_i=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j\\
g_{\mathcal{P}}(\mu_i) &= \theta_i=\ln(\mu_i)=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j\\
g_{\mathcal{B}}(\mu_i) &= \theta_i=\ln\left(\frac{p}{1-p}\right)=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j\\
g_{\text{NB-C}}(\mu_i) &= \theta_i=\ln\left(1-\frac{1}{\alpha\mu_i+1}\right)=-\ln\left(\frac{1}{\displaystyle\sum_{j=0}^{p-1}x_{j,i}\beta'_j}+1\right)
\end{aligned} \tag{14.1.1071}$$

We notice that the hypotheses of use of the Binomial Negative GLM remain trivially the independence of the explanatory variables, the homoscedasticity is on the other hand no more assumed, the linearity of the model is always a hypothesis and the expected mean is linear only under a logarithmic transformation chosen a little bit empirically in the canonical case...

14.1.12.7.5 Gamma GLM

Let's do the same as before but now with the Gamma law (see section Statistics page 767). We therefore start from:

$$\Gamma(a,\lambda)=\frac{x^{a-1}e^{-\lambda x}}{\Gamma(a)}\lambda^{a}\cdot 1_{]0,+\infty]} \qquad (14.1.1072)$$

by just changing the notation a bit to not confuse with one of the GLM parameters:

$$\Gamma(\alpha,\lambda)=\frac{x^{\alpha-1}e^{-\lambda x}}{\Gamma(\alpha)}\lambda^{\alpha}\cdot 1_{]0,+\infty]} \qquad (14.1.1073)$$

assuming that the scale parameter λ is known (...). Why? Because the expected mean of the Gamma law is for recall given by (see the proof in the section Statistics page 767):

$$\mu=\frac{\alpha}{\lambda} \qquad (14.1.1074)$$

and therefore controlling only one of the two parameters is enough to scan the entire desired definition domain (yes, simply!).

The use of the Gamma law is justified, besides by its domain of definition which is not in the negatives, by the fact that the relation between its expected mean and its variance gives:

$$\frac{\mu}{\sigma^2}=\frac{\frac{\alpha}{\lambda}}{\frac{\alpha}{\lambda^2}}=\lambda \qquad (14.1.1075)$$

So the relationship between expected mean is the variance is constant regardless of their respective values (so when mean increases, the variance increase too as for the Poisson distribution)! Another way of looking at this is that the variance is proportional to the expected mean since:

$$\sigma^2=\frac{\mu}{\lambda} \qquad (14.1.1076)$$

The reason why the GLM Gamma is interesting is that we can "adjust" the relationship between variance and expected mean by choosing the value of λ, which other models seen so far can not do!

Therefore we get:

$$\begin{aligned}Y_i&=\frac{y_i^{\alpha_i-1}e^{-\lambda y_i}}{\Gamma(\alpha_i)}\lambda^{\alpha_i}\cdot 1_{]0,+\infty]}=\exp\left(\ln\left(\frac{y_i^{\alpha_i-1}e^{-\lambda y_i}\lambda^{\alpha_i}}{\Gamma(\alpha_i)}\right)\right)\\&=\exp\left(\ln(y_i^{\alpha_i-1})+\ln(e^{-\lambda y_i})+\ln(\lambda^{\alpha_i})-\ln\left(\Gamma(\alpha_i)\right)\right)\\&=\exp\left((\alpha_i-1)\ln(y_i)-\lambda y_i+\alpha_i\ln(\lambda)-\ln\left(\Gamma(\alpha_i)\right)\right)\\&=\exp\left(\frac{(-\lambda y_i+\alpha_i\ln(\lambda))}{1}+(\alpha_i-1)\ln(y_i)-\ln\left(\Gamma(\alpha_i)\right)\right)\end{aligned} \qquad (14.1.1077)$$

Now, let us as always the identification with:

$$f(y_i,\theta_i,\varphi,\omega_i)=\exp\left(\frac{y_i\theta_i-b(\theta_i)}{a_i(\varphi)}+c(y_i,\varphi)\right) \qquad (14.1.1078)$$

We therefore get:

$$\begin{aligned}\theta_i&=\theta=-\lambda\\ b(\theta_i)&=b(-\lambda)=-\alpha_i\ln(\lambda)\\ a_i(\varphi)&=1\\ c(y_i,\varphi)&=\alpha_i\ln(y_i)-\ln\left(\Gamma(\alpha_i)\right)-\ln(y_i)\end{aligned}\tag{14.1.1079}$$

Now, let's have a look at what gives the derivatives used earlier above:

$$\frac{\mathrm{d}b(\theta_i)}{\mathrm{d}\theta_i}=\frac{\mathrm{d}\left(-\alpha_i\ln(\lambda)\right)}{-\mathrm{d}\lambda}=-\alpha_i\frac{\mathrm{d}\left(\ln(\lambda)\right)}{-\mathrm{d}\lambda}=\alpha_i\frac{\mathrm{d}\left(\ln(\lambda)\right)}{\mathrm{d}\lambda}=\frac{\alpha_i}{\lambda}=\mu\tag{14.1.1080}$$

and:

$$\frac{\mathrm{d}^2b(\theta_i)}{\mathrm{d}\theta_i^2}a_i(\varphi)=\frac{\mathrm{d}\left(\frac{\alpha_i}{\lambda}\right)}{\mathrm{d}\theta_i}\cdot 1=\frac{\mathrm{d}\left(\frac{\alpha_i}{\lambda}\right)}{-\mathrm{d}\lambda}=-\alpha_i\frac{\mathrm{d}\left(\frac{1}{\lambda}\right)}{\mathrm{d}\lambda}=\frac{\alpha_i}{\lambda^2}\tag{14.1.1081}$$

So we can once again fall back on the expected mean and variance but this time of the Gamma law!

Let us also indicate that compared to the famous "canonical parameter" (since expected mean and variance ultimately depend on it), we have in this case:

$$\theta_i=-\lambda=-\frac{\alpha_i}{\mu_i}\tag{14.1.1082}$$

so the canonical function is:

$$g(\mathrm{E}(Y))=-\frac{\alpha_i}{\mu_i}=\frac{-\alpha_i}{\sum\limits_{j=0}^{p-1}x_{j,n}\beta_j}=\frac{1}{\frac{1}{-\alpha_i}\sum\limits_{j=0}^{p-1}x_{j,n}\beta_j}=\frac{1}{\sum\limits_{j=0}^{p-1}x_{j,n}\frac{\beta_j}{-\alpha_i}}=\frac{1}{\sum\limits_{j=0}^{p-1}x_{j,n}\beta'_j}\tag{14.1.1083}$$

in this case, the canonical function is named the "negative inverse link" and is often denoted in the following form (because finally put that $-\alpha_i=1$ is simply equivalent to change the values of the parameters β_j):

$$g(\mathrm{E}(Y))=\frac{1}{\mu_i}=\frac{1}{\sum\limits_{j=0}^{p-1}x_{j,i}\beta_j}\tag{14.1.1084}$$

So in view of this expression we can make regression of very various type of curves.

Let us now compare the generalized form of the Normal law of the regression with that of Poisson and the Binomial law and the Gamma law:

$$\begin{aligned}Y_{i,\mathcal{N}}&=\exp\left(\frac{y_i\mu_i-\mu_i^2/2}{\sigma^2}-\frac{1}{2}\left(\frac{y_i^2}{\sigma^2}-\ln\left(2\pi\sigma^2\right)\right)\right)\\ Y_{i,\mathcal{P}}&=\exp\left(\left(\frac{y_i\ln(\mu_i)-\mu_i}{1}\right)-\ln\left(y_i!\right)\right)\\ Y_{i,\mathcal{B}}&=\exp\left(\left(\frac{y_i\ln\left(\frac{p}{1-p}\right)+N\ln\left(1-p\right)}{1}\right)+\ln\left(C_{y_i}^N\right)\right)\\ Y_{i,\text{NB-C}}&=\exp\left(\frac{y_i\ln\left(1-q_i\right)+R\ln\left(q_i\right)}{1}+\ln\left(C_{y_{i-1}}^{y_i+R-1}\right)\right)\\ Y_{i,\Gamma}&=\exp\left(\frac{\left(-y_i\lambda+\alpha_i\ln(\lambda)\right)}{1}+\alpha_i\ln(y_i)-\ln\left(\Gamma(\alpha_i)\right)-\ln(y_i)\right)\end{aligned}\tag{14.1.1085}$$

and also the link functions:

$$\begin{gathered}
g_{\mathcal{N}}(\mu_i)=\theta_i=\mu_i=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j\\
g_{\mathcal{P}}(\mu_i)=\theta_i=\ln(\mu_i)=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j\\
g_{\mathcal{B}}(\mu_i)=\theta_i=\ln\left(\dfrac{p}{1-p}\right)=\vec{x}_i^T\vec{\beta}=\sum_{j=0}^{p-1}x_{j,i}\beta_j\\
g_{\text{NB-C}}(\mu_i)=\theta_i=\ln\left(1-\dfrac{1}{\alpha\mu_i+1}\right)=-\ln\left(\dfrac{1}{\displaystyle\sum_{j=0}^{p-1}x_{j,i}\beta'_j}+1\right)\\
g_{\Gamma(\mu_i)}=\dfrac{1}{\vec{x}_i^T\vec{\beta}'}=\dfrac{1}{\displaystyle\sum_{j=0}^{p-1}x_{j,i}\beta'_j}
\end{gathered} \tag{14.1.1086}$$

We notice that the hypotheses of use of the GLM Gamma remain trivially the independence of the explanatory variables, the homoscedasticity is on the other hand no more assumed, the linearity of the model is always a hypothesis and the expected mean is linear only under an inverse transformation.

Obviously (as always...) the subject is more complex than it may seems. There are plenty of other GLM models that exist. The reader can see a sample of the most known one in the table below:

Family	Link type	Mean function
Gaussian	Identity	$\mu_i=\vec{x}_i^T\vec{\beta}$
Binomial	Logit (logistic)	$\mu_i=\frac{\exp\left(\vec{x}_i^T\vec{\beta}\right)}{1+\exp\left(\vec{x}_i^T\vec{\beta}\right)}$
Binomial	Probit	$\mu_i=\Phi\left(\vec{x}_i^T\vec{\beta}\right)$
Binomial	Robit	$\mu_i=T_{(\nu-1)/\nu}\left(\vec{x}_i^T\vec{\beta}\right)$
Binomial	loglog (nloglog)	$\mu_i=\exp\left(-\exp\left(\vec{x}_i^T\vec{\beta}\right)\right)$
Binomial	Cloglog (gombit)	$\mu_i=1-\exp\left(-\exp\left(\vec{x}_i^T\vec{\beta}\right)\right)$
Binomial	Cauchit	$\mu_i=\frac{1}{\pi}\arctan(\vec{x}_i^T\vec{\beta})+0.5$
Poisson	Log	$\mu_i=\exp\left(\vec{x}_i^T\vec{\beta}\right)$
Poisson	Identity	$\mu_i=\vec{x}_i^T\vec{\beta}$
Poisson	Sqrt	$\mu_i=\left(\vec{x}_i^T\vec{\beta}\right)^2$
Gamma	Inverse	$\mu_i=\left(\vec{x}_i^T\vec{\beta}\right)^{-1}$
Gamma	Identity	$\mu_i=\vec{x}_i^T\vec{\beta}$
Gamma	Log	$\mu_i=\exp\left(\vec{x}_i^T\vec{\beta}\right)$
Inverse gaussian	Inverse squared	$\mu_i=\left(\vec{x}_i^T\vec{\beta}\right)^{-1/2}$
...	...	...

Table 14.16: **Link functions and mean functions of some Generalized Linear Models (GLM)**

✍**Examples:**

E1. Let us now see after all these developments a first practical example using the most important case: the negative binomial regression. So that everyone can practice, we are going to do this regression with the spreadsheet software of Microsoft (a version made with `R` is also available in the corresponding companion book).

We collected a dataset of days of absence from 316 young college students (below the reader can see only the 32 first). Our explanatory variables of interest are their average score in foreign languages and their gender (boy or girl: B/G):

	A	B	C
1	Gender B/(	Average score in foreign language	Days of absence
2	1	42.45086	4
3	1	46.82059	4
4	0	43.56657	2
5	0	43.56657	3
6	0	27.24847	3
7	0	48.41482	13
8	0	40.73543	11
9	1	15.35938	7
10	1	52.11514	10
11	1	42.45086	9
12	0	36.45115	4
13	1	13.13055	5
14	0	62.27464	5
15	0	44.66451	3
16	1	25.25478	1
17	1	61.04388	0
18	0	49.47205	1
19	0	65.56011	0
20	1	46.82059	2
21	1	6.748048	24
22	0	42.45086	2
23	1	64.87473	0
24	1	55.33549	1
25	1	44.66451	0
26	0	38.34572	8
27	1	50	3
28	1	6.748048	7
29	0	40.15026	0
30	1	57.54914	2
31	1	71.82729	0
32	1	45.2079	0

Before going any further, it is first trivial to notice that the days of absence are non-negative with integer values and that the majority are never absent, a Gaussian regression is not the most suitable because its support sweeps away all the positive and negative real numbers (this does not necessarily mean that the result would be bad, however!). In addition, the standard deviation of days of absence is significantly different from the average of these same days of absence, therefore in extenso the Poisson regression is not the most suitable ... (however, this also does not mean necessarily that the result would be bad!).

So here is how to proceed with Microsoft® Excel® 14.0.7106 (the reader can find the equivalent example made with the `R` software in the corresponding companion book):

First we prepare an area which contains the 2 coefficients, the intercept and the parameter α of the negative binomial model (which for reminder is the inverse of the number of successes or respectively of failures and whose value must be at least equal the unit!!!) in an area of the sheet as visible below to which we associate a weak positive value written in hard on the keyboard (therefore no formulas here!):

	F	G
1	Start with low non-zero initial values!	
2	Alpha (α):	0.1
3	Intercept (β_0):	0.1
4	Beta 1 (β_1):	0.1
5	Beta 2 (β_2)::	0.1

Then, in column `D`, we will write the relation of the NB-2 log-likelihood which for reminder is given by:

$$\begin{aligned}&\ln\left[L\left(\alpha,Y_i,\vec{x},\vec{\beta}\right)\right]\\&=\sum_{i=1}^{n}\left(\begin{array}{l}\ln\left(\Gamma\left(\frac{1}{\alpha}+Y_i\right)\right)-\ln\left(\Gamma\left(\frac{1}{\alpha}\right)\right)-\ln\left(\Gamma\left(Y_i+1\right)\right)-\left(Y_i+\frac{1}{\alpha}\right)\ln\left(\alpha e^{\vec{x}_i^T\vec{\beta}}+1\right)\\+Y_i\ln\left(\alpha e^{\vec{x}^T\vec{\beta}}\right)\end{array}\right)\end{aligned}\tag{14.1.1087}$$

and since this spreadsheet software does not have Euler's Gamma function built in at the day we write these lines, we will rewrite it as follows:

$$\begin{aligned}&\ln\left[L\left(\alpha,Y_i,\vec{x},\vec{\beta}\right)\right]\\&=\sum\nolimits_{i=1}^{n}\left(\begin{array}{l}\ln\left(\ln\left(\left(\frac{1}{\alpha}+Y-1\right)!\right)\right)-\ln\left(\ln\left(\left(\frac{1}{\alpha}-1\right)!\right)\right)\\-\ln\left(\ln\left(\left(Y_i+1-1\right)!\right)\right)\\-\left(Y_i+\frac{1}{\alpha}\right)\ln\left(\alpha e^{-T}\vec{\beta}+1\right)\\+Y_i\ln\left(\alpha e^{-\vec{x}_i^T\vec{\beta}}\right)\end{array}\right)\end{aligned}\tag{14.1.1088}$$

Which gives with the Microsoft® Excel® formula syntax:

```
=LN(LN(FACT(1/$G$2+C2-1)))-LN(LN(FACT(1/$G$2-1)))
-IFERROR(LN(LN(FACT(C2+1-1)));1) -
(C2+1/$G$2)*LN($G$2*EXP($G$3+$G$4*A2+$G$5*B2)+1)
+C2*LN($G$2*EXP($G$3+$G$4*A2+$G$5*B2))
```

By writing this formula into column `D` and dragging it down we get first the following values:

	A	B	C	D
1	Gender B/G	Average score in foreign language	Days of absence	NB-2 Log-Likelihood
2	1	42.45086	4	-23.56860974
3	1	46.82059	4	-27.40784959
4	0	43.56657	2	-22.17858793
5	0	43.56657	3	-23.10529944
6	0	27.24847	3	-11.41480665
7	0	48.41482	13	-29.76050064
8	0	40.73543	11	-23.38335356
9	1	15.35938	7	-12.87617195
10	1	52.11514	10	-33.5552392
11	1	42.45086	9	-25.03816418
12	0	36.45115	4	-17.98537732
13	1	13.13055	5	-10.45212462
14	0	62.27464	5	-41.40350617
15	0	44.66451	3	-24.06195756
16	1	25.25478	1	-10.60633008
17	1	61.04388	0	-41.19920436
18	0	49.47205	1	-28.96600855
19	0	65.56011	0	-44.66206556
20	1	46.82059	2	-25.99241099
21	1	6.748048	24	-43.68585356
22	0	42.45086	2	-21.20921838
23	1	64.87473	0	-44.97275153
24	1	55.33549	1	-35.49451654
25	1	44.66451	0	-25.53757714
26	0	38.34572	8	-20.9338217
27	1	50	3	-29.80991321
28	1	6.748048	7	-14.91843578
29	0	40.15026	0	-20.63663154
30	1	57.54914	2	-36.15123337
31	1	71.82729	0	-51.86343663
32	1	45.2079	0	-26.0353948

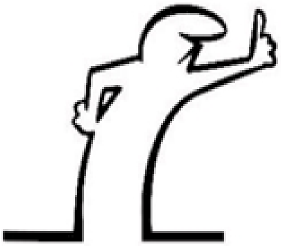
Now in a cell, we will report the sum of the NB-2 log-likelihood values. In this case we have chosen to put it in `G7`:

With everything that we have seen since the beginning of this textbook in the field of Statistics and Numerical methods, we can now provide the following summary table of some naive statistical tests that we have derived mathematically with all necessary details previously and that therefore the reader should therefore be able to grasp:

Type of dependant variable	**Type of independant variable**						
	Ordinal / Categorical				**Normal / Interval (ordinal)**	**More than 1**	**None**
	Two groups		**More groups**				
	Paired	**Unpaired**	**Paired**	**Unpaired**			
2 categrories	McNemar Test, Sign Test	Fisher Test, Chi-squared Test	Cochran's Q-Test	Fisher Test, Chi-squared Test	(Conditional) Logistic Regression	Logistic Regression	Chi-squared Test
Nominal	Bowker Test	Fisher Test, Chi-squared Test		Fishier Test, Chi-squared Test	Multinomial Logistic Regression	Multinomial Logistic Regression	Binomial Test
Ordinal	Wilcoxon Test, Sign Test	Wilcoxon-Mann-Whitney Test	Friedman Test	Kruskal-Wallis Test	Spearman Rank Test	Ordered Logit	Median Test
Interval	Wilcoxon Test, Sign Test	Wilcoxon-Mann-Whiney Test	Friedman Test	Kruskal-Wallis Test	Spearman Rank Test	Multivariate Linear Model	Median Test
Normal	T-Test (for paired)	T-Test (for unpaired)	Linear Model (ANOVA)	Linear Model (ANOVA)	Pearson Correlation Test	Multivariate Linear Model	T-Test
Censored Interval	Log Rank Test		Survival Analysis, Cox proportional hazards regression				
None	Clustering, Factor Analysis, PCA, Canonical Correlation						

Table 14.17: **Summary of naive fundamental statistical tests**

And keep in mind that excellent meme by Adrian Olszewski:



- Variable transformation

Box-Cox, Logarithm, Johnson, Manly, etc.

⊳ Change a LOT of things

- Rank-based methods

Mann-Whitney, Kruskal-Wallis, Friedman, etc.

⊳ Totally change H_0; complex interpretation, may fool you about medians

---

- More general (semi-) parametric methods

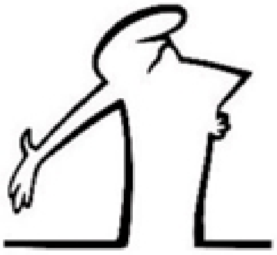
GLM, GLS, [G]LMM, GEE

⊳ Retain null hypotheses, handle heteroscedasticity, dependency, non-normality

- Computer intensive testing

Permutation tests, Bootstrap & Jackknife resampling

⊳ Retain null hypotheses, handle heteroscedasticity, dependency, non-normality, partially - outliers



14.1.12.8 Robust, M-estimators and W-estimators

The M-Estimators naturally appear in statistics when we see the problem of the aspect of the variance which is a function of squared deviations from the mean (hence a parabola) that is therefore a little too sensitive to extreme values (this is especially the case of many linear regression techniques, hence the fact that M-estimators are introduced mainly in textbooks related to regression techniques!). The idea then is to ask if it is not possible to construct something other than a square of deviations (hence a more robust statistic!) and then to define the corresponding sample mean, everything being distribution free, that we will name a "M-estimator of location[29]" (the reader should know that there are also M-estimators for the sample variance named "M-estimator of scale" like the τ-estimator!).

We have placed this subject in the section of Theoretical Computing instead of the section of Statistics because for most of these estimators, as we will see it further below, no closed form solution exists and an iterative approach to computation is required[30], the mathematics are quite ugly and most of the time there are different worldwide definitions for the same thing and also computer implementations that differ from their theoretical definition! .

Remark

Peter J. Huber (11964, 11967 according to holocene calendar) introduced M-estimators and their asymptotic properties (the proposed estimating the center of symmetry of symmetric distributions). They played an important part of the development of modern robust statistics. Liang and Zeger (11986 according to holocene calendar) helped popularize M-estimators in the biostatistics literature under the name "generalized estimating equations" (GEE). Since then many other robust estimators has been developed like MM-estimators, S-estimators, GM-estimators, τ-estimators, etc. (basically, MM-estimators are M-estimators initialized by an S-estimator...).

The best-known example of M-estimator is the arithmetic mean μ_a, as we have just mentioned, indeed it is it that trivially maximizes the function of the sum of squares of the deviations as we have seen earlier above:

$$\frac{\partial}{\partial \mu_a}\sum_{i=1}^{n}(x_i-\mu_a)^2=0 \tag{14.1.1089}$$

But some statistician have had the idea (in their purpose to always generalize everything thank to a lot of coffee) to define an M-estimator as the expression of the average that maximizes any function f whose argument is by definition $x_i-\theta$ such that:

$$\frac{\partial}{\partial \theta}\sum_{i=1}^{n}f(x_i-\theta)=0 \tag{14.1.1090}$$

And for example, in the case of the most familiar variance, this function f is the square of the argument, i.e. $f(x_i-\theta)=(x_i-\theta)^2$. It is customary, however, in statistics to denote the function f with the letter ρ (so do not confuse with the correlation coefficient or anything of the same kind!). We will continue our explanations by aligning ourselves with this traditional notation!

---

[29] Then by extension M-estimators are a broad class of extremum estimators for which the objective function is a sample average!

[30] It is possible to use standard function optimization algorithms, such as Newton–Raphson (solver!)

What ultimately makes us look for a θ that for a particular function ρ' gives:

$$\frac{\partial}{\partial\theta}\sum_{i=1}^{n}\rho(x_i-\theta)=\sum_{i=1}^{n}\rho'(x_i-\theta)=\sum_{i=1}^{n}\psi(x_i-\theta)=0 \tag{14.1.1091}$$

where ψ is named the "influence function" (both ρ and ψ should be obviously symmetric!). When the partial derivative exist, we speak of "ψ-type M-estimator" otherwise of "ρ-type M-estimator".

Remark

If $\rho=f$, the probability density function related to the random variable X, then the reader may have noticed that we fall back on the MLE (Maximum Likelihood Estimator) as introduced in the section of Statistics page 818!

We would like any good M-estimator of location to be location and scale equivariant, that is, we would like it to respond in a reasonable manner to linear changes across the sample. An M-estimator is "location equivariant" if, when every observation is shifted by some amount a, the θ of that shifted sample also shifts by a. An M-estimator of location is scale equivariant if, when every observation is multiplied by some non-zero constant b, the θ of that altered sample is b times the θ of the unaltered sample. An M-estimator of location that possesses both these characteristics is location-and-scale equivariant. In other words, we want the following to hold:

$$\theta(ax_1+b,ax_2+b,\ldots,ax_n+b)=b\theta(x_1,x_2,\ldots,x_n)+a \tag{14.1.1092}$$

In order for an M-estimator of location to be location-and-scale-equivariant, it is often necessary to scale the observations when computing ρ and ψ. This is often done whether rescaling is necessary or not because it makes notation simpler.

The matter of location-equivariance is fairly simple! It can be satisfied by making the input of the form $x_i-\theta$. Adjusting for scale is not as straightforward. We must pick some estimator of the scale of the sample, noted (without surprise...) s_i, which is a function of the observations $x_1,x_2,\ldots,x_n$. s is scale-equivariant and location invariant, meaning that it is unaffected by a shift in the sample as described above.

It is then common to define the standardized residual:

$$z_i=\frac{x_i-\theta}{c\cdot s_i}=\frac{r_i}{c} \tag{14.1.1093}$$

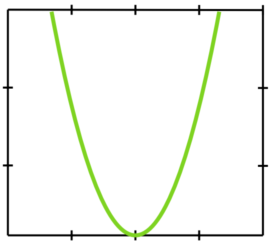
where s_i is a strictly positive robust estimator of scale (typically the median absolute deviation but it's not the only choice!) and c is a tuning constant, then we can write obviously:

$$\frac{\partial}{\partial\theta}\sum_{i=1}^{n}\rho(z_i)=\sum_{i=1}^{n}\rho'(z_i)=\sum_{i=1}^{n}\psi(z_i)\frac{\partial z_i}{\partial\theta}=0 \tag{14.1.1094}$$

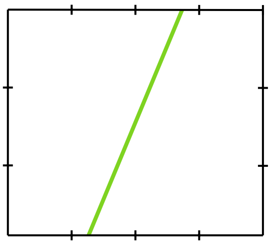
Definition (#14.1.561): Thus, more generally, a "M-estimator of location" may be defined to the value of a sample mean $\hat{\theta}$ that leads to a zero value of an estimating function given by:

$$\boxed{\hat{\theta}=\min_{\theta}\left(\sum_{i=1}^{n}\rho(z_i,\theta)\right)} \tag{14.1.1095}$$

Ideally, it is desirable that the function ρ' had as main property of being bounded (which immediately eliminates the arithmetic mean as an ideal M-estimator) which avoids typical deviations from the standard deviation (where $\rho(r_i)=r_i^2/2$ and hence $\psi(r_i)=r_i$):



ρ-function



ψ (influence) function

Figure 14.48: L^2-norm (influence function)

But we also require at least the four following properties for the $\rho(r_i)$ function:

P1. $\rho(r_i)\geq 0$ for all r_i and has a minimum at 0

P2. $\rho(r_i)=\rho(-r_i)$ for all r_i

P3. $\rho(r_i)$ increases as r_i increases from 0, but doesn't get too large as r increases

P4. $\rho(r_i)$ should be differentiable

and the following four properties for the $\psi(r_i)$ function:

P1. Be piece-wise continuous function

P2. Be an odd function, i.e. $\psi(-r_i)=-\psi(r_i)$

P3. $\psi(r_i)\geq 0$ for $r_i\geq 0$ and $\psi(r_i)>0$ for $0<r_i<k$

P4. Its slope is 1 at 0, i.e. $\psi'(0)=1$

Note that the last property is not strictly required mathematically, but we use it for standardization in those case where ψ is continuous at 0. Then if follow from the first property that $\psi(0)=0$, and we require $\psi(0)=0$ also for the case where ψ is discontinuous in 0, as it is, e.g., for the M-estimator defining the median.

Albert E. Beaton and John W. Tukey in their article [45] also define a new weighted function ω (without justifying it, but it's probably a mathematical trick to simplify some calculations that we will see further below) such that:

$$\psi(r_i)=r_i w(r_i)\Leftrightarrow w(r_i)=\frac{\psi(r_i)}{r_i} \tag{14.1.1096}$$

Thus:

$$\sum_{i=1}^{n}\psi(r_i)=\sum_{i=1}^{n}\frac{\psi(r_i)}{r_i}r_i=\sum_{i=1}^{n}w_i(r_i)r_i=0 \tag{14.1.1097}$$

What E. Beaton and John. W. Tukey write explicitly in their original article:

$$\sum_{i=1}^{n}w_i(z_i)z_i=\sum_{i=1}^{n}w_i\left(\frac{x_i-\theta}{c\cdot s_i}\right)\frac{x_i-\theta}{c\cdot s_i}=0 \tag{14.1.1098}$$

We can eliminate the $c\cdot s_i$ of the second fraction if we assume, same like Beaton and Tukey did, that it is equal for all i such that (relation that we use later):

$$\boxed{\sum_{i=1}^{n}w_i\left(\frac{x_i-\theta}{c\cdot S}\right)(x_i-\theta)=0} \tag{14.1.1099}$$

Definition (#14.1.562): The "breakpoint of an estimator" is the maximum proportion of observations (hence a number between 0 and 1) that can be changed without changing the estimator. For example the breakpoint of the arithmetic average is 0, that of the median is (obviously) 0.5.

Remark

Andrews et al. (11972 according to holocene calendar) (the Princeton Robustness Study), at which time it was expected that all statistical analyses would, by default, be robust wrote: «*any author of an applied article who did not use the robust alternative would be asked by the referee for an explanation*» and also that «*From the 1970s to 2000 we would see... extensions to linear models, time series, and multivariate models, and widespread adoption where every statistical package would take the robust method as the default...*»

Sadly, we see that even in 12018 (the day we write these lines according to holocene calendar), it's always not the case even if all softwares have largely the possibility to do so using nonparametric or brute force statistical methods (human inertia to change issue...).

Before introducing a list of some well-known ρ, ψ and ω functions, let us introduce two one well known robust estimator and one well known M-estimators of location (these both being introduced in the form of the objective function introduced just earlier above!).

1. The "trimmed mean", also named "truncated mean" or "pruned mean", is the robust estimator consisting in the arithmetic mean obtained by removing from the observed values those below and above a given quantile. It is customary to denote $\alpha/2$ the corresponding

percentile and that if we have n values then we return the $[\alpha n]$ largest values and the $n-[\alpha n]$ smaller (remember that $[\ldots]$ is the notation for "integer value" as seen on page 6293).

Mathematically, we denote elegantly the pruned average of ordered realizations x_i in descending order to increasing of a random variable X in the following form:

$$\boxed{\mu_{T_\alpha}=\frac{1}{n-2[n\alpha]}\sum_{i=[n\alpha]+1}^{n-[n\alpha]} x_i} \tag{14.1.1100}$$

Remark

We can find trimmed mean in many spreadsheets softwares for example under the function name `TRIMMEAN( )`, or in statistical software like `R` (just by passing an argument to the default `MEAN( )` function!

It is quite obvious that this robust estimator is an M-Estimator as it respects the definition seen above since we are only replacing some values of the original series with other values and that's finally equivalent to an arithmetic mean!

2. The "Winzorised (Huber) mean" is the robust estimator consisting in the arithmetic mean calculated after that the $[\alpha n]$ smallest values have been replaces by the value $x_{[\alpha n]+1}$ and the $[\alpha n]$ biggest values by the value $x_{n-[\alpha n]}$.

   Mathematically we denote elegantly the Winsorized mean of the ordered realizations x_i in descending order to increasing of a random variable X in the following way (discrete version):

$$\boxed{\mu_W=\frac{1}{n}\left[([n\alpha]+1)x_{[\alpha n]+1}+\sum_{i=[n\alpha]+2}^{n-[n\alpha]-1} x_i+([n\alpha]+1)x_{n-[\alpha n]-1}\right]} \tag{14.1.1101}$$

   Again it is obvious that this robust estimator is an M-Estimator as it respects the definition seen above since we are only replacing some values of the original series with other values and that's finally equivalent to an arithmetic mean!

Remark

We can find the Huber's mean in software like `R` using the function `HUBER( )` of the MASS package

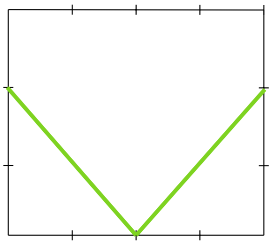
3. The "median", that we already well know, that satisfies (discrete version under the form of an M-estimator):

$$\boxed{\sum_{i=1}^{n}\operatorname{sgn}(x_i-M_e)=0} \tag{14.1.1102}$$

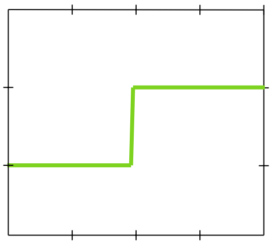
   where:

$$\operatorname{sgn}(x)=\begin{cases}-1 & x<0\\ 0 & x=0\\ +1 & x>0\end{cases} \tag{14.1.1103}$$

is for recall named the "signum function" or simply "sign function".



ρ-function



ψ (influence) function

Figure 14.49: **Median (influence function)**

✍**Example:**

Consider the values $2, 4, 5, 10, 200$. We then have first:

$$\mu_a = 44.2 \qquad M_e = 5$$

We then have for the 20% trimmed mean:

$$\mu_{T_\alpha} = \frac{4+5+10}{3} = 6.\bar{3}$$

and for the 20% Winsorized mean:

$$\mu_W = \frac{4+4+5+10+10}{5} = 6.6$$

Remark

The mean μ_a, the trimmed mean μ_{T_α}, the Winsorized mean μ_W and the median M_e are particular cases of "*L*-statistic" (linear combination of order statistics):

$$M_l\left(y_1, \ldots, y_n\right) = \sum_{i=1}^{n} a_i Y_{(i)} \quad a_{i,n} = \frac{1}{n} \Rightarrow \bar{y}$$

For example:

$$a_{i,n} = \frac{1}{n} \Rightarrow \bar{y}$$

lead to the mean μ_a:

$$a_{i,n}=\begin{cases}\text{for } n \text{ odd} & \\ 1 & i=\dfrac{n+1}{2}\\ 0 & i\neq\dfrac{n+1}{2}\end{cases}\qquad a_{i,n}=\begin{cases}\text{for } n \text{ even} & \\ \dfrac{1}{2} & i=\dfrac{n}{2},\dfrac{n}{2}+1\\ 0 & \text{otherwise}\end{cases}$$

leads to the median M_e.

Let's look at some of ρ, ψ and ω functions that build some common M-estimators:

Type	$\rho(r_i)$	$\psi(r_i)$	$\omega(r_i)$
L_2 (least-squares)	$r_i^2/2$	r_i	1
L_1 (least-absolute)	$\lvert r_i\rvert$	$\text{sgn}(r_i)$	$\dfrac{1}{\lvert r_i\rvert}$
L_1-L_2	$2\left(\sqrt{1+r_i^2/2}-1\right)$	$\dfrac{r_i}{\sqrt{1+r_i^2/2}}$	$\dfrac{1}{\sqrt{1+r_i^2/2}}$
L_p	$\dfrac{\lvert r_i\rvert^{\nu}}{\nu}$	$\text{sgn}(r_i)\lvert r_i\rvert^{\nu-1}$	$\lvert r_i\rvert^{\nu-2}$
"Fair"	$c^2\left[\dfrac{\lvert r_i\rvert}{c}-\log\left(1+\dfrac{\lvert r_i\rvert}{c}\right)\right]$	$\dfrac{r_i}{1+\lvert r_i\rvert/c}$	$\dfrac{1}{1+\lvert r_i\rvert/c}$
Huber $\begin{cases}\text{if } \lvert r_i\rvert\leq k\\ \text{if } \lvert r_i\rvert\geq k\end{cases}$	$\begin{cases}r_i^2/2\\ k(\lvert r_i\rvert-k/2)\end{cases}$	$\begin{cases}r_i\\ k\text{sgn}(r_i)\end{cases}$	$\begin{cases}1\\ k/\lvert r_i\rvert\end{cases}$
Cauchy	$\dfrac{c^2}{2}\log\left(1+(r_i/c)^2\right)$	$\dfrac{r_i}{(1+r_i^2)^2}$	$\dfrac{1}{(1+r_i^2)^2}$
Geman-MacClure	$\dfrac{r_i^2/2}{1+r_i^2}$	$\dfrac{r_i}{(1+r_i^2)^2}$	$\dfrac{1}{(1+r_i^2)^2}$
Welsch	$\dfrac{c^2}{2}\left[1-\exp\left(-(r_i/c)^2\right)\right]$	$r_i\exp\left(-(r_i/c)^2\right)$	$\exp\left(-(r_i/c)^2\right))$
Tukey $\begin{cases}\text{if } \lvert r_i\rvert\leq c\\ \text{if } \lvert r_i\rvert> c\end{cases}$	$\begin{cases}\dfrac{c^2}{6}\left(1-\left[1-(r_i/c)^2\right]^3\right)\\ (c^2/6)\end{cases}$	$\begin{cases}r_i\left[1-(r_i/c)^2\right]^2\\ 0\end{cases}$	$\begin{cases}\left[1-(r_i/c)^2\right]^2\\ 0\end{cases}$

Table 14.18: **Table of a few common dispersion M-estimators**

As far as I know (as redactor of this topic on M-estimators), they are all empirical and there is no "beautiful" way to derive them from a logical process.

Here is a graphical representation of the different functions of the above table:

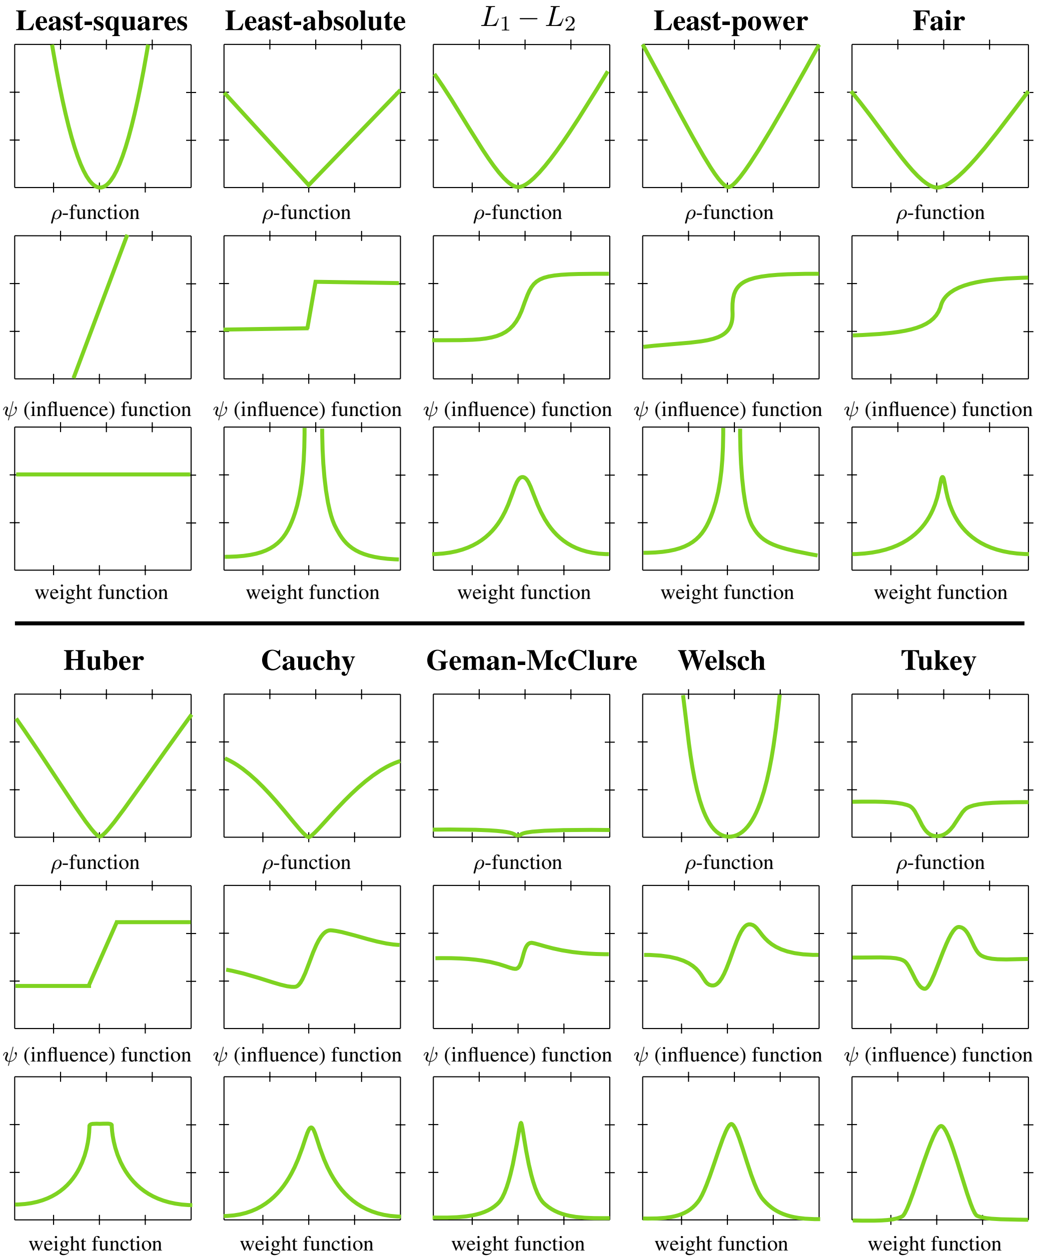


Figure 14.50: Graphical representation of a few common dispersion M-estimators

Briefly we give a few description of these functions:

- The "L_2 (least-squares) estimators", associated to the classic well known Pearson variance, are not robust because their influence function is not bounded.
- The "L_1 (least-absolute) estimators", associated to the mean absolute deviation, are not stable because the ρ-function $|r_i|$ is not strictly convex in r_i. Indeed, the second derivative at $r_i = 0$ is unbounded, and an indeterminate solution may result. This estimator in comparison of the L_2 reduce the influence of large errors, however they still have an influence because the influence function has no cutoff point.
- The "$L_1 - L_2$ estimators" take both the advantage of the L_1 estimators to reduce the influence of large errors and that of L_2 estimators to be convex.

- The "L_p (least-power) estimators" represents a family of functions. It is L_2 with $p=2$ and L_1 with $p=1$. It appears that p must be fairly moderate to provide a relatively robust estimator or, in other words, to provide an estimator scarcely perturbed by outlying data. The selection of an optimal p seems to have been investigated, and for p around 1.2, a good estimate may be expected. However, many difficulties are encountered in the computation when parameter p is in the rage of $1<p<2$, because zero residuals are troublesome.

- The "fair estimators" have everywhere defined continuous derivatives of first three orders, and yields a unique solution. The 95% asymptotic efficiency on the standard Normal distribution is obtained with the tuning constant $c=1.3998$.

- The "Huber's estimators" are parabola in the vicinity of zero, and increases linearly at a given level $|r_i|>k$. The idea is to penalize small residuals quadratically, and large residuals linearly. The 95% asymptotic efficiency on the standard Normal distribution is obtained with the tuning constant $k=1.345$. These estimators are so satisfactory that it has been recommended for almost all situations; very rarely they have been found to be inferior to some other ρ-function. However, from time to time, difficulties are encountered, which may be due to the lack of stability in the gradient values of the ρ-function of discontinuous second derivative:

$$\frac{\mathrm{d}^2\rho(r_i)}{\mathrm{d}r_i^2}=\begin{cases}1 & \text{if } |r_i|\leq k\\ 0 & \text{if } |r_i|\geq k\end{cases} \qquad (14.1.1104)$$

- The "Cauchy's estimators", also known as the "Lorentzian estimators", do not guarantee a unique solution. With a descending first derivative, such a function has a tendency to yield erroneous solutions in a way which cannot be observed. The 95% asymptotic efficiency on the standard Normal distribution is obtained with the tuning constant $c=2.3849$.

- The other remaining functions have the same problem as the Cauchy function. As can be seen from the influence function, the influence of large errors only decreases linearly with their size. The "Geman-McClure estimators and "Welsch estimators" try to further reduce the effect of large errors, and the "Tukey's biweight estimators" even suppress the outliers. The 95% asymptotic efficiency on the standard Normal distribution of the Tukey's biweight function is obtained with the tuning constant $c=4.6851$; that of the Welsch function, with $c=2.9846$.

There still exist many other ρ-functions, such as Andrew's cosine wave function, the GGW (Generalized Gauss-Weight), the LQQ (Linear Quadratic Quadratic), the "Optimal", etc.

Definition (#14.1.563): "Redescending M-estimators" are ψ-type M-estimators which have ψ functions that are non-decreasing near the origin, but decreasing toward 0 far from the origin. Their ψ functions can be chosen to redescend smoothly to zero, so that they usually satisfy $\psi(r_i)=0$ for all r_i with $|r_i|>k$, where k is referred to as the "minimum rejection point". Due to these properties of the ψ function, these kinds of estimators are very efficient, have a high breakdown point and, unlike other outlier rejection techniques, they do not suffer from a masking effect. They are efficient because they completely reject gross outliers, and do not completely ignore moderately large outliers (like median).

Regarding to the previous figure, the Cauchy, Geman-McClure, Welsch, Tukey but also Andrew M-estimators are Redescending M-estimators!

Let us see now practically how explicitly, as it is not really obvious..., are computationally implemented two of these estimator typically with a language like R (notice the iteration in the Huber estimator, it is the iterative reweighted least squares (IRLS)!):

Figure 14.51: **Implementation of Tukey's biweight and Huber M-estimator in R (source: R affy package)**

As the reader may have noticed by reading these script, we are very far from what we have theoretically introduced earlier before! So to understand why, let us focus for example on Tukey's biweight, and the reader will see that it will lead us to the concept of "W-estimators"!

For this, the reader let us recall that Beaton and Tukey had introduced in their article:

$$\sum_{i=1}^{n} w_i\left(\frac{x_i-\theta}{c\cdot S}\right)(x_i-\theta)=0 \quad (14.1.1105)$$

We can extract θ quite easily :

$$\theta = \frac{\sum_{i=1}^{n} w_i\left(\frac{x_i-\theta}{c\cdot S}\right)x_i}{\sum_{i=1}^{n} w_i\left(\frac{x_i-\theta}{c\cdot S}\right)} \qquad (14.1.1106)$$

In the case of Tukey's biweight we have then (this corresponds to the `t.bi.mu` in the script above):

$$\theta = \frac{\sum_{i=1}^{n}\left(1-\left(\frac{x_i-\theta}{c\cdot S}\right)^2\right)^2 x_i}{\sum_{i=1}^{n} w_i\left(\frac{x_i-\theta}{c\cdot S}\right)} \qquad (14.1.1107)$$

As there is a circular reference between the θ on the left and the θ on the right, the idea of some Tukey's biweight computer implementation is to take an estimate of the θ on the right (same idea to estimate S). Then we can see for example that Tukey's biweight M-estimator of location is computed in the affy package of the `R` software as:

$$\hat{\mu}_{T.b.} \cong \frac{\sum_{i=1}^{n} w_i x_i}{\sum_{i=1}^{n} w_i} = \frac{\sum_{i=1}^{n}\left(1-\left(\frac{x_i-M_e}{c\cdot \text{MAD}}\right)^2\right)^2 x_i}{\sum_{i=1}^{n}\left(1-\left(\frac{x_i-M_e}{c\cdot \text{MAD}}\right)^2\right)^2} \qquad (14.1.1108)$$

where we put $w_i = 0$ if:

$$\left|\frac{x_i-M_e}{c\cdot \text{MAD}}\right| > c \qquad (14.1.1109)$$

Such an approach (one-shot iteration using a weight function trick) to calculate an M-estimator should, according to Beaton and Tukey article, be named a "W-estimator". But we can iterate the process by writing:

$$\theta^{[k+1]} = \frac{\sum_{i=1}^{n}\left(1-\left(\frac{x_i-\theta^{[k]}}{c\cdot S}\right)^2\right)^2 x_i}{\sum_{i=1}^{n} w_i\left(\frac{x_i-\theta^{[k]}}{c\cdot S}\right)} \qquad (14.1.1110)$$

where the weights for a particular $\theta^{[k]}$ depend upon the previous values of $\theta^{[k-1]}$. We simply start with a reasonable guess of the values of $\theta^{[0]}$ (as we did just above) and also especially of the first initial estimate $\theta^{[0]}$, and iterate until the estimates have converged to within whatever we consider to be a reasonable margin of accuracy, that is, until $(\theta^{[k+1]}-\theta^{[k]})^2$ is less than some predicted values. This procedure is an example of the process of iteratively reweighted least squares (IRLS) that Beaton and Tukey in their article recommend to name W^k-estimators depending on the number $[k]$ of iterations...

Remark

IRLS can have some negative effects. Indeed, when IRLS is employed, more and more points can be eliminated from the data set with each iteration. At each step, the most extreme outliers are dropped from the sample because they are outside of a certain main body of the data. Left unchecked, IRLS can sometimes give zero weight to every point and whittle the data set away to nothing, so IRLS estimators need constraints applied to them that will counteract the effect of the redescending weight function. Such constrained estimators are named "S-estimators".

So far, the ready should have a better understanding why M-estimators are more a subject related to "statistical engineering" rather than "pure Statistics": different implementations and also even sometimes different definitions, quite arbitrary parameters, etc...!!!!

Remark

It can be proved that like the trimmed mean, M-estimators, τ-estimator and MM estimator are unbiased and asymptotically Normal at symmetric distributions (useful property to calculate their confidence intervals!).

14.1.13 Interpolation Techniques

The main difference between interpolation and regression, is the definition of the problem they solve.

Given n data points, when you interpolate, you look for a function that is of some predefined form that has the values in that points exactly as specified. That means given pairs (x_i, y_i) you look for f of some predefined form that satisfies $f(x_i) = y_i$. Most commonly f is chosen to be polynomial, spline (low degree polynomials on intervals between given points).

When you do regression, you look for a function that minimizes some cost, usually sum of square of errors, You don't require the function to have the exact values at given point, you just want a good approximation. In general, your found function f might not satisfy $f(x_i) = y_i$ for any data point, but the cost function, i.e. $\sum_{i=1}^{n}(f(x_i) - y_i)^2$ will be the smallest possible of all the functions of given form.

There are numerous polynomials interpolation techniques more or less complex and sophisticated. We propose here to present some in ascending order of difficulty.

14.1.13.1 Bézier Curves (Bézier Splines)

The Russian engineer Pierre Bézier, at the beginnings of the Computer Aided Design (CAD), in the years 11960 (holocene calendar), gave a way to define curves and surfaces from points. This allows direct manipulation, geometric, of curves without having to give a series of equation to the machine to describe a complex curve!!

The application field of Bezier curves is a multifaceted to, very rich, at the crossroads of many diverse mathematical areas: Analysis, Kinematic, Differential Geometry, Affine Geometry, Projective Geometry, Fractal Geometry, Probabilities, Statistics, Finance (rates curve), etc.

The Bezier are also become essential in their concrete applications in industry, and computer graphics. Most non-engineer and non-scientific people know them through the usage of some drawing tools included in Adobe Illustrator, Adobe Photoshop, 3D Studio Max, Blender, Rhino, Adobe InDesign, Microsoft Office Visio and even Microsoft Office Word and Microsoft Office PowerPoint. Most computer fonts are made with Bézier curves too!

Let us present and study in detail the mathematical approach of this technique:

First, we know that the equation of a segment line which we will denote in this field of study M (with respect for the tradition) joining two points $A(x_1, y_1), B(x_2, y_2)$ is:

$$M_1(t) = t(B - A) + A = (1 - t)A + B \tag{14.1.1111}$$

and named a "linear interpolation" (LERP).

This is right since when $t = 0$ we are on A and when $t = 1$ we are on B. Therefore $t \in [0, 1]$ and the point M describes the whole straight segment $[AB]$.

By definition, the straight segment denoted $[AB]$ is a "Bézier curve of degree 1" with control points A and B and the polynomials on t or on $t-1$ are the "Bernstein polynomials of degree 1".

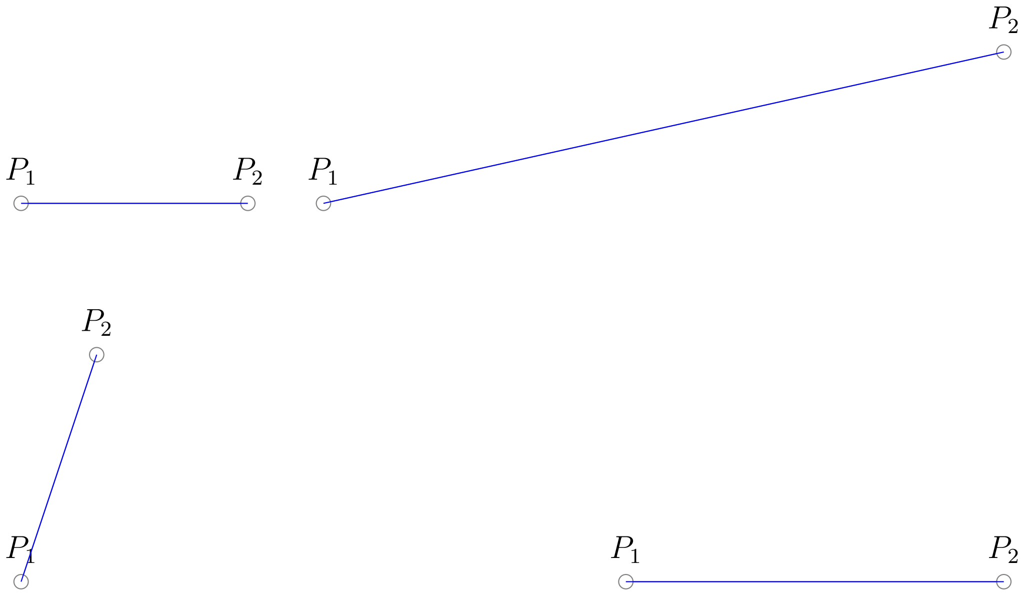

Figure 14.52: A few 1st order Bézier curves

Let us now build a parametric curve by adding a second step to what we just seen:

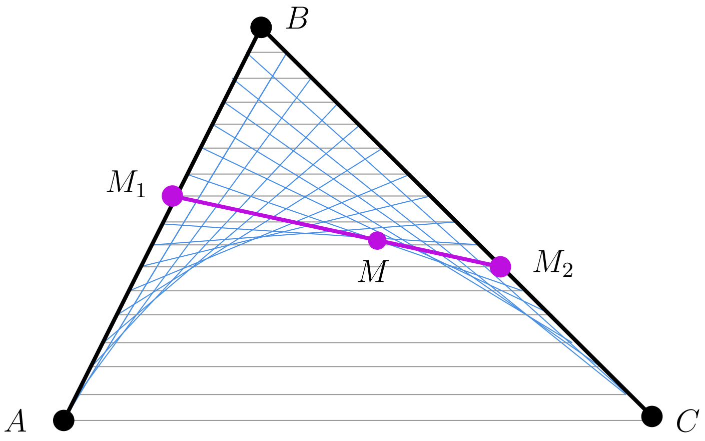

Figure 14.53: Idea behind 2nd order Bézier curves

1. 1st step:
    (a) Given $M_1(t)$ the barycenter of $(A, 1-t)$ and (B, t) and where $M_1(t)$ describes the segment $[AB]$.
    (b) Given $M_2(t)$ the barycenter of $(B, 1-t)$ and (C, t) and where $M_2(t)$ describes the segment $[BC]$.
2. 2nd step:

    Given $M(t)$ the barycenter of $(M_1(t), 1-t), (M_2(t), t)$.

> By construction $M(t)$ is therefore at the same proportion of the segment $[M_1(t), M_2(t)]$ relative to the segment $[AB]$ or to $M_2(t)$ compared to the segment $[BC]$.
>
> The curve obtained is then the envelope of the segments $[M_1(t), M_2(t)]$: at any point $M(t)$, the tangent to the curve is therefore the segment $[M_1(t), M_2(t)]$.

$M(t)$ then describes a Bézier curve of order 2, which, by construction starts at A and ends at C, and has for tangents $[AB]$ on A and $[CB]$ on C.

This is in fact a parabolic arc (that we denote logically by $[ABC]$ in this field of study):

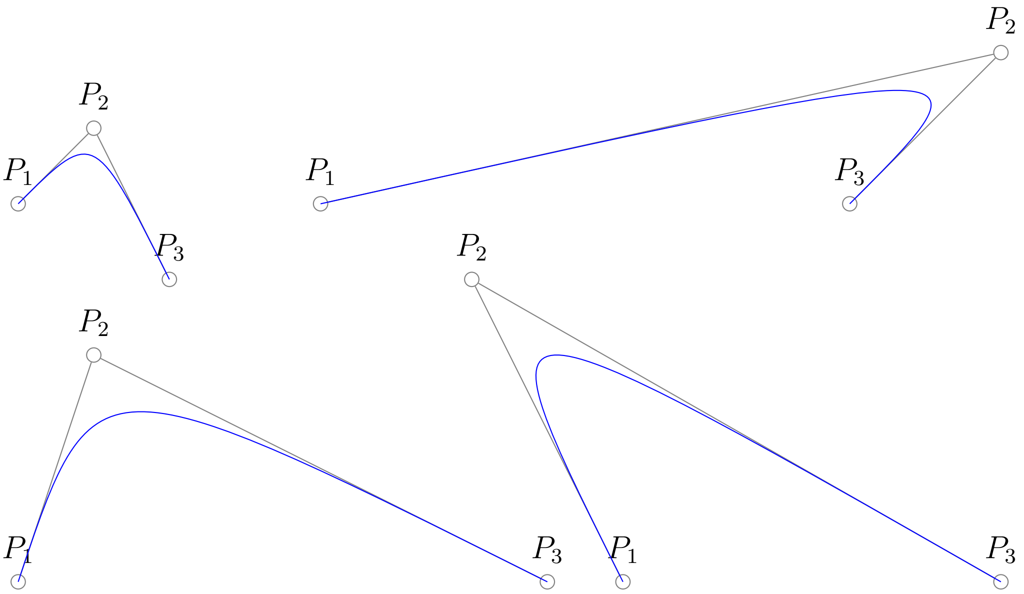

Figure 14.54: **A few 2nd order Bézier curves**

This is the magic of Bézier curves! We get smooth curves only by using combinations of linear interpolations (LERP)!! The example above is for example a quadratic Bézier curve, or a Bézier curve of order 2.

By the same pattern, we can define a Bézier curve of n points P_i with $i = 1...n$. This is what we name the "Casteljau algorithm" (the underlying idea is to recursively LERP until there is nothing more to LERP). Thus, given:

$$\forall r \in [1, n-1] \tag{14.1.1112}$$

We get:

$$b_i^{(r)}(t) = (1-t)b_i^{(r-1)}(t) + tb_{i+1}^{(r-1)}(t) \tag{14.1.1113}$$

The recurrence ending for:

$$b_i^{(0)}(t) = P_i \tag{14.1.1114}$$

Thus, for $n = 2$ we have:

$$M_2(t) = b_i^{(1)}(t) = (1-t)b_i^{(0)}(t) + tb_{i+1}^{(0)} \tag{14.1.1115}$$

Therefore:

$$\boxed{M_2(t)=b_1^{(1)}(t)=(1-t)b_1^{(0)}(t)+tb_2^{(0)}=(1-t)P_1+tP_2} \tag{14.1.1116}$$

Thus, we have necessarily with two points the equation of a straight line (Bézier curve of order 1).

Now consider $M_3(t)$ the Bézier curve of order 2, therefore we have the points always defined by:

$$M_3(t)=b_i^{(r)}(t)=(1-t)b_i^{(r-1)}(t)+tb_{i+1}^{(r-1)}(t) \tag{14.1.1117}$$

We then have by the recurrence relation:

$$\begin{aligned}
b_1^{(0)}&=P_1\\
b_2^{(0)}&=P_2\\
b_3^{(0)}&=P_3\\
b_1^{(1)}&=(1-t)b_1^{(0)}(t)+tb_2^{(0)}(t)\\
b_2^{(1)}&=(1-t)b_2^{(0)}(t)+tb_3^{(0)}(t)\\
&\cancel{b_3^{(1)}=(1-t)b_3^{(0)}(t)+tb_4^{(0)}(t)}\\
b_1^{(2)}&=(1-t)b_1^{(1)}(t)+tb_2^{(1)}(t)\\
b_2^{(2)}&=(1-t)b_2^{(1)}(t)+tb_3^{(1)}(t)\\
&\cancel{b_3^{(2)}=(1-t)b_3^{(1)}(t)+tb_4^{(1)}(t)}
\end{aligned} \tag{14.1.1118}$$

where we have eliminated the terms containing unspecified points.

We have therefore:

$$\begin{aligned}
b_1^{(1)}&=(1-t)P_1+tP_2\\
b_2^{(1)}&=(1-t)P_2+tP_3\\
b_1^{(2)}&=(1-t)b_1^{(1)}(t)+tb_2^{(1)}(t)\\
b_2^{(2)}&=(1-t)b_2^{(1)}(t)+tb_3^{(1)}(t)
\end{aligned} \tag{14.1.1119}$$

Therefore it comes for the 2nd order Bézier curves:

$$\boxed{M_3(t)=(1-t)^2P_1+2t(1-t)P_2+t^2P_3} \tag{14.1.1120}$$

or in vector form (more consistent with the usual mathematical notation and therefore we also better understand the meaning of "vectorial drawing"):

$$\boxed{\overrightarrow{\text{O}P}=\vec{M}_3(t)=\begin{pmatrix}x\\y\end{pmatrix}=(1-t)^2\overrightarrow{\text{O}P_1}+2t(1-t)\overrightarrow{\text{O}P_2}+t^2\overrightarrow{\text{O}P_3}} \tag{14.1.1121}$$

and in matrix form (the matrix visible below is named the "Bézier caracteristic matrix" sometimes):

$$M_3(t)=\begin{pmatrix}t^2 & t & 1\end{pmatrix}\begin{bmatrix}1 & -2 & 1\\ -2 & 2 & 0\\ 1 & 0 & 0\end{bmatrix}\begin{pmatrix}P_1\\ P_2\\ P_3\end{pmatrix} \tag{14.1.1122}$$

By the same reasoning, we get for a Bézier curve of order 3 (it's by far the most common Bézier curve in graphic design!):

$$\boxed{M_4(t)=(1-t)^3P_1+3t(1-t)P_2+3t^3(1-t)P_3+t^3P_4} \tag{14.1.1123}$$

or in vector form:

$$\overrightarrow{\text{O}P}=\vec{M}_4(t)=\begin{pmatrix}x\\ y\end{pmatrix}=(1-t)^3\overrightarrow{\text{O}P_1}+3t(1-t)^2\overrightarrow{\text{O}P_2}+3t^2(1-t)\overrightarrow{\text{O}P_3}+t^3\overrightarrow{\text{O}P_4} \tag{14.1.1124}$$

Which corresponds generically to:

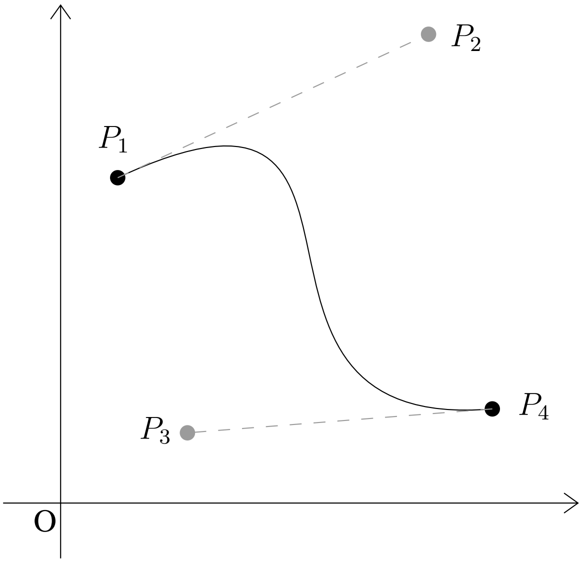

Figure 14.55: **Examples of Bézier curves of order** 3

Or:

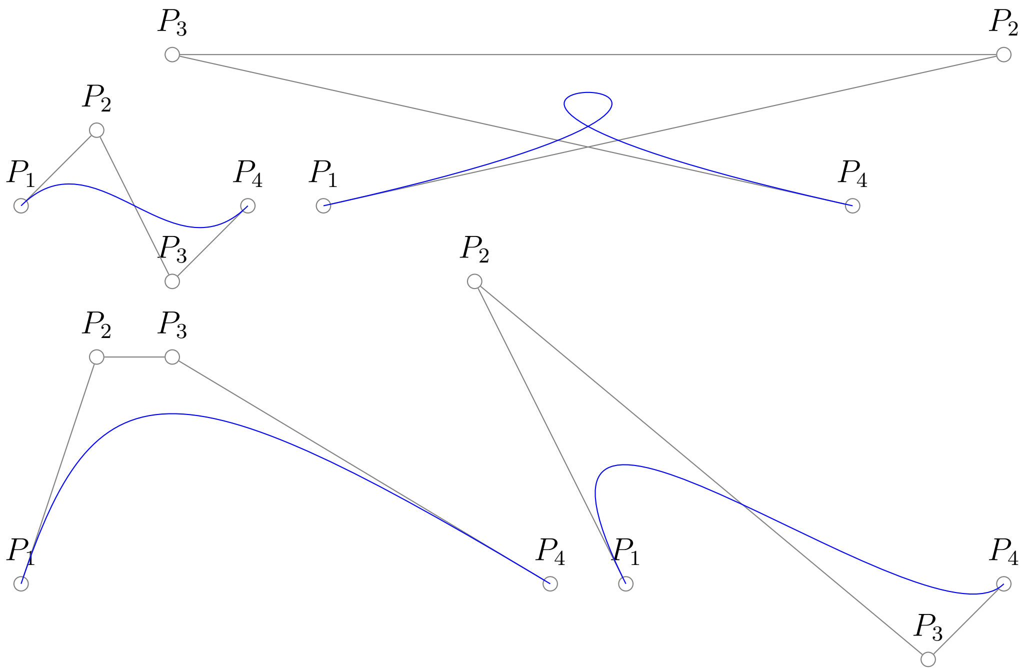

Figure 14.56: **A few 3rd order Bézier curves**

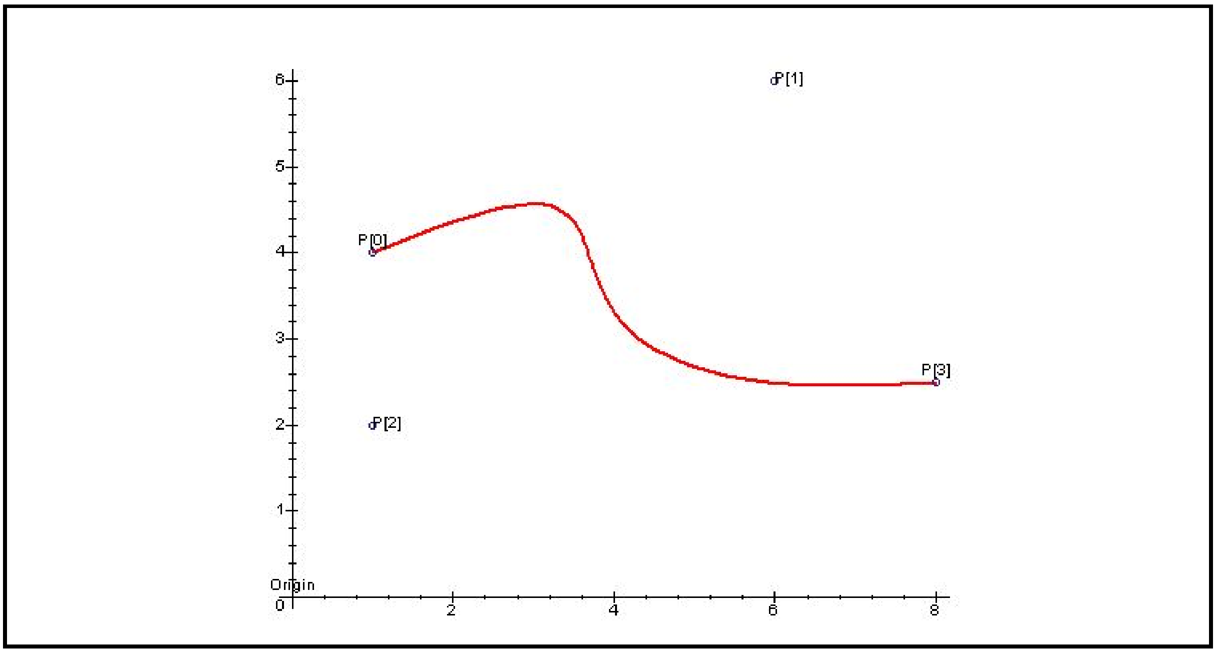
✍**Example:**

Let us plot now a Bézier curve of order 4 with Maple™ 4.00b. For this purpose we will use the following commands:

```
>restart:with(plots):
>x[0]:=1:  y[0]:=4:
>x[1]:=6:  y[1]:=6:
>x[2]:=1:  y[2]:=2:
>x[3]:=8:  y[3]:=2.5:
>f:=t->x[0]*(1-t)^3+3*x[1]*t*(1-t)^2+3*x[2]*t^2*(1-t)+x[3]*t^3;
>g:=t->y[0]*(1-t)^3+3*y[1 ]*t*(1-t)^2+3*y[2]*t^2*(1-t)+y[3]*t^3
>G:=plot([f(t),g(t),t=0..1],thickness=2):
>t0:=textplot([x[0],y[0],‘P[0]‘],align=ABOVE):
>t1:=textplot([x[1],y[1],‘P[1]‘],align=RIGHT):
>t2:=textplot([x[2],y[2],‘P[2]‘],align=RIGHT):
>t3:=textplot([x[3],y[3],‘P[3]‘],align=ABOVE):
>Or:=textplot([0,0,‘Origin‘],align=ABOVE):
>pp:=pointplot([x[0],y[0]],[x[1],y[1]],[x[2],y[2]],[x[3],y[3]],
symbol=circle,color=navy):
>display(G,t0,t1,t2,t3,pp,Or);
```

This will give:



Now let us take again the previous Bezier curve with a different notation:

$$M_4(t)=B_1P_1+B_2P_2+B_3P_3+B_4P_4=\sum_{i=1}^{4}B_iP_i \quad (14.1.1125)$$

We first notice easily the following proportionality:

$$B_i\propto c^{te}t^{i-1}(1-t)^{n-1} \quad (14.1.1126)$$

and if we look more closely at the coefficients, we notice that we have also:

$$\begin{aligned}\text{order } 2: &\quad 1\\ \text{order } 3: &\quad 121\\ \text{order } 4: &\quad 1331\end{aligned} \quad (14.1.1127)$$

It is neither more nor less than the Pascal's triangle !! So the coefficients are simply the binomial coefficients (see section Calculus page 1364) given for the order n in our example by:

$$C_{i-1}^{n-1}=\frac{(n-1)!}{(i-1)!((n-1)-(i-1))!}=\frac{(n-1)!}{(1-i)!(n-i)!} \quad (14.1.1128)$$

Thus, "Bernstein polynomials" are defined by:

$$B_{i,n}(t)=\frac{(n-1)!}{(1-i)!(n-i)!}t^{i-1}(1-t)^{n-i}=C_{i-1}^{n-1}t^{i-1}(1-t)^{n-i} \quad (14.1.1129)$$

and finally the Bernstein curves of order n are given by:

$$\boxed{M_n(t)=\sum_{i=1}^{n}B_{i,n}(t)P_i=\sum_{i=1}^{n}C_{i-1}^{n-1}t^{i-1}(1-t)^{n-i}P_i} \quad (14.1.1130)$$

In fact, if we had denoted previously the sum as follows:

$$M_4(t)=B_0P_0+B_1P_1+B_2P_2+B_3P_3=\sum_{i=0}^{3}B_iP_i \tag{14.1.1131}$$

we would then have the Bernstein polynomials that are given (which is more respectful of the traditions ...) by:

$$B_{i,n}(t)=C_i^n t^{i-1}(1-t)^{n-i} \tag{14.1.1132}$$

This is a very practical relation because it allows easily and quickly to calculate the polynomial corresponding to a sequence of Bezier curve of order n. The Bernstein polynomials can be geometrically interpreted as a factor of each point taken as a vector and summing them up to get the final Bézier curve! These polynomials might seem to come out of nowhere but we have seen that's what we get when rearranging the LERP maths to be expressed as a facto of each point. These polynomials act as influence of each control point. So in the beginning, the first point has all influence, this is then slowly sifht over the second control point, etc. until de last control point has all the influence. This is a special type of weighted sum, named "convex combination".

Then we have:

$$\boxed{\begin{aligned}x(t)&=\sum_{i=0}C_i^n t^i(1-t)^{n-i}x_i\\ y(t)&=\sum_{i=0}C_i^n t^i(1-t)^{n-i}y_i\end{aligned}} \tag{14.1.1133}$$

Remark

A Bezier curve is completely changed as soon as at least on point is moved. Then we say that the method of Bezier is a "global method".

Bézier curves have a huge issue however. If we move a control point, all the curve is influenced! In other words: we have no local control of the curve! Every movement of every point, affects the entire curve! And another issue is that given the number of LERP or polynomials to calculate, it's computationnaly unstable/expensive to calculate!

A well-known example of Bézier curves of order 3 is the "Pen tool" of Adobe Photoshop or Adobe Illustrator softwares. Indeed, these tools create a series of Bézier curves of order 3 whose point P_2 is set afterwards with the mouse using something named "Handles" or "Control Points" in Adobe practitioners language... Here is below an example taken from one of these programs done with the Pen tool with 5 points (thus 4 splines):

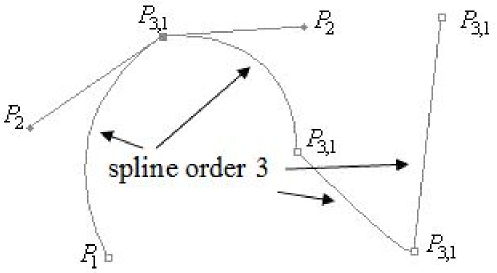


Figure 14.57: Screenshot of a Bézier spline with a drawing program

As the user does not move the points handles all points are aligned on the straight line. We then feel like to have a spline of order 2.

In the figure below we have a spline with 4 Bézier curves having obviously each one its own Bernstein Polynomials:

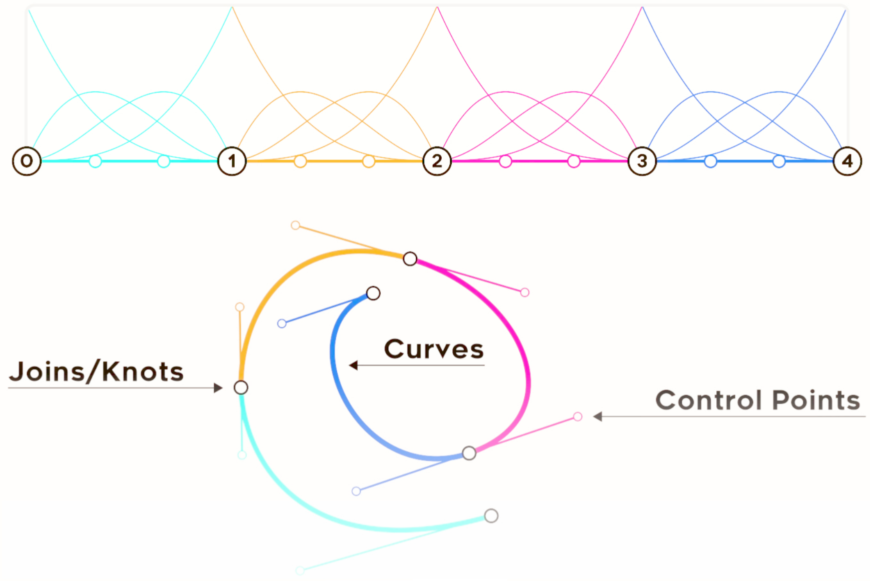

Figure 14.58: **Example of a Bézier spline with its underlying construction (author: Freya Holmér)**

✍**Example:**

A circle, drawn by a professional drawing software is in practice composed of 4 Bezier arcs. To observe this particularity, simply draw a circle with Adobe Illustrator for example, and then select it to reveal the Bezier control points arcs that defines it.

We will look at the best way to choose the control points of these arcs so that they look like circle quadrants, and then we will see the difference between the drawing produced (vector circle) and true (bitmap) circle:

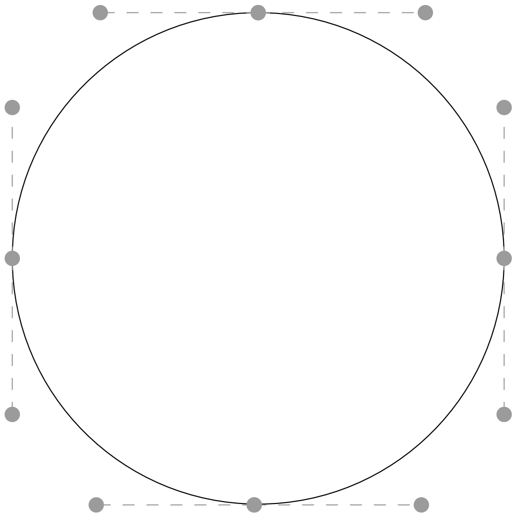

Figure 14.59: **Example of constructing a circle with Bézier curves**

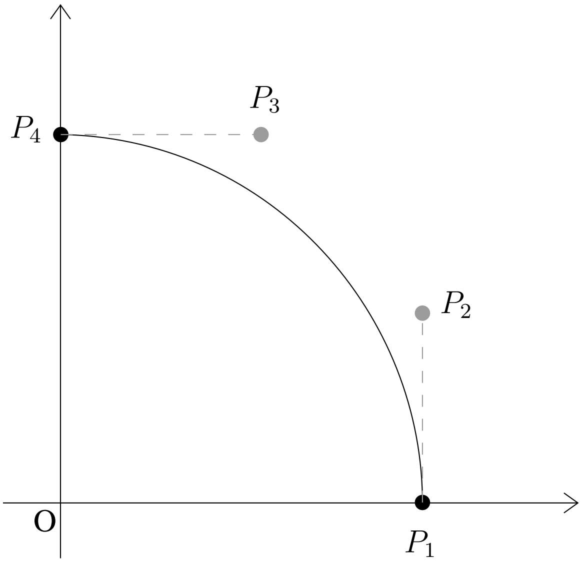
Let us take the first quadrant or radius 1 centered at the origin:



It is approached by a Bézier arc whose control points are P_1, P_2, P_3, P_4. The ends of the Bézier arc being P_1 and P_4, it is natural to choose $P_1(1,0)$ and $P_4(0,1)$. Intuition leads us to choose $P_2(1,k)$ and $P_3(k,1)$ and it remains to find a positive value of k so that the Bezier curve looks like a circular arc.

We thus obtain the parametric equation of the Bézier curve:

$$\begin{pmatrix} x \\ y \end{pmatrix} = (1-t)^3 \begin{pmatrix} 1 \\ 0 \end{pmatrix} + 3t(1-t)^2 \begin{pmatrix} 1 \\ k \end{pmatrix} + 3t^2(1-t) \begin{pmatrix} k \\ 1 \end{pmatrix} + t^3 \begin{pmatrix} 0 \\ 1 \end{pmatrix} \qquad (14.1.1134)$$

Therefore:

$$\begin{aligned} x(t) &= (1-t)^3 + 3t(1-t)^2 + 3t^2(1-t)k \\ y(t) &= 3t(1-t)^2k + 3t^2(1-t) + t^3 \end{aligned} \qquad (14.1.1135)$$

We can look for example the value of k for which the arc passes through the point:

$$P=\left(\frac{\sqrt{2}}{2},\frac{\sqrt{2}}{2}\right) \tag{14.1.1136}$$

in $t=0.5$. It then becomes very simple from the parametric equation to determine k. It is simply for x (or y) of a simple equation of one unknown.

With this tool we can now create plenty of illustrations (static or animated[31]) on computers!

---

[31] However animation with Bézier splines have huge flaws that requires to build a new kind of spline named "Hermite spline"

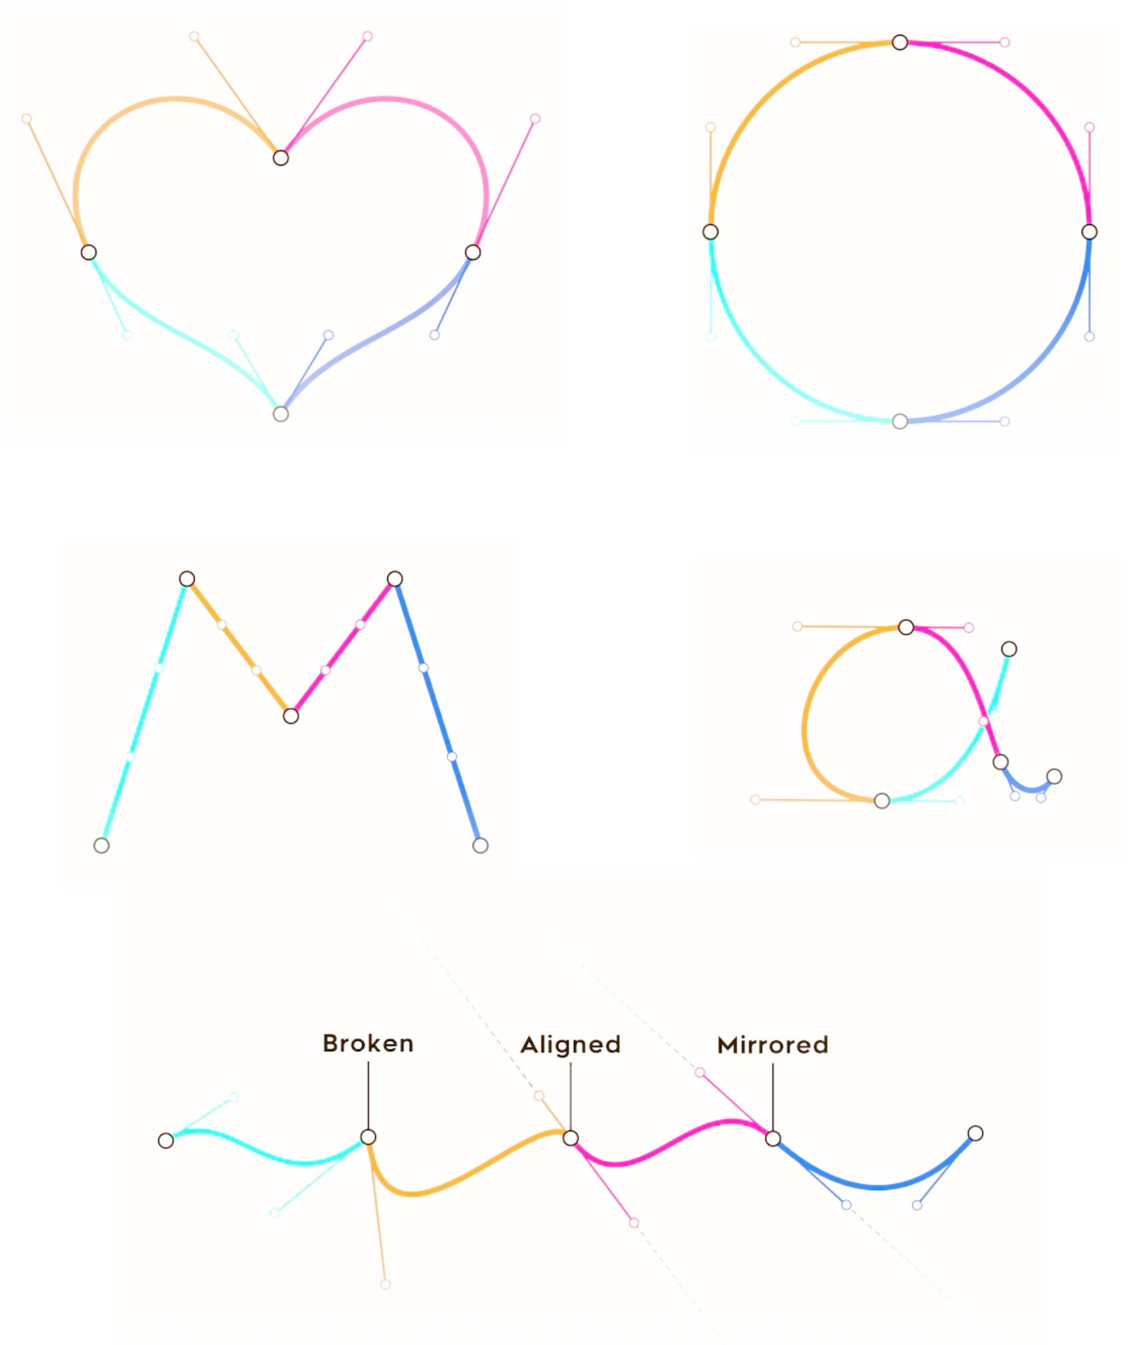


Figure 14.60: **A few practical example of Bézier splines (author: Freya Holmér)**

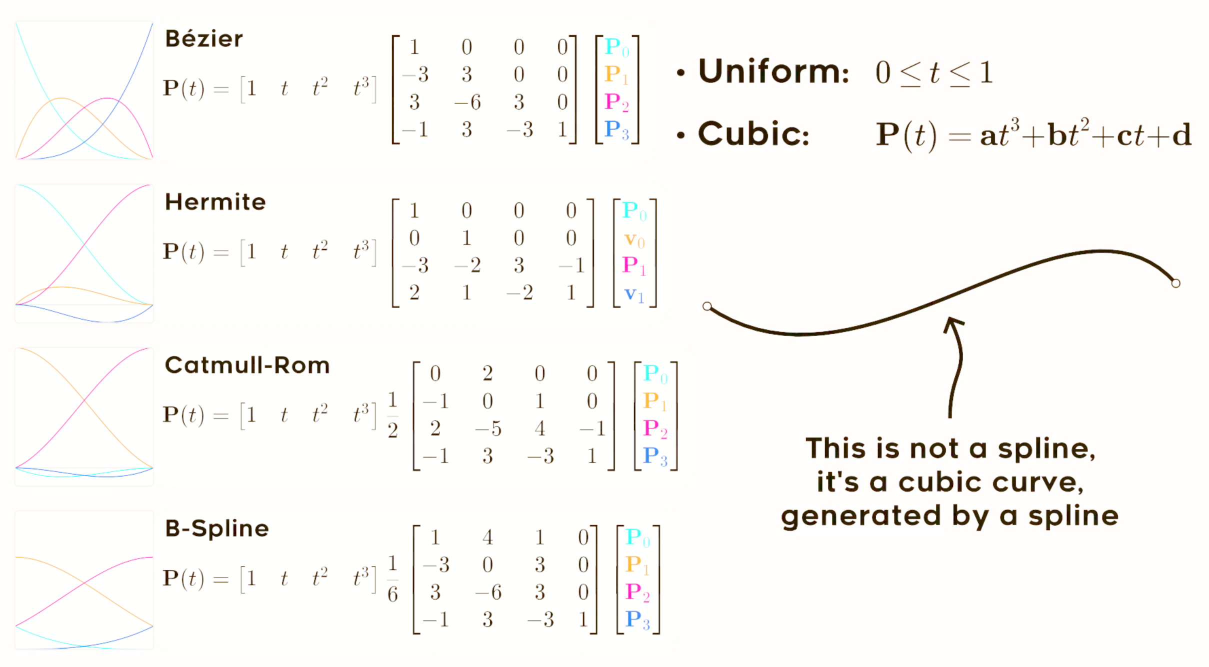
There are plenty of other splines useful in practice used to eliminate various flaws (but each of these splines has also some flaws): Uniform splines, Nonuniform splines, Natural splines, Hermite splines, Cardinal splines, B-splines (the "B" is not an abreviation for Bézier but for "basis"), Catmull-Rome splines, Interpolating splines, Non-uniform rational B-spline (NURBS)...



Bézier
P(t) = [1 t t² t³] [1 0 0 0; −3 3 0 0; 3 −6 3 0; −1 3 −3 1] [P0; P1; P2; P3]
Hermite
P(t) = [1 t t² t³] [1 0 0 0; 0 1 0 0; −3 −2 3 −1; 2 1 −2 1] [P0; v0; P1; v1]
Catmull-Rom
P(t) = [1 t t² t³] 1/2 [0 2 0 0; −1 0 1 0; 2 −5 4 −1; −1 3 −3 1] [P0; P1; P2; P3]
B-Spline
P(t) = [1 t t² t³] 1/6 [1 4 1 0; −3 0 3 0; 3 −6 3 0; −1 3 −3 1] [P0; P1; P2; P3]
• Uniform: 0 ≤ t ≤ 1
• Cubic: P(t) = at³+bt²+ct+d
This is not a spline, it's a cubic curve, generated by a spline

Figure 14.61: A visual summary of naive splines (author: Freya Holmér)

Bézier	3	C^0/C^1	manual	some	shapes, fonts, vector graphics
Hermite	3	C^0/C^1	explicit	all	animation, physics simulation, interpolation
Catmull-Rom	3	C^1	auto	all	animation, path smoothing
B-Spline	3	C^2	auto	none	curvature-sensitive shapes, animations such as camera paths
Linear	1	C^0	auto	all	dense data & interpolation where smoothness doesn't matter
...	...	...	...	...	...

Table 14.19: Table summary of naive splines (inspired by Freya Holmér)

Remark

Keep in mind, as the vocabulary may be confusing, that:

- If there is only one (polynomial) segment, the spline is often named a "Bézier curve".
- If each segment is expressed in Bézier form (using Bernstein basis functions), then you might say that the spline is a "Bézier spline".
- If each polynomial segment has degree 3, the spline is named a "cubic spline".
- If each segment is described by its ending positions and derivatives, it is said to be in "Hermite form".
- The B-spline approach (for which we will detail the underlying mathematics in the future) gives a way of ensuring continuity between segments. In fact, we show that

every spline can be represented in B-spline form. So, in that sense, every spline is a B-spline.

Figure 14.62: Summary of different ways of calculating Bézier curves (author: Freya Holmér)

14.1.13.2 Linear ordering isotonic regression

"Linear ordering isotonic regression" can be understood as approximating given series of 1-dimensional observations with non-decreasing function. It is similar to inexact smoothing splines, with the difference that we use monotonicity, rather than smoothness, to remove noise from the data. Isotonic relation is quite well known in the field of machine learning for models calibration.

Given values $\vec{a} \in \mathbb{R}^n$ and weights $\vec{w} \in \mathbb{R}^n$ such that $w_i > 0$ for all i, we want to approximate them by $y_1, \dots y_n$ as close as possible, subject to a set of constraints of kind $y_i \geq y_j$, i.e. we want to minimize (obviously sometimes other metrics are used instead of the Euclidean metric!):

$$\sum_i w_i \left(y_i - a_i\right)^2 \tag{14.1.1137}$$

with respect to $\vec{y} \in \mathbb{R}^n$ subject to $y_1 \leq y_2 \leq \ldots \leq y_n$.

If all weights equal to 1, the problem is named "unweighted isotonic regression", otherwise it is named "weighted isotonic regression".

In pseudocode (non-unique and very likely not optimized):

Algorithm 6: Pool Adjacent Violators Algorithm (PAVA) pseudocode algorithm

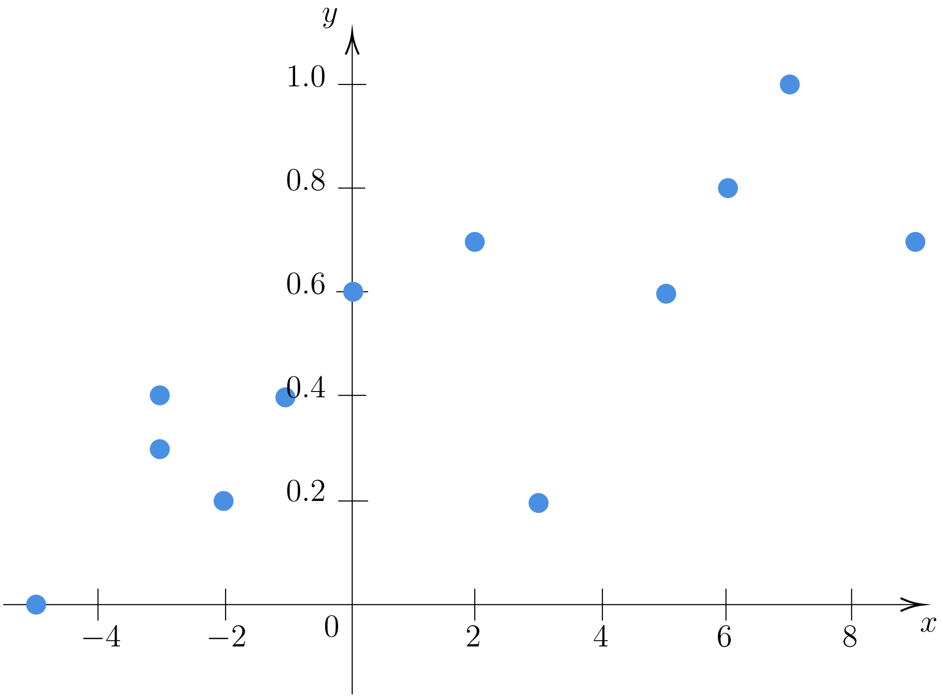
```
Data: $\vec{a}$,$\vec{w}$
Result: $\vec{y}$
initialization;
$a'_1 := a_1$;
$w'_1 := w_1$;
$j := 1$;
$S_0 := 0$;
$S_1 := 1$;
for $i = 2, 3, \ldots, n$ do
    $j := j + 1$ ;
    $a'_j := a_i$ ;
    $w'_j := w_i$;
    while $j > 1$ AND $a'_j < a'_{j-1}$ do
        $a'_{j-1} = \dfrac{w'_j a'_j + w'_{j-1} a'_{j-1}}{w'_j + w'_{j-1}}$;
        $w'_{j-1} = w'_j + w'_{j-1}$;
        $j := j - 1$;
    $S_j := i$;
for $k = 1, 2, \ldots, j$ do
    for $l = S_{k-1} + 1, \ldots, S_k$ do
        $y_l = a'_k$;
```

Here S defines to which old points each new point corresponds.

Let us see a very detailed companion example (thanks to Wojciech Kotłowski for having authorized us to reproduce it!).

Let us consider:

x	7	-1	-2	9	2	0	6	3	-3	5	-3	7	-5
y	1	0.4	0.2	0.7	0.7	0.6	0.8	0.2	0.3	0.6	0.4	1	0



Step 1: We sort the data in the increasing order of x.

x	7	−1	−2	9	2	0	6	3	−3	5	−3	7	−5
y	1	0.4	0.2	0.7	0.7	0.6	0.8	0.2	0.3	0.6	0.4	1	0

$\Downarrow \quad \Downarrow \quad \Downarrow$

x	−5	−3	−3	−2	−1	0	2	3	5	6	7	7	9
y	0	0.4	0.3	0.2	0.4	0.6	0.7	0.2	0.6	0.8	1	1	0.7

Step 2: We split the data into blocks $B_1, \ldots, B_r$, such that points with the same x_t fall into the same block.

We assign value f_i to each block ($i = 1, \ldots, r$) which is the average of labels in this block.

x	−5	−3	−3	−2	−1	0	2	3	5	6	7	7	9
y	0	0.4	0.3	0.2	0.4	0.6	0.7	0.2	0.6	0.8	1	1	0.7

$\Downarrow \quad \Downarrow \quad \Downarrow$

block	B_1	B_2	B_3	B_4	B_5	B_6	B_7	B_8	B_9	B_{10}	B_{11}
data	$\{1\}$	$\{2, 3\}$	$\{4\}$	$\{5\}$	$\{6\}$	$\{7\}$	$\{8\}$	$\{9\}$	$\{10\}$	$\{11, 12\}$	$\{13\}$
f_i	0	0.35	0.2	0.4	0.6	0.7	0.2	0.6	0.8	1	0.7

Step 3: While there exists a "violator", i.e. a pair of blocks B_i, B_{i+1} such that $f_i > f_{i+1}$, we merge B_i and B_{i+1} and assign a weighted average:

$$f_i = \frac{|B_i| f_i + |B_{i+1}| f_{i+1}}{|B_i| + |B_{i+1}|} \tag{14.1.1138}$$

block	B_1	B_2	B_3	B_4	B_5	B_6	B_7	B_8	B_9	B_{10}	B_{11}

$$\Downarrow \quad \Downarrow \quad \Downarrow$$

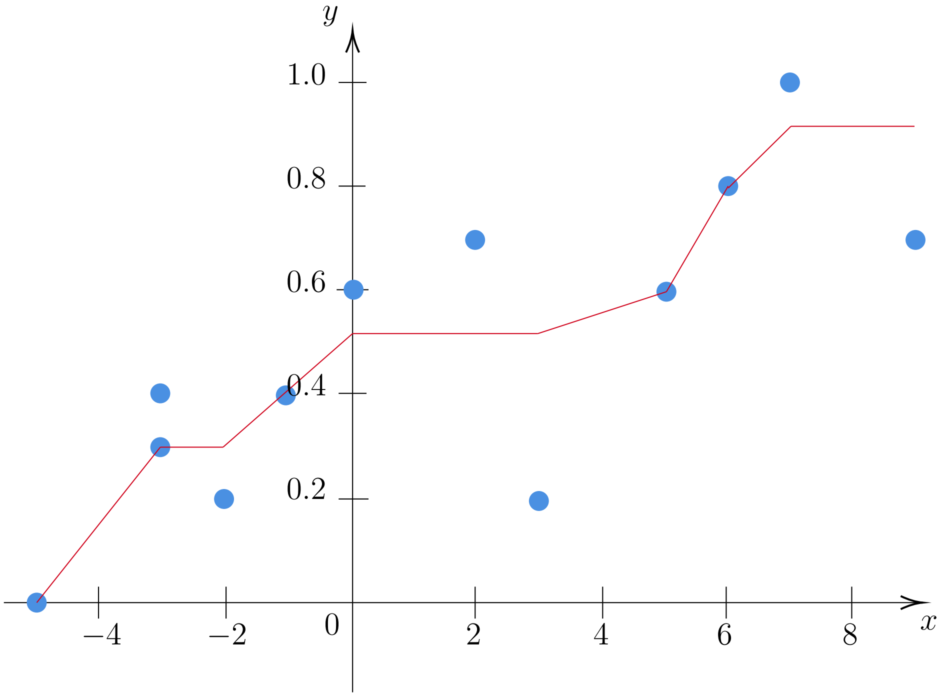
x	-5	-3	-3	-2	-1	0	2	3	5	6	7	7	9
y	0	0.4	0.3	0.2	0.4	0.6	0.7	0.2	0.6	0.8	1	1	0.7
f^*	0	0.3	0.3	0.3	0.4	0.5	0.5	0.5	0.6	0.8	0.9	0.9	0.9

Which gives:



This corresponds perfectly to what we get with the `R` software (see our companion book on the subject!).

14.1.13.3 Euler Method

Strictly speaking the Euler Method is much more than an interpolation method. But it can be introduced first as a liner piece-wise interpolation technique. In fact it provides an approximation (in the broadest sense) of a function $f(x)$ whose first derivative is known.

The interpolated points are not necessarily equidistant as the interpolation is piece-wise but as soon we extrapolate, the step is therefore by tradition equidistant and denoted by h and the distance between two points given by: $x_i = x_0 + ih$. We denote by $f(x)$ the exact value and y_i the approximate value.

The idea is quite simple. If in $\mathbb{R}^2$ we know two points (y_i, x_i) and (y_{i+1}, x_{i+1}) we can calculate piece-wise the slope as:

$$\frac{y_{i+1}-y_i}{x_{i+1}-x_i} = \frac{y_{i+1}-y_i}{\delta x} := \frac{y_{i+1}-y_i}{h} \cong f' \tag{14.1.1139}$$

In more complicated examples and real applications of the Euler methods we know the true derivative on x_i.

The previous relation can be written:

$$y_{i+1} \cong y_i + hf' \tag{14.1.1140}$$

And therefore for small h we can do a linear interpolation between two points.

If the derivative is known (and the derivative can be of non-linear function!) we have the more general relation:

$$y_{i+1}=y_i+hf'(x_i) \tag{14.1.1141}$$

That is traditionally written:

$$\boxed{y_{i+1}=y_i+hy'(x_i)} \tag{14.1.1142}$$

named also the "Euler difference equation". This relation can also be used to solve some simple numerical differential equation as illustrated by the following example:

✍**Examples:**

E1. Let's solve the following initial value problem ("Cauchy problem" style with $y'(x)=f'(x)$ and $y(x_0)=y_0$):

$$y'=y\,;\; y(0)=1$$

using the Euler's method. The recurrence relation can be written in is this special case:

$$y_{n+1}=(1+h)y_n \qquad y_0=1$$

i.e.:

$$y_n=(1+h)^n$$

For a given x we have:

$$n=\frac{x}{h}$$

and thus:

$$y_n=(1+h)^{\frac{x}{h}}=[(1+h)^{\frac{1}{h}}]^x$$

For $h\rightarrow 0_+$ the approximate solution y_n converges to the exact solution e^x.

E2. Suppose that we are given the equation $5y'-3y=0$ with boundary condition $y=y_0$ at $x=0$. This gives a unique function y. We can approximate this by considering discrete steps of length h between x_n and x_{n+1} (using the simple Euler numerical scheme) we can approximate the equation by:

$$5\frac{y_{n+1}-y_n}{h}-3y_n\approx 0$$

Rearranging the terms, we have $y_{n+1}\approx(1+\frac{3}{5}h)y_n$. Applying the relation successively, we have

$$\begin{aligned}y_n&=\left(1+\frac{3}{5}h\right)y_{n-1}\\&=\left(1+\frac{3}{5}h\right)\left(1+\frac{3}{5}h\right)y_{n-2}\end{aligned}$$

$$=\left(1+\frac{3}{5}h\right)^n y_0$$

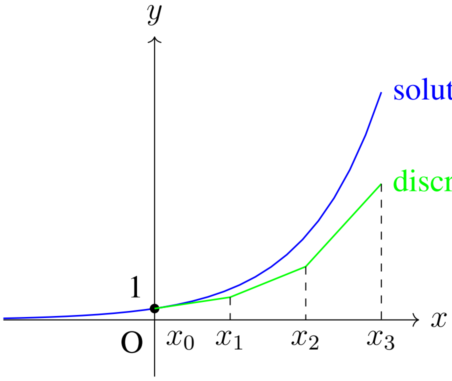
For each given value of x, choose $h=x/n$, so:

$$y_n=y_0\left(1+\frac{3}{5}(x/n)\right)^n$$

Taking the limit as $n\rightarrow\infty$, we have:

$$y(x)=\lim_{n\rightarrow+\infty} y_0\left(1+\frac{3x/5}{n}\right)^n=y_0e^{3x/5}$$

in agreement with the solution of the differential equation.



The "local truncation error" (LTE) of the Euler method is an error made in a single step. It is the difference between the numerical solution after one step.

To calculate this error we can write first:

$$y_1=y_0+hf(x_0) \quad (14.1.1143)$$

For the exact solution (considered as exact...), we use the Taylor expansion (see section Sequences and Series page 1696):

$$y(x_0+h)=y(t_0)+hy'(t_0)+\frac{1}{2}h^2y''(t_0)+\mathcal{O}(h^3) \quad (14.1.1144)$$

Also sometimes written:

$$y(x_n+h):=y_{n+1}=y_n+h=y'(x_n)+\frac{h^2}{2}y''(x_n)+\ldots+\frac{h^p}{p!}y^{(p)}(x_n)+\mathcal{O}(h^{p+1}) \quad (14.1.1145)$$

This relation can also be used to solve some simple numerical differential equation as illustrated by the following example:

✍**Example:**

We want to use the method of Taylor's expansion of the third order to solve the following initial value problem (again a "Cauchy problem" style with $y'(x)=f'(x)$ and $y(x_0)=y_0$):

$$y'=\frac{4}{x^2}-y^2-\frac{y}{x} \qquad \text{with: } y(1)=0$$

For $n=0,1,2,\ldots$ we have:

$$y(x_n+h):=y_{n+1}=y_n+hy'(x_n)+\frac{h^2}{2}y''(x_n)+\frac{h^3}{3!}y'''(x_n)+\mathcal{O}(h^4)$$

Here:

$$\begin{aligned}
x_0=1\,, \qquad & y_0=0\,,\\
y'(x_n) &= \frac{4}{x_n^2}-y_n^2-\frac{y_n}{x_n}\,,\\
y''(x_n) &= -\frac{8}{x_n^3}-2y_ny'(x_n)-\frac{y'(x_n)x_n-y_n}{x_n^2}=-\frac{12}{x_n^3}-\frac{6y_n}{x_n^2}+\frac{3y_n^2}{x_n}+2y_n^3\,,\\
y'''(x_n) &= \frac{24}{x_n^4}-2(y'(x_n))^2-2y_ny''(x_n)-\frac{y''(x_n)x_n^2-2(y'(x_n)x_n-y_n)}{x_n^3}\\
&= \frac{12}{x_n^4}-\frac{42y_n}{x_n^3}+\frac{21y_n^2}{x_n^2}-\frac{12y_n^3}{x_n}-6y_n^4\,.
\end{aligned}$$

The table below shows the computed values of the solution in the point $x_N=2$ for various N (and thus for various $h=1/N$):

	x	1	1.2	1.4	1.6	1.8	2
$h=0.2$	$y(x)$	0	0.576000	0.835950	0.920226	0.920287	0.884745
$h=0.1$		0	0.581645	0.838338	0.919251	0.918141	0.882631
$h=0.05$		0	0.582110	0.838443	0.919062	0.917872	0.882386
Exact solution: $y(x)=\dfrac{2(x^4-1)}{x(x^4+1)}$, $y(2)=0.882353$							

The local truncation error (one step!!!) introduced by the Euler method is given by the difference between these equations:

$$\text{LTE}=y(x_0+h)-y_1=\frac{1}{2}h^2y''(t_0)+\mathcal{O}(h^3) \qquad (14.1.1146)$$

This shows that for small h, the local truncation error is approximately proportional to h^2. This makes the Euler method less accurate (for small h) than other higher-order techniques such as Runge-Kutta methods that we will see later.

14.1.13.4 Polynomial of collocation

In the section of Sequences and Series we discussed the general unsuitability of Taylor polynomials for approximation. These polynomials are useful only over small intervals for functions whose derivatives exist and are easily evaluated. In this section we find approximating polynomials that can be determined simply by specifying certain points on the plane through which they must pass.

Given $y=f(x)$ a known function in explicit form or in tabulated form, and suppose that a given number of values:

$$f_i=f(x_i) \quad i=0,1,\ldots,n \tag{14.1.1147}$$

are given. The known points $(x_i, f(x_i))$ are named "support points".

"Interpolate f" in this context means to estimate the values of f for the horizontal x knows values located between x_0 and x_n, that is to say in the range of interpolation by an approximate function $y=P(x)$, which satisfies the "collocations conditions" (nothing to do with your roommate...!):

$$P(x_i)=f(x_i) \quad i=0,1,\ldots,n \tag{14.1.1148}$$

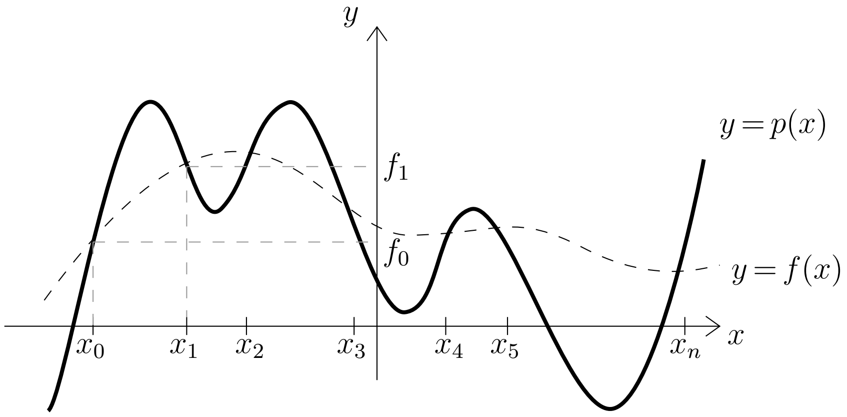


Figure 14.63: Illustration of the interpolation concept with the collocation technique

The function P is named "collocation function" on the x_i. When P is a polynomial, we speak of "collocation polynomial" or of "interpolation polynomial".

"Extrapolate" a function means study the $f(x)$ by $P(x)$ for x-located "outside" of the interpolation interval.

Remark

It goes without saying that the interpolation is a very important tool for all researchers, statisticians and others.

When we know a polynomial of degree n on $n+1$ points, we can know then by a simple way (but not very fast - but there are several methods) this polynomial completely.

To determine the polynomial, we will use the results presented above in our study of systems of linear equations. The disadvantage of the method presented here is that you have to guess to what type of polynomial you are dealing with (the order at least) and know what are the good points to chose (when there is a choice...).

A particular example should suffice for understanding this method, the generalization being quite simple (see further below).

Given the univariate second degree polynomial:

$$P_2(x)=a_0+a_1x+a_2x^2 \tag{14.1.1149}$$

and we know the following point (you will notice the ingenuity of the points selected by the authors of these lines ...):

$$P(0)=4, P(1)=8, P(-1)=2 \tag{14.1.1150}$$

We deduce therefore the following system of equations:

$$\begin{aligned}
&a_0+a_10+a_20^2=4\\
&a_0+a_11+a_21^2=2\\
&a_0+a_1(-1)+a_2(-1)^2=8
\end{aligned} \tag{14.1.1151}$$

System that once solved using the state of the art techniques (see section Linear Algebra page 1929) gives us:

$$a_0=4, a_1=-3, a_2=1 \tag{14.1.1152}$$

Let us see the general case:

Theorem 14.4. Given $(x_i, f(x_i))$ support points, with $x_i \neq x_j$ if $i \neq j$. Then there exists a polynomial $P_n(x)$ of degree less than or equal to n, and only one, such as $P_n(x_i)=f_i$ for $i=0,1,\ldots,n$.

Proof 14.4.1. Let us write:

$$P_n(x)=a_0+a_1x+\ldots+a_nx^n \tag{14.1.1153}$$

The collocation conditions:

$$P_(x_i)=f_i \quad i=0,1,\ldots,n \tag{14.1.1154}$$

are thus written:

$$\begin{aligned}
&a_0+a_1x_0+a_2x_0^2+\ldots+a_nx_0^n=f_0\\
&a_0+a_1x_1+a_2x_1^2+\ldots+a_nx_1^n=f_1\\
&\vdots\\
&a_0+a_1x_n+a_2x_n^2+\ldots+a_nx_n^n=f_n
\end{aligned} \tag{14.1.1155}$$

This is a system of $n+1$ equations in $n+1$ unknowns.

Its determinant is written (see section Linear Algebra page 1961):

$$D_n=\det\begin{vmatrix}1 & x_0 & x_0^2 & \cdots & x_0^n\\ 1 & x_1 & x_1^2 & \cdots & x_1^n\\ \vdots & \vdots & \vdots & \ddots & \vdots\\ 1 & x_n & x_n^2 & \cdots & x_n^n\end{vmatrix}=\prod_{n\geq i>j\geq 0}^{n}(x_i-x_j) \tag{14.1.1156}$$

relation that we name "Vandermonde determinant". We know that if the system has a solution, the determinant of the system must be non-zero (see section Linear Algebra page 1980).

Let us show by an example (by taking a polynomial of the same degree as the one we used above) that the determinant is calculated using the previous relation (the reader will generalize by induction):

Therefore in the case $n=2$, we consider the determinant:

$$D_2=\det\begin{vmatrix}1 & x_0^1 & x_0^2\\ 1 & x_1^1 & x_1^2\\ 1 & x_2^1 & x_2^2\end{vmatrix} \tag{14.1.1157}$$

thus corresponding to the system (for reminder):

$$\begin{aligned}a_0\cdot 1+a_1x_0^1+a_2x_0^2&=f_0\\ a_0\cdot 1+a_1x_1^1+a_2x_1^2&=f_1\\ a_0\cdot 1+a_1x_n^1+a_2x_2^2&=f_2\end{aligned} \tag{14.1.1158}$$

Let us calculate this determinant following the column 1 (by making use of cofactors as proved in the section of Linear Algebra at page 1980):

$$\begin{aligned}D_n=\det\begin{vmatrix}1 & x_0^1 & x_0^2\\ 1 & x_1^1 & x_1^2\\ 1 & x_2^1 & x_2^2\end{vmatrix}&=1\cdot\det\begin{vmatrix}x_1^1 & x_1^2\\ x_2^1 & x_2^2\end{vmatrix}-1\cdot\det\begin{vmatrix}x_0^1 & x_0^2\\ x_2^1 & x_2^2\end{vmatrix}+1\cdot\det\begin{vmatrix}x_0^1 & x_0^2\\ x_1^1 & x_1^2\end{vmatrix}\\ &=x_1^1x_2^2-x_2^1x_1^2-x_0^1x_2^2+x_2^1x_0^2+x_0^1x_1^2-x_1^1x_0^2\end{aligned} \tag{14.1.1159}$$

This polynomial can be written:

$$D=(x_1-x_0)(x_2-x_0)(x_2-x_1) \tag{14.1.1160}$$

Which is written:

$$D_2=\prod_{n\geq i>j\geq 0}^{n}(x_i-x_j) \tag{14.1.1161}$$

As the x_9 is in the statement of our problem are all different such that $x_i\neq x_j$ then the system has a unique solution! This proves that there is always an interpolation polynomial.

■ Q.E.D.

It should be noted however that it is not a method of polynomial regression. Indeed, with a method of polynomial regression, we might choose a higher degree for the polynomial as the number of points we have.

14.1.13.5 Lagrange polynomials

The interpolation polynomial Lagrange method (used a lot in practice because the algorithm is very simple and therefore effective) consider that we initially have (know) $n+1$ points such as:

$$\begin{aligned} y_0 &= f(x_0) \\ y_1 &= f(x_1) \\ &\ldots \\ y_i &= f(x_i) \\ &\ldots \\ y_n &= f(x_n) \end{aligned} \tag{14.1.1162}$$

and that we are looking for a collocation polynomial that passes through all the points. The idea of polynomial interpolation of Lagrange is therefore simple and very clever (as always someone must have think to it first...). Let us observe the chart below where we have 5 points by which we seek to pass a collocation polynomial:

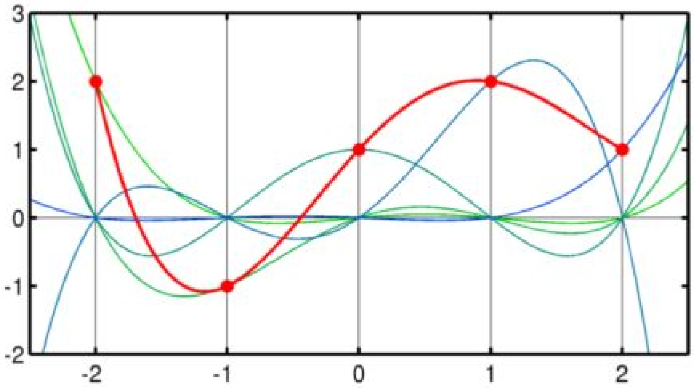

Figure 14.64: **Illustration of concept of Lagrange interpolation (source: Wikipedia)**

To find the collocation polynomial in red (we obviously suppose we don't know it initially), the idea is that for every x_i we associate a different polynomial of degree n and not null on $f(x_i)$ but null on all other points $(x_j)_{j\neq i}$. For this, as we see in the graph above, it is necessary that for each i we associate a polynomial that has n roots as:

$$\begin{aligned} f_0(x) &= A_0(x-x_1)(x-x_2)(x-x_3)(x-x_4) \\ f_1(x) &= A_1(x-x_0)(x-x_2)(x-x_3)(x-x_4) \\ f_2(x) &= A_2(x-x_0)(x-x_1)(x-x_3)(x-x_4) \\ f_3(x) &= A_3(x-x_0)(x-x_1)(x-x_2)(x-x_4) \\ f_4(x) &= A_4(x-x_0)(x-x_1)(x-x_2)(x-x_3) \end{aligned} \tag{14.1.1163}$$

So we see that we have 5 polynomials, each with 4 roots (hence of order 4) and which are respectively zero on all the points $x_j \neq x_i$ (as you can see on the graph). The coefficients A_i are constants to be determined.

Now nothing prevents us to sum all polynomial together since we will always have the right value on $f(x_i)$ (since the other polynomials are zero on this same point). Either by generalization the notation, the sum becomes:

$$\begin{aligned}P(x)=&A_0(x-x_1)(x-x_2)(x-x_3)\ldots(x-x_n)+A_1(x-x_0)(x-x_2)(x-x_3)\ldots(x-x_n)\\&+A_i(x-x_0)\ldots(x-x_{i-1})(x-x_{i+1})\ldots(x-x_n)+A_n(x-x_0)(x-x_1)(x-x_2)\ldots(x-x_{n-1})\end{aligned} \tag{14.1.1164}$$

By injecting respectively $x_0,x_1,\ldots,x_i,\ldots,x_n$, we get in the general case:

$$\begin{aligned}P(x_0)&=f(x_0)=A_0(x_0-x_1)(x_0-x_2)(x_0-x_3)\cdots(x_0-x_n)\\P(x_1)&=f(x_1)=A_1(x_1-x_0)(x_1-x_2)(x_1-x_3)\cdots(x_1-x_n)\\P(x_2)&=f(x_2)=A_2(x_2-x_0)(x_2-x_1)(x_2-x_3)\cdots(x_2-x_n)\\&\ldots\\P(x_n)&=f(x_n)=A_n(x_n-x_0)(x_n-x_1)(x_n-x_2)\cdots(x_n-x_{n-1})\end{aligned} \tag{14.1.1165}$$

We deduce then immediately in the general case:

$$\begin{aligned}A_0&=\frac{f(x_0)}{(x_0-x_1)(x_0-x_2)(x_0-x_3)\cdots(x_0-x_n)}\\A_1&=\frac{f(x_1)}{(x_1-x_0)(x_1-x_2)(x_1-x_3)\cdots(x_1-x_n)}\\A_2&=\frac{f(x_2)}{(x_2-x_0)(x_2-x_1)(x_2-x_3)\cdots(x_2-x_n)}\\&\ldots\\A_n&=\frac{f(x_n)}{(x_n-x_0)(x_n-x_1)(x_n-x_2)\cdots(x_n-x_{n-1})}\end{aligned} \tag{14.1.1166}$$

Substituting the values of the constants in the initial expression of the sum, we get:

$$\begin{aligned}P(x)=&A_0(x-x_1)(x-x_2)(x-x_3)\ldots(x-x_n)+A_1(x-x_0)(x-x_2)(x-x_3)\ldots(x-x_n)\\&+A_i(x-x_0)\ldots(x-x_{i-1})(x-x_{i+1})\ldots(x-x_n)+A_n(x-x_0)(x-x_1)(x-x_2)\ldots(x-x_{n-1})\\&=\frac{(x-x_1)(x-x_2)(x-x_3)\ldots(x-x_n)}{(x_0-x_1)(x_0-x_2)(x_0-x_3)\cdots(x_0-x_n)}f(x_0)+\frac{(x-x_0)(x-x_2)(x-x_3)\ldots(x-x_n)}{(x_1-x_0)(x_1-x_2)(x_1-x_3)\cdots(x_1-x_n)}f(x_1)\\&+\frac{(x-x_0)(x-x_1)(x-x_2)\ldots(x-x_{n-1})}{(x_n-x_0)(x_n-x_1)(x_n-x_2)\cdots(x_n-x_{n-1})}f(x_n)\end{aligned} \tag{14.1.1167}$$

Which can be written in condensed form (this relation will be useful to us later for some numerical integration methods!):

$$\boxed{P(x)=\sum_{j=0}^{n}\left(\prod_{i=0,i\neq j}^{n}\frac{x-x_i}{x_j-x_i}\right)f(x_j)} \tag{14.1.1168}$$

where the term:

$$L_j(x)=L(x_j)=\prod_{i=0,i\neq j}^{n}\frac{x-x_i}{x_j-x_i} \tag{14.1.1169}$$

is named "Lagrange polynomial interpolation coefficients".

Notice that if we use the Lagrange polynomial to approximate a known analytic and continuous function (hence with an infinite number of points), then obviously there may be an approximation error. This will be denoted:

$$P(x)-f(x)=\varepsilon(x) \tag{14.1.1170}$$

✍**Example:**

Let us approximate the function $y=f(x)=x\sin(2x+\pi/4)+1$ by a polynomial P_n of degree $n=3$, based on the following $n+1=4$ points:

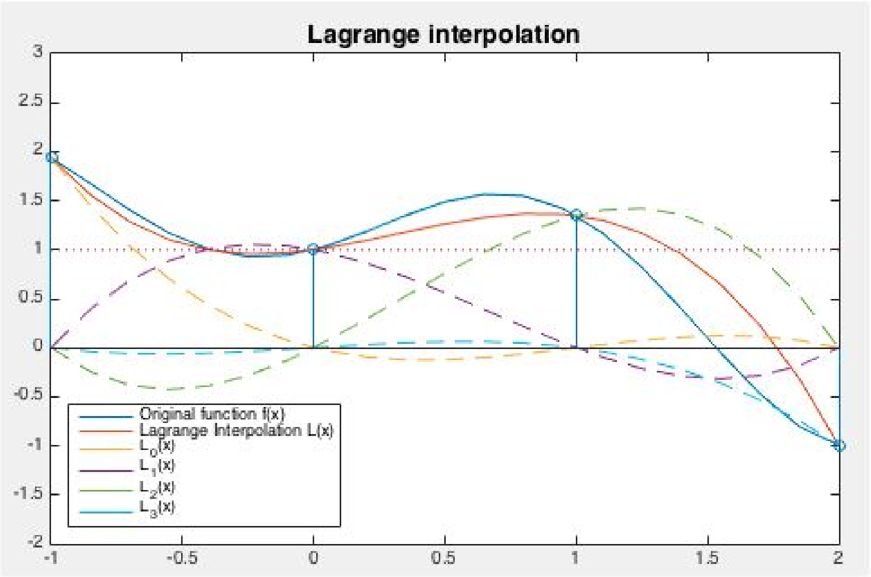
i	0	1	2	3
x_i	-1	0	1	2
$y_i=f(x_i)$	1.937	1.000	1.349	-0.995

Based on these points, we construct the Lagrange polynomials as the basis functions of the polynomial space:

$$\begin{aligned}
L_0(x)&=\dfrac{(x-0)(x-1)(x-2)}{-6}=\dfrac{x^3-3x^2+2x}{-6}\\
L_1(x)&=\dfrac{(x+1)(x-1)(x-2)}{2}=\dfrac{x^3-2x^2-x+2}{2}\\
L_2(x)&=\dfrac{(x+1)(x-0)(x-2)}{-2}=\dfrac{x^3-x^2-2x}{-2}\\
L_3(x)&=\dfrac{(x+1)(x-0)(x-1)}{6}=\dfrac{x^3-x}{6}
\end{aligned}$$

Note that indeed $L_0(x)+L_1(x)+L_2(x)+L_3(x)=1$. The interpolating polynomial can be obtained as a weighted sum of these basis functions:

$$P_3(x)=1.937L_0(x)+1.0L_1(x)+1.349L_2(x)-0.995L_3(x)=1.0+0.369x+0.643x^2-0.663x^3$$



14.1.13.6 Newton polynomials (divided differences)

As we have just seen, the Lagrange interpolation relies on the $n+1$ interpolation points:

$$\{x_i,\, y_i = f(x_i),\, i = 0,\dots,n\} \tag{14.1.1171}$$

all of which need to be available to calculate each of the basis polynomials $l_i(x)$.

The goodness of an approximation depends on the number of approximating points and also on their locations. One problem with the Lagrange interpolating polynomial is that we need n additions, $2n^2+2n$ subtractions, $2n^2+n-1$ multiplications, and $n+1$ divisions to evaluate $P(x)$ at a given point x. Even after all the denominators have been calculated once and for all we still need n additions, n^2+n subtractions, and n^2+n multiplications.

Furthermore, if additional points are to be used when they become available, all basis polynomials need to be recalculated. Another problem is that in practice, one may be uncertain as to how many interpolation points to use. So one may want to increase them over time and see whether the approximation gets better. In doing so, one would like to use the old approximation. It is not clear how to do that easily with the Lagrange form. In this sense, the Lagrange form is not incremental (plus it is also awkward to program).

In comparison, in the Newton interpolation, when more data points are to be used, additional basis polynomials and the corresponding coefficients can be calculated, while all existing basis polynomials and their coefficients remain unchanged. Due to the additional terms, the degree of interpolation polynomial is higher and the approximation error may be reduced (e.g., when interpolating higher order polynomials).

Specifically, the basis polynomials of the Newton interpolation are calculated as below:

$$n(x_0) = n_0(x) = 1, \quad n(x_i) = n_i(x) = \prod_{j=0}^{i-1}(x-x_j), \qquad i = 1,\dots,n \tag{14.1.1172}$$

and the Newton interpolating polynomial is constructed:

$$\begin{aligned}N_n(x) &= \sum_{i=0}^{n} c_i n_i(x) = c_0 + \sum_{i=1}^{n} c_i\left(\prod_{j=0}^{i-1}(x-x_j)\right)\\ &= c_0 + c_1(x-x_0) + c_2(x-x_0)(x-x_1) + \ldots + c_n\prod_{j=0}^{n-1}(x-x_j)\end{aligned} \tag{14.1.1173}$$

Note that the last data point (x_n, y_n) is not used in any of the basis polynomials, but it is used for calculating the last coefficient c_n, as shown below. For the nth degree polynomial $N_n(x)$ to pass all $n+1$ points $(x_i,\, y_i)$, $(i = 0,\dots,n)$, it needs to satisfy the following $n+1$ equations:

$$\begin{cases} y_0 = N_n(x_0) = c_0 \\ y_1 = N_n(x_1) = c_0 + c_1(x_1-x_0) \\ y_2 = N_n(x_2) = c_0 + c_1(x_2-x_0) + c_2(x_2-x_0)(x_2-x_1) \\ y_3 = N_n(x_3) = c_0 + c_1(x_3-x_0) + c_2(x_3-x_0)(x_3-x_1) + c_3(x_3-x_0)(x_3-x_1)(x_3-x_2) \\ \dots\dots\dots\dots \\ y_n = N_n(x_n) = c_0 + c_1(x_n-x_0) + c_2(x_n-x_0)(x_n-x_1) + \ldots + c_n\prod_{i=0}^{n-1}(x_n-x_i) \end{cases} \tag{14.1.1174}$$

The last relation is named the "Newton's divided-difference formula".

The relation can also be expressed in matrix form:

$$\begin{bmatrix} 1 & & & & & \\ 1 & x_1-x_0 & & & & \\ 1 & x_2-x_0 & (x_2-x_0)(x_2-x_1) & & & \\ 1 & x_3-x_0 & (x_3-x_0)(x_3-x_1) & (x_3-x_0)(x_3-x_1)(x_3-x_2) & & \\ \vdots & \vdots & & \vdots & \ddots & \\ 1 & x_n-x_0 & (x_n-x_0)(x_n-x_1) & (x_n-x_0)(x_n-x_1)(x_n-x_2) & \ldots & \prod\limits_{i=0}^{n-1}(x_n-x_i) \end{bmatrix} \begin{pmatrix} c_0 \\ c_1 \\ c_2 \\ c_3 \\ \vdots \\ c_n \end{pmatrix} = \begin{pmatrix} y_0 \\ y_1 \\ y_2 \\ y_3 \\ \vdots \\ y_n \end{pmatrix} \tag{14.1.1175}$$

The $n+1$ coefficients $c_0,\ldots,c_n$ can be obtained by solving these $n+1$ equations in the triangular equation system progressively from top down:

$$\begin{aligned} c_0 &= y_0 = f\,(x_0) = f\,[x_0] \\ c_1 &= \dfrac{y_1-y_0}{x_1-x_0} = f\,[x_0,x_1] \\ c_2 &= \dfrac{\dfrac{y_2-y_0}{x_2-x_0}-\dfrac{y_1-y_0}{x_1-x_0}}{x_2-x_1} = f\,[x_0,x_1,x_2] \\ &= \dfrac{y_0}{(x_0-x_2)\,(x_0-x_1)} + \dfrac{y_1}{(x_1-x_0)\,(x_1-x_2)} + \dfrac{y_2}{(x_2-x_0)\,(x_2-x_1)} \\ c_3 &= \dfrac{\dfrac{\dfrac{y_3-y_0}{x_3-x_0}-\dfrac{y_1-y_0}{x_1-x_0}}{x_3-x_1}-\dfrac{\dfrac{y_2-y_0}{x_2-x_0}-\dfrac{y_1-y_0}{x_1-x_0}}{x_2-x_1}}{x_3-x_2} = f\,[x_0,\ldots,x_3] \\ &= \dfrac{y_0}{(x_0-x_1)(x_0-x_2)(x_0-x_3)} + \dfrac{y_1}{(x_1-x_0)(x_1-x_2)(x_1-x_3)} \\ &+ \dfrac{y_2}{(x_2-x_0)(x_2-x_1)(x_2-x_3)} + \dfrac{y_3}{(x_3-x_0)(x_3-x_1)(x_3-x_2)} \\ &\ldots \end{aligned} \tag{14.1.1176}$$

In general, we have the:

$$c_k = f[x_0,\ldots,x_k] = \sum_{j=0}^{k} \dfrac{f(x_j)}{\prod\limits_{i=0,\,i\neq j}^{k}(x_j-x_i)}, \qquad k=0,\ldots,n \tag{14.1.1177}$$

which is the expanded form of the kth divided differences $f[x_0,\ldots,x_k]$ of the first $k+1$ points. Now the Newton polynomial interpolation can be written as:

$$\boxed{N_n(x) = \sum_{i=0}^{n} c_i n_i(x) = \sum_{i=0}^{n} f[x_0,\ldots,x_i]n_i(x) = f[x_0] + \sum_{i=1}^{n} f[x_0,\ldots,x_i]\left(\prod_{j=0}^{i-1}(x-x_j)\right)} \tag{14.1.1178}$$

Due to the uniqueness of the polynomial interpolation (here "uniqueness" means only in the way that all previous polynomial interpolation methods are such that for some given points $\{(x_i,y_i)\}_{i=0}^n$ we just have $p_n(x_i)=y_i$... and nothing more!), this Newton interpolation polynomial is the same as that of the Lagrange and the power (i.e. Taylor) function interpolations:

$$N_n(x)=L_n(x)=P_n(x) \tag{14.1.1179}$$

They are the same nth degree polynomial but expressed in terms of different basis polynomials weighted by different coefficients.

We can now consider some important facts all related to the Newton polynomial interpolation.

- When an additional node point $(x_{n+1},\, y_{n+1})$ is available and to be used, all previous basis polynomials and their corresponding coefficients remain unchanged, we only need to obtain a new basis polynomial of degree $n+1$:

  $$n_{n+1}(x)=n_n(x)(x-x_n)=\prod_{i=0}^{n-1}(x-x_i)(x-x_n)=\prod_{i=0}^{n}(x-x_i)=\omega(x) \tag{14.1.1180}$$

  together with its coefficient, the $(n+1)$th divided difference $c_{n+1}=f[x_0,\ldots,x_n,x_{n+1}]$. The new interpolation polynomial of degree $n+1$ can then be obtained by including an extra term in the summation above:

  $$N_{n+1}(x)=\sum_{i=0}^{n+1}c_in_i(x)=\sum_{i=0}^{n}c_in_i(x)+c_{n+1}n_{n+1}(x)=N_n(x)+f[x_0,\ldots,x_n,x_{n+1}]\omega(x) \tag{14.1.1181}$$

  As $N_{n+1}(x)$ passes through the new point $(x_{n+1},\, y_{n+1})$, we have:

  $$f(x_{n+1})=N_{n+1}(x_{n+1})=N_n(x_{n+1})+f[x_0,\ldots,x_n,x_{n+1}]\omega(x) \tag{14.1.1182}$$

  But x_{n+1} is just an arbitrary point, we can replace it by x, and get:

  $$f(x)=N_n(x)+f[x_0,\ldots,x_n,x]\omega(x) \tag{14.1.1183}$$

- If all $n+1$ points $x_0=a\leq x_1\leq\ldots\leq x_{n-1}\leq x_n=b$ are equally spaced, i.e.:

  $$x_{i+1}-x_i=h=\frac{b-a}{n},\quad i=0,\ldots,n-1 \tag{14.1.1184}$$

  then Newton's divided difference interpolation can take a simpler form. For any point $x\in(a,\,b)$, we let $c=(x-x_0)/h$ so that it can be represented as $x=x_0+ch$, and $x-x_i=(x_0+ch)-(x_0+ih)=(c-i)h$, now the Newton polynomial can be written as:

  $$\begin{aligned}N(x)=N(x_0+ch)&=f[x_0]+\sum_{i=1}^{n}f[x_0,\ldots,x_i]\prod_{j=0}^{i-1}(x-x_j)\\&=f[x_0]+f[x_0,x_1]ch+f[x_0,x_1,x_2]c(c-1)h^2+\ldots+f[x_0,\cdots,x_n]c(c-1)\ldots(c-n+1)h^n\\&=\sum_{i=0}^{n}f[x_0,\ldots,x_i]c(c-1)(c-2)\ldots(c-i+1)h^i=\sum_{i=0}^{n}f[x_0,\ldots,x_i]\begin{pmatrix}c\\i\end{pmatrix}i!\,h^i\end{aligned} \tag{14.1.1185}$$

  where we used the binomial-coefficient notation:

  $$\begin{pmatrix}c\\i\end{pmatrix}=\frac{c!}{i!(c-i)!}=\frac{c(c-1)(c-2)\cdots(c-i+1)}{i!} \tag{14.1.1186}$$

✍**Example:**

Let us approximate the function $y = f(x) = x\ \sin(2x+\pi/4)+1$ by a polynomial of degree $n=3$, based on the following $n+1=4$ points:

i	0	1	2	3
x_i	-1	0	1	2
$y_i = f(x_i)$	1.937	1.000	1.349	-0.995

Based on $f[x_i] = f(x_i)$, $(i=0,\cdots,n)$, we can find all other divided differences recursively in tabular form as shown below. In general, $f[x_i,\cdots,x_j]$ can be found based on its left neighbour $f[x_{i+1},\cdots,x_j]$ and top-left neighbour $f[x_i,\cdots,x_{j-1}]$:

$$f[x_i,\cdots,x_j] = \frac{f[x_{i+1},\ldots,x_j] - f[x_i,\ldots,x_{j-1}]}{x_j - x_i}$$

x_i	0th	1st	2nd	3rd
$x_0 = -1$	$f[x_0] = 1.937$			
$x_1 = 0$	$f[x_1] = 1.000$	$f[x_0,x_1] = -0.937$		
$x_2 = 1$	$f[x_2] = 1.349$	$f[x_1,x_2] = 0.349$	$f[x_0,x_2] = 0.643$	
$x_3 = 2$	$f[x_3] = -0.995$	$f[x_2,x_3] = -2.343$	$f[x_1,x_3] = -1.346$	$f[x_0,x_3] = -0.663]$

The coefficients are the four divided differences along the diagonal:

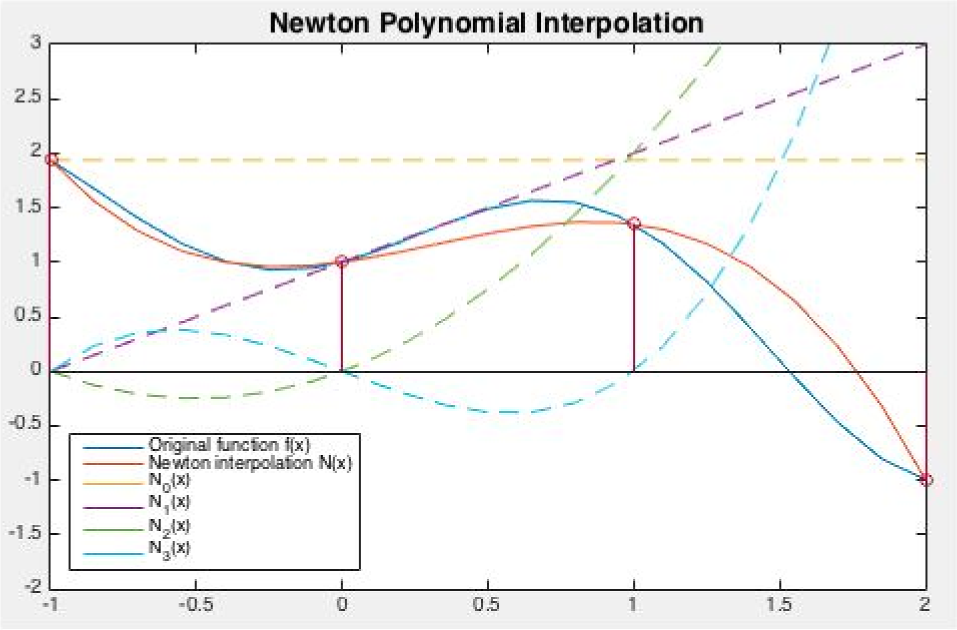
$$c_0 = f[x_0] = f(x_0) = y_0 = 1.937, c_1 = f[x_0,x_1] = -0.937, c_2 = f[x_0,x_1,x_2] = 0.643$$

and $c_3 = f[x_0,x_1,x_2,x_3] = -0.663$. Alternatively, they can also be represented in the expanded form:

$$c_i = f[x_0,\dots,x_i] = \sum_{j=0}^{n} \frac{f(x_j)}{\prod_{i=0,\,i\neq j}^{n}(x_j - x_i)}$$

Now the Newton interpolating polynomial can be obtained as:

$$\begin{aligned} N_3(x) &= \sum_{i=0}^{3} c_i n_i(x) = 1.937 - 0.937(x+1) + 0.643(x+1)(x-0) \\ &= -0.663(x+1)(x-0)(x-1) = 1 + 0.369x + 0.643x^2 - 0.663x^3 \end{aligned}$$



Using the Newton interpolating polynomials is then usually the best choice in comparison of Taylor, Vandermonde (i.e. collocation polynomial[32]) or Lagrange polynomials. It has the advantage that data pairs can be added and interpolated by merely adding one additional term to the previous interpolating polynomial. Under other restrictions the coefficients give information about the derivatives of a function being approximated as well as the error.

---

[32] Using the Vandermonde matrix is indeed not a very good method for any situation. The system is ill-conditioned and therefore the coefficients may be calculated very inaccurately. Also the amount of work is excessive!

14.1.13.7 Errors in Polynomial Interpolation

There are multiple ways to derive the approximation error of polynomial interpolation. In our personal and subjective point of view, all proofs known to us so far are not really convincing...

So let us introduce the error term in an engineer way rather than in a tricky mathematician one. For this, let us recall that during our Study of Taylor series, we have proved that the Lagrange remainder (see section Sequences and Series page 1722) was given by:

$$R_n(x)=f(x)-P_n(x)=\frac{f^{(n+1)}(z)}{(n+1)!}(x-x_0)^{n+1} \tag{14.1.1187}$$

For the case of polynomial where we have multiple points $x_0,x_1,\ldots,x_n$ rather than a unique one x_0, we can guess that the error may be written:

$$\varepsilon_n(x)=f(x)-P_n(x)=\frac{f^{(n+1)}(z)}{(n+1)!}\prod_{i=0}^{n}(x-x_i) \tag{14.1.1188}$$

In the field of polynomial interpolation (that we use the Taylor, Lagrange or Newton methods) that latter is often written:

$$\boxed{\varepsilon_n(x)=\frac{f^{(n+1)}(\xi)}{(n+1)!}\prod_{i=0}^{n}(x-x_i)} \tag{14.1.1189}$$

where ξ is some (unknown) point in the interval $[a,b]$. The precise location of this point depends on $\{x_i\}_{i=0}^{n}$. Here $f^{(n+1)}(\xi)$ is the $(n+1)$st derivative of $f(x)$ evaluated at the point $x=\xi_x$.

Therefore, for example (an example that will be useful to us when we will study numerical integration), the Lagrange polynomial given for recall by:

$$P(x)=\sum_{j=0}^{n}\left(\prod_{i=0,i\neq j}^{n}\frac{x-x_i}{x_j-x_i}\right)f(x_j)=\sum_{j=0}^{n}L(x_j)f(x_j) \tag{14.1.1190}$$

Will be written in it's full form as:

$$\boxed{P_n(x)=\sum_{j=0}^{n}\left(\prod_{i=0,i\neq j}^{n}\frac{x-x_i}{x_j-x_i}\right)f(x_j)+\frac{f^{(n+1)}(\xi)}{(n+1)!}\prod_{i=0}^{n}(x-x_i)=\sum_{j=0}^{n}L(x_j)f(x_j)+\varepsilon_n(x)} \tag{14.1.1191}$$

14.1.14 Roots search

Many equation encountered in practice or in theory cannot be solved by closed form or analytical methods. Consequently, only a numerical approach can be obtained in a finite number of operations.

The mathematician Évariste Galois has proved, in particular, that the polynomial equation $P_n(x)$ (see section Calculus page 1368) has no algebraic solution if $P_n(x)$ is of degree $n>4$.

There are numerous algorithms that gives the possibility to calculate the roots of equations of the type $f(x)=0$ with an almost arbitrary precision. We will see in this section only the main one.

Caution! The implementation of such algorithms need always at least an approximate knowledge (randomly or deterministic) of the searched value and also the behaviour (shape) of the function near the root. A table of the function values (see section Functional Analysis page 2207) or its graphical representation (see same section) can in simple cases help to acquire this prerequisites knowledge.

If the univariate equation to solve is under the form $g(x)=h(x)$, we plot the curves representing g and h. The roots of the equation $g(x)=h(x)$ being given by the abscissa of the intersection points of the both curves.

Remark

Before solving by numerical methods the equation $f(x)=0$, we have to check that the function f satisfy some constraints. For example, the function f has to be at least strictly monotone near the root that we will denote here by $\bar{x}$, when the Newton's method is applied. It is many times useful, even absolutely necessary, to determine an interval $[a,b]$ such that:

- f is continuous on $[a,b]$ of class $\mathcal{C}^1$
- $f(a)f(b)<0$
- $\exists\bar{x}$ unique, $\bar{x}\in[a,b]$, $f(r)=0$

14.1.14.1 Proportional parts methods

The implementation, on a computer, of this method is particularly simple. The conditions to be satisfied being only that in the interval $[a,b]$:

- f must be continuous on $[a,b]$ of class $\mathcal{C}^1$
- f must be monotone near the root r
- $f(a)f(b)<0$ to be sure that there is a root

As we already know, in a small interval, we can replace a curve by a straight line segment. There are several possible situations but here is a special one but that can be generalized easily to anything:

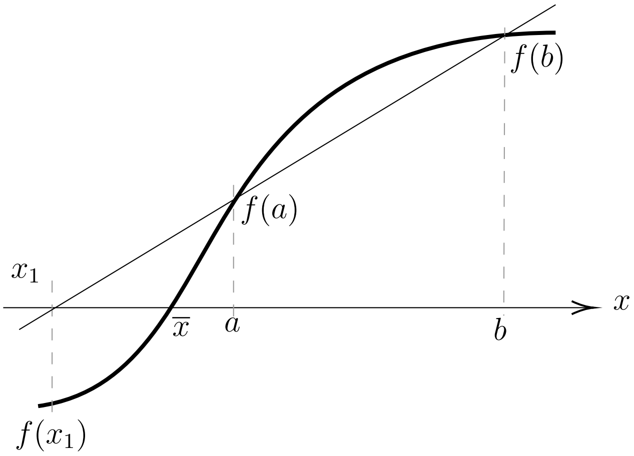


Figure 14.65: **Local approximation of a curve by a straight line segment**

In this figure, we get by using the theorems of Thales (see section Euclidean Geometry page 2610):

$$\frac{x_1-a}{f(a)}=\frac{x_1-b}{f(b)} \tag{14.1.1192}$$

therefore:

$$x_1=\frac{af(b)-bf(a)}{f(b)-f(a)}=a-(b-a)\frac{f(a)}{f(b)-f(a)} \tag{14.1.1193}$$

If $|f(a)| \ll |f(b)|$, we can neglect $f(a)$ at the denominator and it comes:

$$x_1 \cong a-(b-a)\frac{f(a)}{f(b)}=a-(b-a)k \tag{14.1.1194}$$

The algorithm consists therefore in performing the following steps:

1. We fix $\varepsilon>0$ as upper bound of the admissible error tolerance.
2. Choose a and b with opposite signs, calculate $f(a)$ and $f(b)$
3. We calculate $x_1=a-(b-a)k$. If $|f(x_1)|$ is small enough, we stop the calculation and we display x_1 and $f(x_1)$.
4. Otherwise we proceed as following:
   - We replace b by a and $f(b)$ by $f(a)$
   - We replace a by x_1 and $f(a)$ by $f(x_1)$

   and we go back to point (2).

In pseudocode (non-unique and not optimized):

Algorithm 7: Proportional Parts pseudocode algorithm

```
Data: $a$,$b$, $\varepsilon$ expression of $f$
Result: $x_1$
initialization;
$f(a)$,$f(b)$;
while $|f(x_1)| > \varepsilon$ do
    $x_1 = a-(b-a)\dfrac{f(a)}{f(b)}$;
    if $|f(x_1)| > \varepsilon$ then
        $b := a$;
        $f(b) := f(a)$;
        $a := x_1$;
        $f(a) := f(x_1)$;
    Display $x_1$;
```

Obviously this is not the best algorithm especially if there is no root or if the computer is slow. Then a good advice is to take as input a number of limited iterations that have to be done (we will see a more elaborated way to handle such situations in the next algorithm).

14.1.14.2 Secant method (Regula Falsi or False Position)

The "secant method" also named or "regula falsi" (for: regularly false) or also named "false position method" is still a root search algorithm to zero. It's almost exactly the same as the proportional parts methods at the difference we don't make the assumption $|f(a)| \ll |f(b)|$.

To introduce it, consider the following figure:

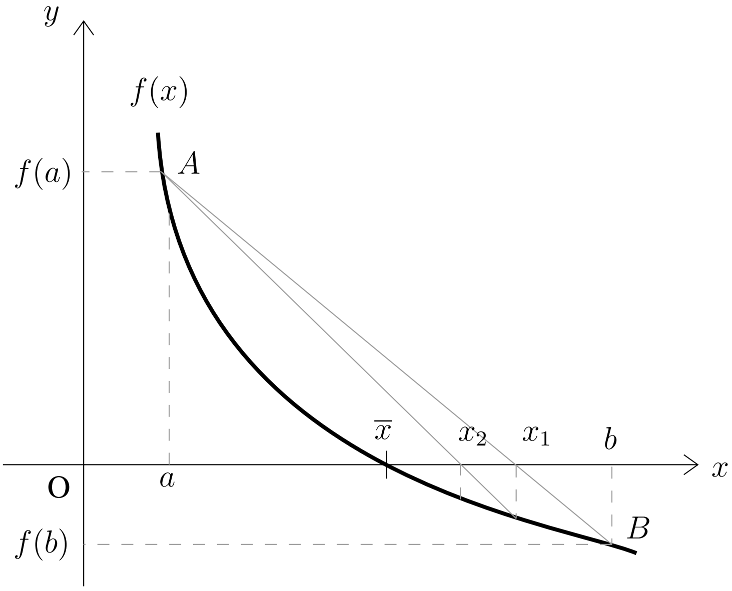

Figure 14.66: **Regula falsi method scheme**

The implementation, on a computer, of this method is particularly simple. The conditions to be satisfied being only that in the interval $[a, b]$:

- f must be continuous on $[a, b]$ of class $\mathcal{C}^1$
- f must be monotone near the root x^*
- $f(a)f(b) < 0$ to be sure that there is a root

If P_n is the point of coordinates $(x_n, 0)$, then the points (A, B, P_n) are aligned on the secant. The following proportion (application of Thales theorem) is then true:

$$\frac{a-b}{a-x_n}=\frac{f(a)-f(b)}{f(a)-0} \qquad (14.1.1195)$$

hence we deduce that:

$$x_n=\frac{af(b)-bf(a)}{f(b)-f(a)} \qquad (14.1.1196)$$

The algorithm consists therefore in performing the following steps:

1. We fix $\varepsilon > 0$ as upper bound of the admissible error tolerance.

2. Calculation of $x_n = \dfrac{af(b)-bf(a)}{f(b)-f(a)}$
3. Evaluation of $f(x_n)$
4. If $|f(x_n)|<\varepsilon$, the job is done. We have to display x_n
5. Otherwise we proceed as following:
    (a) we replace a by x_n if $f(x_n)f(a)>0$.
    (b) we replace b by x_n if $f(x_n)f(b)>0$ or $f(x_n)f(a)<0$.
    (c) we go back in (2)

Once again, the previous step (4) imposes the condition for stopping the calculations. Sometimes it is better to choose another criterion calculation ending. It requires the calculated solution to be contained in an interval of length equation containing the root x^*. This test is enunciate as follows:

4'. If $|b-a|<\varepsilon$, the job is finished and $x_n = \dfrac{af(b)-bf(a)}{f(b)-f(a)}$ is displayed. It is for sure obvious that $|x-\bar{x}|<\varepsilon/2$

In pseudocode (non-unique and not optimized):

Algorithm 8: Regula-Falsi pseudocode algorithm

```
Data: $a$,$b$, $\varepsilon$ expression of $f$
Result: $\bar{x}$
initialization;
$x_n = \dfrac{af(b)-bf(a)}{f(b)-f(a)}$;
while $|f(x)|>\varepsilon$ do
    if $f(x)f(a)>0$ then
        $a := x_n$;
    else if $f(x_n)f(b)>0 \vee f(x_n)f(a)<0$ then
        $b := x$;
    $x_n = \dfrac{af(b)-bf(a)}{f(b)-f(a)}$;
Display $x_n, f(x_n)$;
```

Notice that the initial above relation can also be rewritten:

$$x_n = a - f(a)\frac{a-b}{f(a)-f(b)} \tag{14.1.1197}$$

If we change a little bit the notation we get:

$$x = x_1 - f(x_1)\frac{x_1-x_0}{f(x_1)-f(x_0)} \tag{14.1.1198}$$

often also denoted:

$$x_{n+1}=x_n-\frac{f(x_n)}{f'(x_n)} \tag{14.1.1199}$$

We then use this new value of x in the prior previous relation as x_2 and repeat the process using x_1 and x_2 instead of x_0 and x_1. We continue this process, solving for x_3, x_4, etc., until we reach a sufficiently high level of precision (a sufficiently small difference between x_n and x_n-1):

$$\begin{aligned}
&x_2=x_1-f(x_1)\frac{x_1-x_0}{f(x_1)-f(x_0)}\\
&x_3=x_2-f(x_2)\frac{x_2-x_1}{f(x_2)-f(x_1)}\\
&\ldots\\
&x_n=x_{n-1}-f(x_{n-1})\frac{x_{n-1}-x_{n-2}}{f(x_{n-1})-f(x_{n-2})}
\end{aligned} \tag{14.1.1200}$$

This again an application of the "fixed-point iteration" (related to the theorem of the same name proved in the section of Sequences and Series page 1780).

14.1.14.3 Bisection method (interval-halving)

The bisection method in mathematics is also a root-finding method that repeatedly bisects an interval and then selects a subinterval in which a root must lie for further processing. It is a very simple and robust method, but it is also relatively slow. Because of this, it is often used to obtain a rough approximation to a solution which is then used as a starting point for more rapidly converging methods. The method is also named the "interval halving method", the "binary search method", or the "dichotomy method".

The method is applicable for numerically solving the equation $f(x)=0$ for the real variable x, where f is a continuous function defined on an interval $[a,b]$ and where $f(a)$ and $f(b)$ have opposite signs such that $f(a)f(b)<0$. In this case a and b are also said to bracket a root since, by the intermediate value theorem, the continuous function f must have at least one root in the interval $[a,b]$.

At each step the method divides the interval in two by computing the midpoint $c=(a+b)/2$ of the interval and the value of the function $f(c)$ at that point. Unless c is itself a root (which is very unlikely, but possible) there are now only two possibilities: either $f(a)$ and $f(c)$ have opposite signs and bracket a root, or $f(c)$ and $f(b)$ have opposite signs and bracket a root. The method selects the subinterval that is guaranteed to be a bracket as the new interval to be used in the next step. In this way an interval that contains a zero of f is reduced in width by 50% at each step. The process is continued until the interval is sufficiently small.

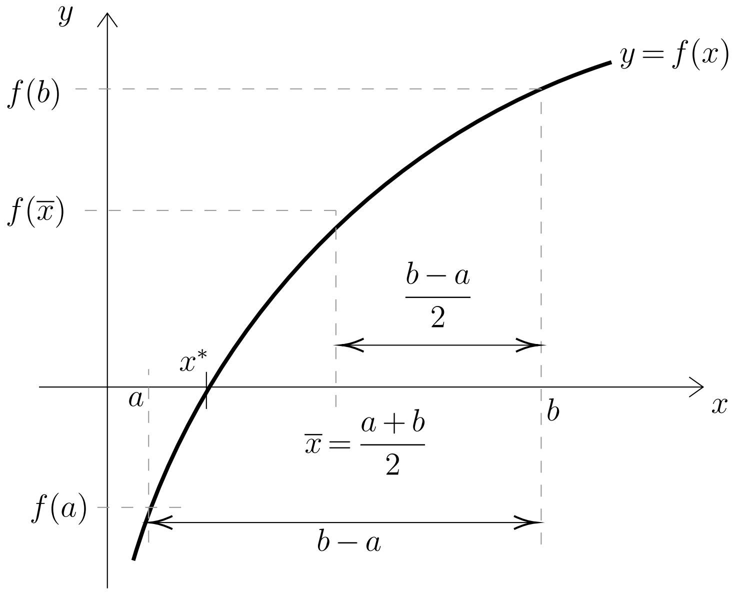

Figure 14.67: **Bisection scheme**

Explicitly, if $f(a)$ and $f(c)$ have opposite signs, then the method sets c as the new value for b, and if $f(b)$ and $f(c)$ have opposite signs then the method sets c as the new a. (If $f(c)=0$ then c may be taken as the solution and the process stops.) In both cases, the new $f(a)$ and $f(b)$ have opposite signs, so the method is applicable to this smaller interval.

The implementation, on a computer, of this method is particularly simple. The conditions to be satisfied being only that in the interval $[a,b]$:

- f must be continuous on $[a,b]$ of class $\mathcal{C}^1$
- f must be monotone near the root $\bar{x}$
- $f(a)f(b)<0$ to be sure that there is a root

The algorithm consists therefore in performing the following steps:

1. We fix $\varepsilon>0$ as upper bound of the admissible error tolerance.
2. We calculate $x=(a+b)/2$
3. We evaluate $f(x)$
4. If $|f(x)|<\varepsilon$ then the job is done, we have to display x and $f(x)$
5. Otherwise we proceed as following
   (a) we replace a by x if $f(x)f(a)>0$.
   (b) we replace b by x if $f(x)f(b)>0$ or $f(x)f(a)<0$.
   (c) we go back in (2)

The previous step (4) imposes the condition for stopping the calculations. Sometimes it is better to choose another criterion calculation ending. It requires the calculated solution to be contained in an interval of length equation containing the root x^*. This test would then be enunciate as follows:

4'. If $|b-a|<\varepsilon$, the job is finished and $x=(a+b)/2$ is displayed. It is for sure obvious that $|x-x^*|<\varepsilon/2$

In pseudocode (non-unique and not optimized):

Algorithm 9: Proportional Parts bisection pseudocode algorithm

```
Data: $a$,$b$, $\varepsilon$ expression of $f$
Result: $x^*$
initialization;
$x=(a+b)/2$;
while $|f(x)|>\varepsilon$ do
    if $f(x)f(a)>0$ then
        $a:=x$;
    else if $f(x)f(b)>0 \vee f(x)f(a)<0$ then
        $b:=x$;
    $x=(a+b)/2$;
Display $x$, $f(x)$;
```

The equivalent Maple™ 4.00b code is given by:

```
>zero:=proc(f,a,b,pre) local M;
M:=f((a+b)/2);
if abs(M)<pre then
RETURN((a+b)/2)
elif M>0 then
zero(f,a,(a+b)/2,pre)
else zero(f,(a+b)/2,b,pre)
fi
end:
```

14.1.14.4 Newton's method

A few years after its discovery of the theory of gravitation, Newton developed a special technique to fast compute the solutions of any equation. This "supernaturally" fast convergence has been used to prove some of the most significant theoretical results of the 120th century (holocene calendar): the Kolmogorov stability theorem, the isometric embedding theorem of Nash ... Alone, this technique transcends the distinction between pure mathematics and applied mathematics!!!

To study the "Newton's method" (also named "Newton-Raphson method[33]" or "Newton approximation scheme") in the plane (hence in the univariate case), consider the following figure:

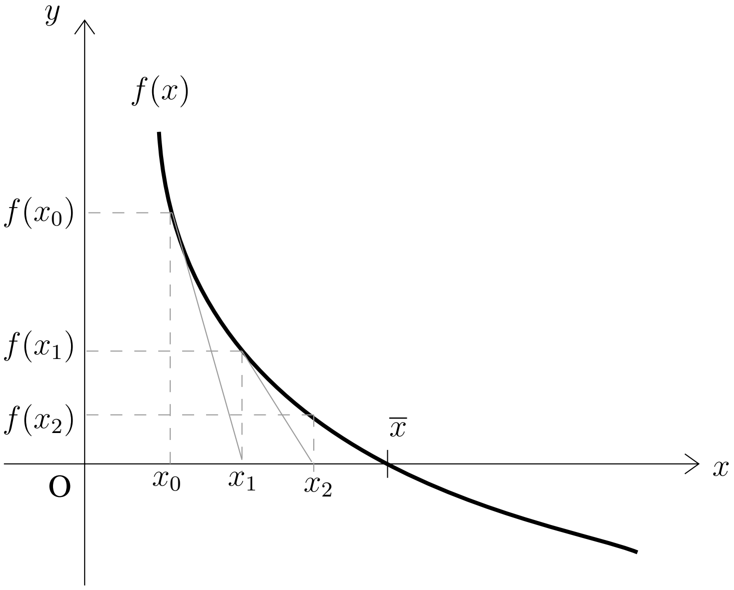

Figure 14.68: Newton's method in the plane

If x_0 is an approximation of the root $\bar{x}$, we notice that x_1 is as better one. The point x_1 is the intersection of the tangent to the curve $(x_0, f(x_0))$ with the x-axis. The point x_2 is even a better approximate of $\bar{x}$, the point x_2 is obtained in the same manner as x_1 but from $(x_1, f(x_1))$.

We may ask ourselves at this point what is the difference between Newton-Raphson and secant method on the basis of geometric interpretation? The two methods are almost the same, from a geometric perspective. The difference is that Newton's method uses a line that is tangent to one point, while the secant method uses a line that is secant to two points.

To use this technique, remember that if we take a function f that is differentiable on x_0, then we can rewrite it in the form (see section Sequences and Series page 1696):

$$f(x)=f(x_0)+f'(x_0)(x-x_0)+\mathcal{O}(x-x_0) \tag{14.1.1201}$$

---

[33] Newton's method was first published in 11685 and in 11690 (holocene calendar), Joseph Raphson published a simplified description. Raphson also applied the method only to polynomials, but he avoided Newton's tedious rewriting process by extracting each successive correction from the original polynomial. This allowed him to derive a reusable iterative expression for each problem. Finally, in 11740, (holocene calendar) Thomas Simpson described Newton's method as an iterative method for solving general non-linear equations using calculus. In the same publication, Simpson also gives the generalization to systems of two equations and notes that Newton's method can be used for solving optimization problems by setting the gradient to zero.

where $f'(x_0)$ is the derivative of f in x_0 and $\mathcal{O}(x-x_0)$ is a function that tends to 0 as $(x-x_0)^n$ when $n \geq 2$ when x tends to x_0 (this is as we know a corrective term for the superior orders of the Taylor series).

Applying this result to solve $f(x)=0$, we get:

$$0=f(\bar{x})=f(x_0)+f'(x_0)(\bar{x}-x_0)+\mathcal{O}(\bar{x}-x_0) \tag{14.1.1202}$$

The function does not permit the resolution of this equation relatively to $\bar{x}$. By neglecting this term we get obviously:

$$0=f(\bar{x})=f(x_0)+f'(x_0)(\bar{x}-x_0) \tag{14.1.1203}$$

This is just the expression of the discrete derivative. Indeed:

$$f'(x_0)=\frac{f(\bar{x})-f(x_0)}{\bar{x}-x_0} \tag{14.1.1204}$$

The latter relation is easily resolved with respect to $\bar{x}$. To see this, let us begin by putting $\bar{x}=x_1$:

$$\boxed{x_1=x_0-\frac{f(x_0)}{f'(x_0)}} \tag{14.1.1205}$$

But x_1 does not satisfy, in general, the equality $f(x_1)=0$. But as we have already pointed it out, $|f(x_1)|$ is smaller than $|f(x_0)|$ if the function f satisfies some conditions.

Newton's method consists in replacing the relation:

$$0=f(\bar{x})=f(x_0)+f'(x_0)(\bar{x}-x_0) \tag{14.1.1206}$$

by:

$$0=f(x_n)+f'(x_n)(x_{n+1}-x_n) \tag{14.1.1207}$$

and to iteratively solve this relation.

The following conditions are sufficient to ensure the convergence of the method in an interval $[a,b]$ including x_0 and $\bar{x}$:

1. The function is twice differentiable (i.e. of class $\mathcal{C}^2$)
2. The derivative f' does not vanish (monotony)
3. The second derivative f'' is continuous and does not vanish (no inflection point)

Remark

It is often sufficient to check the conditions (1) and (2) for the process to converge.

The condition (2) is obvious, indeed if $f'(x)=0$ the iteration can lead to a calculation overflow (singularity).

The third condition (3) is less obvious, but the following figure shows a case of non-convergence. In this case, the process loops calculating alternately x_i and x_j:

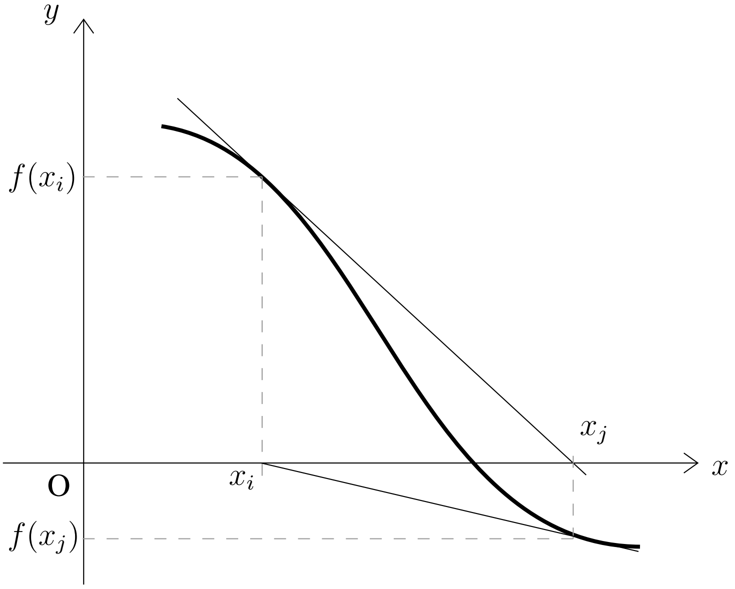

Figure 14.69: **Non-convergence example of Newton's method**

✍Example:

Consider the problem of finding the positive number x with $\cos(x)=x^3$. We can rephrase that as finding the zero of $f(x)=\cos(x)-x^3$. We have $f'(x)=-\sin(x)-3x^2$. Since $\cos(x)\leq 1$ for all x and $x^3>1$ for $x>1$, we know that our solution lies between 0 and 1. We try a starting value of $x_0=0.5$. (Note that a starting value of 0 will lead to an undefined result, showing the importance of using a starting point that is close to the solution!).

$$\begin{array}{rcccccl}
x_1 & = & x_0-\dfrac{f(x_0)}{f'(x_0)} & = & 0.5-\dfrac{\cos(0.5)-(0.5)^3}{-\sin(0.5)-3(0.5)^2} & = & 1.112141637097\\
x_2 & = & x_1-\dfrac{f(x_1)}{f'(x_1)} & = & \vdots & = & \underline{0.}909672693736\\
x_3 & = & \vdots & = & \vdots & = & \underline{0.86}7263818209\\
x_4 & = & \vdots & = & \vdots & = & \underline{0.865477}135298\\
x_5 & = & \vdots & = & \vdots & = & \underline{0.8654740331}11\\
x_6 & = & \vdots & = & \vdots & = & \underline{0.865474033102}
\end{array}$$

The correct digits are underlined in the above example. In particular, x_6 is correct to the number of decimal places given. We see that the number of correct digits after the decimal point increases from 2 (for x_3) to 5 and 10, illustrating the quadratic convergence.

Here is the corresponding pseudocode:

Algorithm 10: Newton's Method

```
Input: Initial guess $x_0$, $f$
Input: number of steps $x_{\max}$
$n \leftarrow 1$;
do
    $x_{n+1} = x_n - \frac{f(x_n)}{f'(x_n)}$;
    $n = n+1$;
while $n \leq x_{\max}$;
```

If the function f is given analytically, its derivative can be determined analytically. But in many cases it is advisable or even necessary to replace $f'(x_n)$ by the differential quotient:

$$f'(x_n) \cong \frac{f(x_n+h)-f(x_n)}{h} \tag{14.1.1208}$$

where h should be chosen as small enough so that the difference:

$$\left| f'(x_n) - \frac{f(x_n+h)-f(x_n)}{h} \right| \tag{14.1.1209}$$

is also small enough.

The iteration is then written:

$$x_{n+1} = x_n - h\frac{f(x_0)}{f(x_n+h)-f(x_n)} \tag{14.1.1210}$$

If the resolution method is converging, the gap between x_{n+1} and $\bar{x}$ decreases at each iteration. This is ensured, for example, if the interval $[a,b]$ containing x_{n+1}, sees its length decreasing at each step.

Theorem 14.5. Newton's method is interesting because the convergence is quadratic:

$$|x_{n+1} - \bar{x}| < \alpha |x_n - \bar{x}|^2 \tag{14.1.1211}$$

while the convergence of other methods is linear such that:

$$|x_{n+1} - \bar{x}| < \alpha |x_n - \bar{x}| \tag{14.1.1212}$$

Let us consider, for example, the method of bisection seen previously. At each iteration the length of the interval $[a,b]$ is halved. This ensures us that the gap $|x_{n+1}-\bar{x}|$ is halved at each step of the calculation:

$$|x_{n+1} - \bar{x}| < 0.5 |x_n - \bar{x}| \tag{14.1.1213}$$

Proof 14.5.1. To prove the quadratic convergence of the Newton's method, we have to make use of the limited Taylor series of f and f' in the neighbourhood of $\bar{x}$:

$$\begin{aligned} f(x_n) &\cong \underbrace{f(\bar{x})}_{=0} + \frac{1}{1!}(x_n-\bar{x})f'(\bar{x}) + \frac{1}{2!}(x_n-\bar{x})^2 f''(\bar{x}) \\ f'(x_n) &= f'(\bar{x}) + \frac{1}{1!}(x_n-\bar{x})f''(\bar{x}) \end{aligned} \tag{14.1.1214}$$

But:

$$x_{n+1}=x_n-\frac{f(x_n)}{f'(x_n)} \tag{14.1.1215}$$

therefore:

$$x_{n+1}=x_n-\frac{\frac{1}{1!}(x_n-\bar{x})f'(\bar{x})+\frac{1}{2!}(x_n-\bar{x})^2f''(\bar{x})}{f'(\bar{x})+\frac{1}{1!}(x_n-\bar{x})f''(\bar{x})} \tag{14.1.1216}$$

Subtracting $\bar{x}$ left and right of the equality and putting the two terms of the second member to the same denominator, we get:

$$x_{n+1}-\bar{x}\cong(x_n-\bar{x})^2\frac{0.5f''(\bar{x})}{f'(\bar{x})+(x_n-\bar{x})f''(\bar{x})} \tag{14.1.1217}$$

and when $x_n-\bar{x}$ is small enough, the denominator can be simplified.

$$x_{n+1}-\bar{x}\cong(x_n-\bar{x})^2\frac{f''(\bar{x})}{f'(\bar{x})} \tag{14.1.1218}$$

which shows that convergence is quadratic.

■ Q.E.D.

✍**Example:**

Here is an application with Maple™ 4.00b of this method:

```
 >with(plots):  with(plottools):
>f:=x->exp(x)*x^2-36;
>D(f)(x);
>x[0]:=3;
>n:=7;
>g:=x->f(x[i-1])+D(f)(x[i-1])*(x-x[i-1]);
>for i from 1 by 1 to n do;
>x[i]:=evalf(solve(g(x)=0,x));
>od;
>lines:=:
>for i from 1 by 1 to n do;
>lines:=lines union {line([x[i-1],0],[x[i-1],f(x[i-1])],color=green),
line([x[i-1],f(x[i-1])],[x[i],0],color=green)};
>od:
>display(plot(f(x),x=2..3.01) union lines);
```

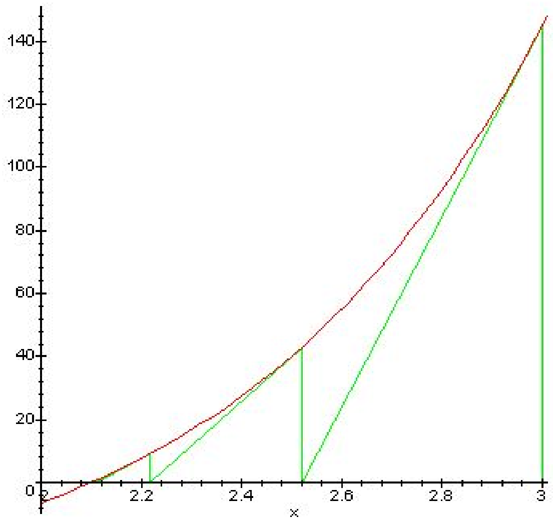

Figure 14.70: **Maple™ 4.00b application of Newton's method**

Now let us prove that Newton's method is reduced to the Babylonian method seen earlier above at page 6295! Indeed. we want to solve $\sqrt{A}$, i.e. looking for a root of $f(x)=x^2-A$. Then:

$$x_{n+1}=x_n-\frac{f(x_n)}{f'(x_n)}=x_n-\frac{x_n^2-A}{2x_n}=\frac{2x_n^2}{2x_n}-\frac{x_n^2-A}{2x_n}=\frac{2x_n^2-(x_n^2-A)}{2x_n}=\frac{1}{2}\left(x_n+\frac{A}{x_n}\right) \tag{14.1.1219}$$

That's it!

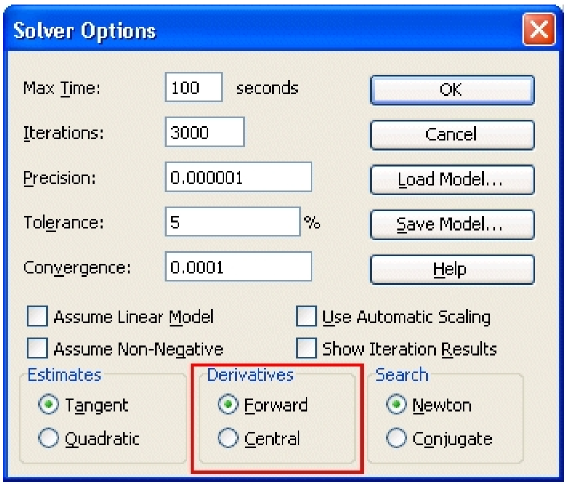
Remark

Let us finally communicate that we will study the Newton's method with several variables during our study of non-linear optimization. It is an pedagogical choice that seemed to us the best subjectively the best one.

14.1.15 Numerical Differentiation

In numerical analysis, numerical differentiation describes algorithms for estimating the derivative of a mathematical function or function subroutine using values of the function and perhaps other knowledge about the function.

Many modelling techniques or numerical resolution technique that we will see further use derivatives as for example the search of optimums (see further below), the finite element methods (see also further below). For example, to name the most famous case, the solver of Microsoft® Excel® 2007 and earlier offers some of the most elementary numerical derivatives that we will study here and reuse further:



Max Time: 100 seconds

Iterations: 3000

Precision: 0.000001

Tolerance: 5 %

Convergence: 0.0001

☐ Assume Linear Model ☐ Use Automatic Scaling

☐ Assume Non-Negative ☐ Show Iteration Results

Estimates: ● Tangent ○ Quadratic

Derivatives: ● Forward ○ Central

Search: ● Newton ○ Conjugate

Figure 14.71: **Screenshot of Microsoft® Excel® 2003 Solver**

To allow a computer processing, the various derivatives present in many algorithms must be approximated numerically. To do this, we use in the most basic case the principle of centered finite difference which is based on the following Taylor series expansion (see section Sequences and Series page 1696):

$$f(x)=\sum_{k=0}^{n}\frac{1}{k!}\frac{\mathrm{d}^k f(x_0)}{\mathrm{d}x^k}(x-x_0)^k=\sum_{k=0}^{n}\frac{\mathrm{d}^{(k)}f(x_0)}{k!}(x-x_0)^k \tag{14.1.1220}$$

On the base of this principle we get then the following development of the second order:

$$\begin{aligned}f\left(x_0+\frac{\mathrm{d}_x}{2}\right)&=f(x_0)+\frac{\mathrm{d}_x}{2}f'(x_0)+\frac{1}{2}\left(\frac{\mathrm{d}_x}{2}\right)^2 f''(x_0)+\ldots\\ f\left(x_0-\frac{\mathrm{d}_x}{2}\right)&=f(x_0)-\frac{\mathrm{d}_x}{2}f'(x_0)+\frac{1}{2}\left(\frac{\mathrm{d}_x}{2}\right)^2 f''(x_0)-\ldots\end{aligned} \tag{14.1.1221}$$

It comes then when neglecting the higher order terms and subtracting and simplifying the two series above:

$$f'(x_0)=\frac{f\left(x_0+\dfrac{\mathrm{d}_x}{2}\right)-f\left(x_0-\dfrac{\mathrm{d}_x}{2}\right)}{\mathrm{d}_x}+\varepsilon(\mathrm{d}_x^2) \tag{14.1.1222}$$

Relation that we name "first centered derivative with tangent estimate" (because we neglect all non-linear terms) or also "symmetric difference quotient". We also find often this latter relation in the following equivalent form:

$$\boxed{f'(x_0)=\frac{f(x_0+h)-f(x_0-h)}{2h}+\mathcal{O}(h^2)} \tag{14.1.1223}$$

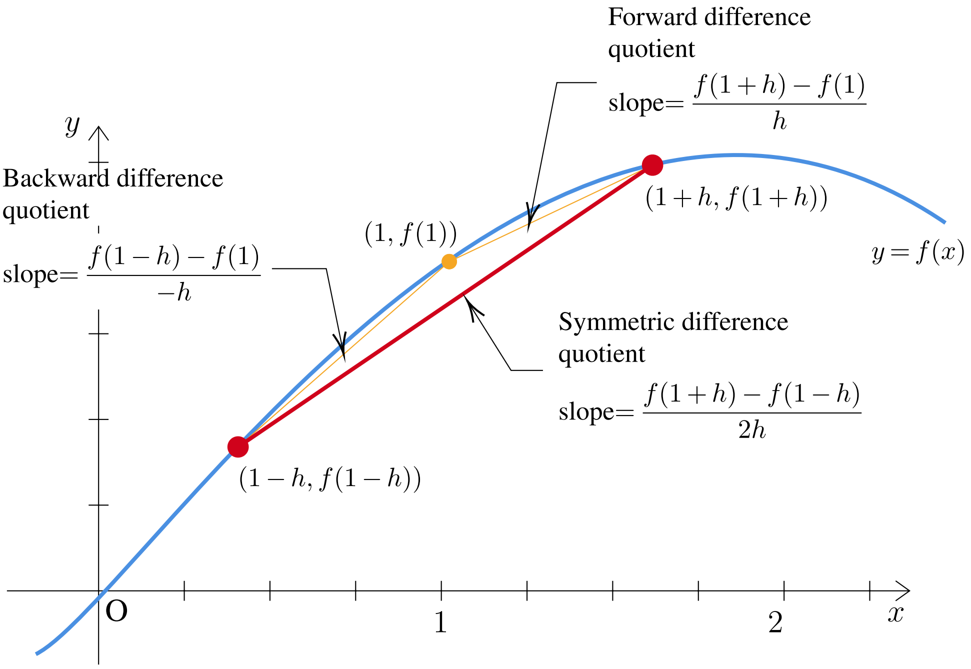
Now let us see what we name the "right first derivative" also named "forward derivatives" (or "forward difference"), which consist simply in the application of the following intuitive algorithm:

$$\boxed{f'(x_i)=\frac{f(x_{i+1})-f(x_i)}{x_{i+1}-x_i}} \tag{14.1.1224}$$

and incidentally we can also define the "left first derivative" also named "backward derivative" (or "backward difference"):

$$\boxed{f'(x_i)=\frac{f(x_i)-f(x_{i-1})}{x_i-x_{i-1}}} \tag{14.1.1225}$$

We see therefore the central derivatives require more calculations but are also more accurate. This below figure gives a quite summary of the previous relations with a special case:



Forward difference quotient
slope= $\frac{f(1+h)-f(1)}{h}$
y
Backward difference quotient
slope= $\frac{f(1-h)-f(1)}{-h}$
$(1,f(1))$
$(1+h,f(1+h))$
$y=f(x)$
Symmetric difference quotient
slope= $\frac{f(1+h)-f(1-h)}{2h}$
$(1-h,f(1-h))$
O
1
2
x

Figure 14.72: Forward/Backward derivatives illustration

We can also develop more elaborate relations through Taylor expansions with superior orders, do averages between different methods and so on... it's quite endless...

14.1.16 Numerical Integration

In numerical analysis, "numerical integration" constitutes a broad family of algorithms for calculating the numerical value of a definite integral, and by extension, the term is also sometimes used to describe the numerical solution of differential equations. This subsection focuses on calculation of definite integrals.

The basic problem in numerical integration is to compute an approximate solution to a definite integral overt the interval $[a,b]$ by evaluating $f(x)$ at a finite number of sample points:

$$\int\limits_a^b f(x)\mathrm{d}x \tag{14.1.1226}$$

to a given degree of accuracy (with an error $\varepsilon(f)$. If $f(x)$ is a smooth function integrated over a small number of dimensions, and the domain of integration is bounded, there are many methods for approximating the integral to the desired precision.

Definition (#14.1.564): Suppose that $a=x_0<x_1<\ldots<x_n=b$. A relation of the form:

$$A(f)\cong\sum_{i=0}^{n} w_i f(x_i)=w_0 f(x_0)+w_1 f(x_1)+w_2 f(x_2)+\ldots+w_n f(x_n) \tag{14.1.1227}$$

with the property that:

$$\int\limits_a^b f(x)\mathrm{d}x=A(f)+\varepsilon(f) \tag{14.1.1228}$$

is named a "numerical integration" or "quadrature formula[34]". The term $\varepsilon(f)$ is named the "truncation error for integration". The values $\{x_i\}_{i=0}^{n}$ are named the quadrature nodes and $\{w_i\}_{i=0}^{n}$ are named the "weights".

Depending on the application, the nodes $\{x_i\}_{i=0}^{n}$ are chosen in various ways. For the Trapezoidal Rule, Simpson's Rule, and Boole's Rule, the nodes are chosen to be equally spaced. For Gauss-Legendre quadrature, the nodes are chosen to be the zeros of certain Legendre polynomials. When the integration formula is used to develop a predictor formula for differential equations, all the nodes are chosen less than b. For all applications, it is necessary to know something about the accuracy of the numerical solution.

Let us consider the following figure:

---

[34] In mathematics, quadrature is a historical term which means the process of determining area. This term is still used nowadays in the context of differential equations, where "solving an equation by quadrature" means expressing its solution in terms of integrals.

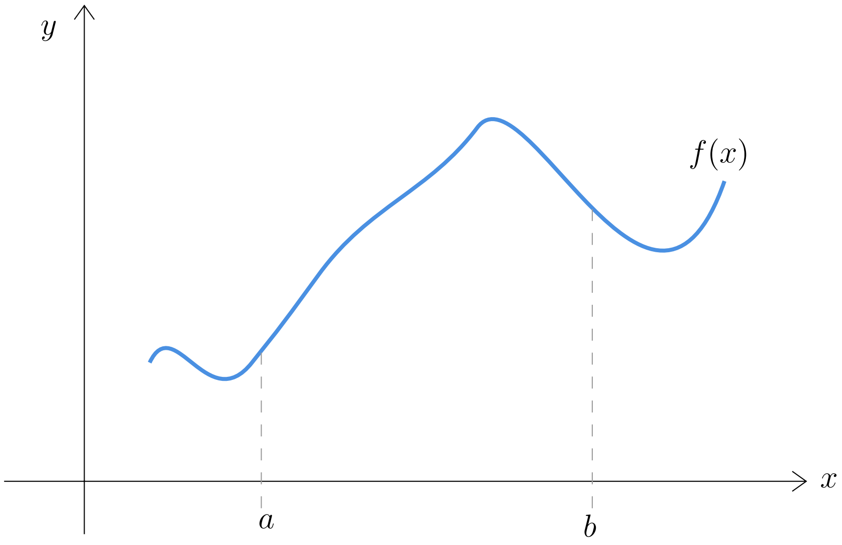


Figure 14.73: **Illustration of an interval under a curve**

We would like to calculate the area between the x axis, the curve f and the straight vertical lines of equations $x=a$ and $x=b$. We assume in this case that the function f is with positive values:

$$f(x)\geq 0 \quad \forall x\in[a,b] \tag{14.1.1229}$$

This problem, in its generality, is difficult or impossible to solve analytically in the most general cases. Below we will see some mainstream numerical methods for the approximate calculation of this area in increasing complexity order (sometimes these methods are used in corporations by employees who have only spreadsheets softwares like Microsoft® Excel® or OpenOffice Calc to calculate integrals...):

- Newton-Cotes formulas: In this case, we obtain methods for numerical integration which can be derived from the Lagrange interpolating method. Alternatively the formulas can also be derived from Taylor expansion. The idea is similar to the way we obtain numerical differentiation schemes. We can easily derive not just integration formulas but also their errors using this technique. The schemes which we develop here will be based on the assumption of equidistant points.

- Composite, Newton - Cotes formulas (open and closed): These methods are composite since they repeatedly apply the simple formulas derived previously to cover longer intervals. This idea allows for piecewise estimates of the integral thus improving the error of our integration (we will also assume equidistant nodes in our introduction of these methods).

- Romberg Integration: This method allows us to improve the error of our integration methods by doing minimal extra work. The idea is based on the Richardson extrapolation (actually we don't present this method here).

- : Adaptive Integration: Here we are free to choose the points over which we calculate the numerical integral of $f(x)$ so as to minimize our error. Adaptive integration does not therefore require equidistant nodes. Thus if the function is not very smooth at some interval the step size h of the numerical integration method decreases to make sure we do not accumulate too much error in our calculation (actually we don't present this method here).

- Gaussian Integration: We explore methods which can achieve optimal error reduction provided we place the nodes at specific locations. Computing the best weights for our numerical quadratures guarantees optimal approximation of our integral (actually we don't present this method here).
- Monte Carlo Integration: Use random number generation and a ratio of the target random points relatively to all random generated points. At this method employs a non-deterministic approach: each realization provides a different outcome! There are different methods to perform a Monte Carlo integration, such as uniform sampling, stratified sampling, importance sampling, sequential Monte Carlo (also known as a particle filter), and mean field particle methods (see page 6708).

14.1.16.1 Rectangles method

The "rectangle methods" computes an approximation to a definite integral, made by finding the area of a collection of rectangles whose heights are determined by the values of the function by different approach.

We divide the interval $[a,b]$ into n subintervals which bounds are the x_i. The lengths of these subintervals are $h_i = x_{i+1} - x_i$. We build rectangles which sides are h_i and in the case of the "" the height is $f(x_i)$.

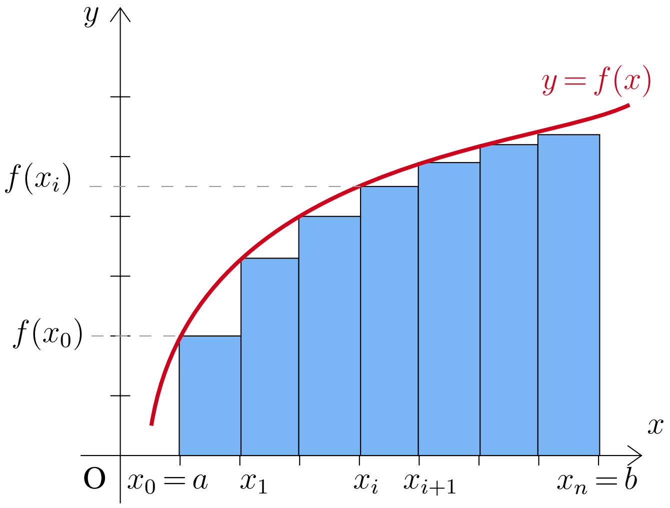

Figure 14.74: Approach of the area under a curve by lower left rectangles method

The area of these rectangles is:

$$A_G = \sum_{i=0}^{n-1} (x_{i+1} - x_i) f(x_i) = \sum_{i=0}^{n-1} h_i f(x_i) \tag{14.1.1230}$$

If the h_i are small enough, A_G is a good approximation of the sought approached area by the left method.

We can start this exercise again by choosing h_i and $f(x_{i+1})$ as sides of the rectangles (so the approach is named the "right rectangle method"). We then get:

$$A_D = \sum_{i=0}^{n-1}(x_{i+1}-x_i)f(x_{i+1}) = \sum_{i=0}^{n-1} h_i f(x_{i+1}) \tag{14.1.1231}$$

The correspondent figure is therefore the following:

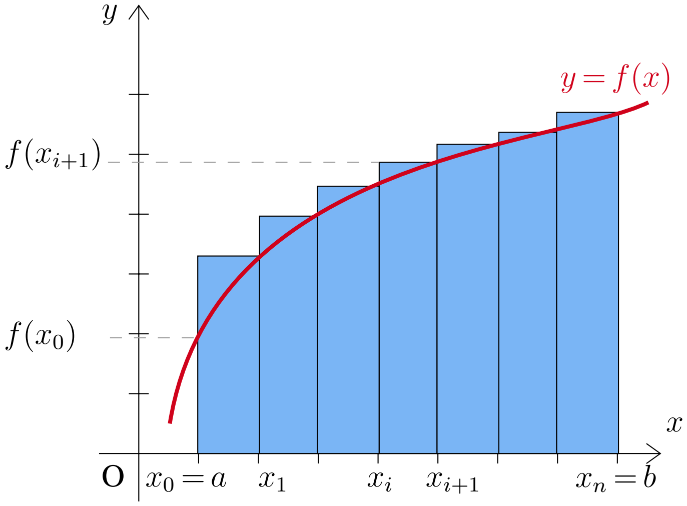

Figure 14.75: Approach of the area under a curve by upper right rectangles method

Again, the area of these rectangles approaches the area searched. To simplify computer code, it is useful to choose identical length intervals:

$$|x_{i+1}-x_i| = h \qquad \forall i \tag{14.1.1232}$$

If we have n rectangles, h is then equal to $(b-a)/n$. The areas A_D and A_G become:

$$A_D = h\sum_{i=0}^{n-1} f(x_{i+1}) \qquad A_G = h\sum_{i=0}^{n-1} f(x_i) \tag{14.1.1233}$$

We can also mixed the both method above as we will illustrate it further below in the figure that will summarize the for more common methods.

14.1.16.2 Trapezoidal method

In the purpose to increase the accuracy, it is possible to calculate:

$$A_T = \frac{A_D + A_G}{2} \tag{14.1.1234}$$

In the case where all the intervals are of equal length, A_T is equal to:

$$\begin{aligned} A_T &= \frac{1}{2}h\left(\sum_{i=0}^{n-1} f(x_{i+1}) + \sum_{i=0}^{n-1} f(x_i)\right) = \frac{1}{2}h\left(\sum_{i=1}^{n} f(x_i) + \sum_{i=0}^{n-1} f(x_i)\right) \\ &= \frac{1}{2}h\left(f(x_0) + 2\sum_{i=1}^{n-1} f(x_i) + f(x_n)\right) \end{aligned} \tag{14.1.1235}$$

That we often find in the academic literature, in the form:

$$\begin{aligned}A_T &= \frac{1}{2}\frac{b-a}{2}\left(f(a)+2\sum_{i=1}^{n-1}f(x_i)+f(b)\right)\\ &= \frac{b-a}{2}\left(\frac{f(a)+f(b)}{2}+\sum_{i=1}^{n-1}f(x_i)\right)\end{aligned} \tag{14.1.1236}$$

There are many other methods for solving this type of problem (including the Monte Carlo method that we will see further below).

In the case where the function f is not made of only positive values, we no longer speak anymore about "area" but of "Riemann sum". The sum to calculate are then:

$$S_D = h\sum_{i=0}^{n-1}f(x_{i+1}) \qquad S_G = h\sum_{i=0}^{n-1}f(x_i) \tag{14.1.1237}$$

and:

$$S_T = \frac{1}{2}h\left(f(x_0)+2\sum_{i=1}^{n-1}f(x_i)+f(x_n)\right) \tag{14.1.1238}$$

Hence to summarize we have the following four following more typical univariate integral numerical methods:

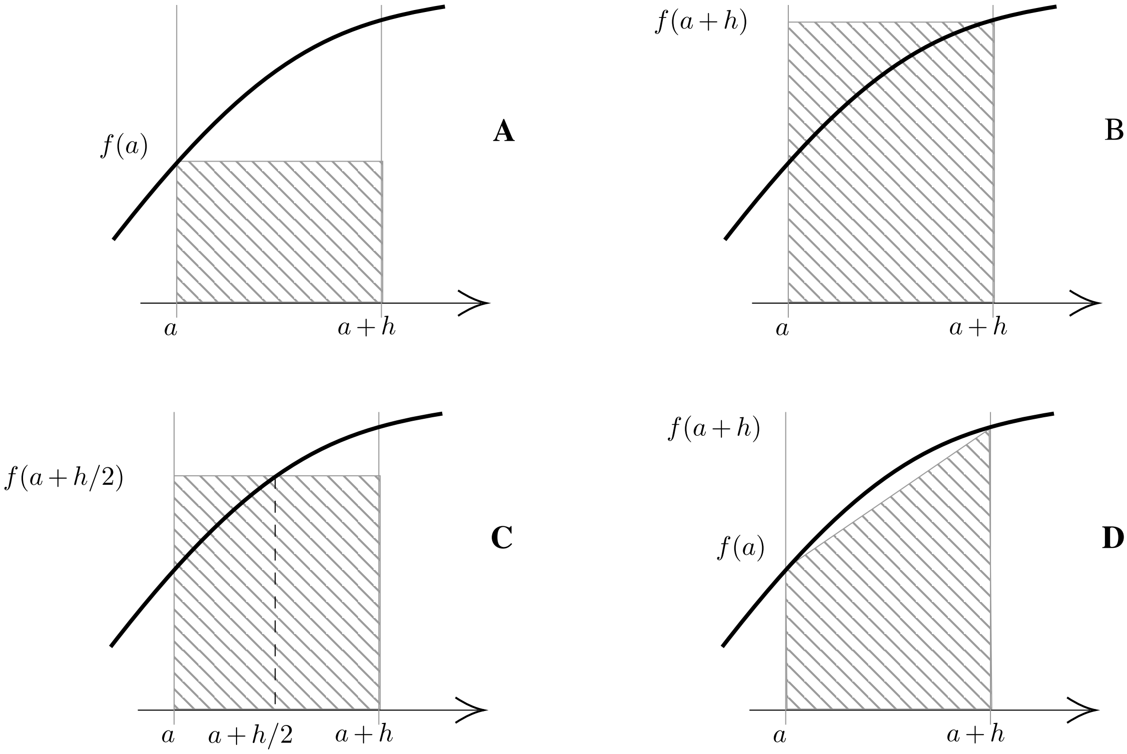

Figure 14.76: A: left rectangle method, B: right rectangle point, C: mid-point method, D: Trapezoidal method

14.1.16.3 Newton–Cotes formulas

The "Newton–Cotes formulas", also named the "Newton–Cotes quadrature rules" or simply "Newton–Cotes rules", are a group of formulas for numerical integration (also named "quadrature formulas as we have already mention it) based on evaluating the integrand at equally spaced points (they are named after Isaac Newton and Roger Cotes) and where the weights w_i of:

$$A(f) \cong \int_a^b f(x)\mathrm{d}x \approx \sum_{i=0}^{n} w_i f(x_i) \qquad (14.1.1239)$$

are derived from the Lagrange basis polynomials (see page 6594).

Let us see now three mainstream of the many "Newton-Cotes quadrature formulas". They are all based on Lagrange Polynomials (with or without the error term):

$$P_n(x) = \sum_{i=0}^{n} f(x_i)L(x_i) + \frac{f^{(n+1)}(\xi)}{(n+1)!}\prod_{i=0}^{n}(x-x_i) \qquad (14.1.1240)$$

Since the Taylor polynomials (see section Sequences and Series page 1723) have the property that all the information used in the approximation is concentrated at the single point x_0, it is not uncommon for these polynomials to give inaccurate approximations as we move away from x_0. This limits Taylor polynomial approximation to the situation in which approximations are needed only at points close to x_0.

The more the simple Newton-Cotes methods are based on high degree polynomials, the slower they are and the more difficult they are to code, but the more precise they are. Most often in practice, the total integration domain $[a,b]$ is much too large and the function varies too much on this domain for these methods to give satisfactory results. They are therefore almost never used as such.

The total domain $[a,b]$ is therefore subdivided into a large number of small intervals over each of which the simple Newton-Cotes methods can be successfully applied. We then speak of "composite Newton-Cotes method".

14.1.16.3.1 Trapezoidal Rule

We derive the Trapezoidal rule for approximating $\int_a^b f(x)\mathrm{d}x$ using the Lagrange polynomial method, with the linear Lagrange polynomial (see page 6594).

Let $x_0 = a$, $x_1 = b$, and $h = b - a$:

$$\begin{aligned}
\int\limits_{a=x_0}^{b=x_1} f(x)\mathrm{d}x &= \int\limits_{x_0}^{x_1} P_1(x)\mathrm{d}x + \frac{1}{2}\int\limits_{x_0}^{x_1} f''(\xi)\left(x-x_0\right)\left(x-x_1\right)\mathrm{d}x \\
&= \int\limits_{x_0}^{x_1}\left[\frac{x-x_1}{x_0-x_1}f\left(x_0\right)+\frac{x-x_0}{x_1-x_0}f\left(x_1\right)\right]\mathrm{d}x + \frac{1}{2}\int\limits_{x_0}^{x_1} f''(\xi)\left(x-x_0\right)\left(x-x_1\right)\mathrm{d}x \\
&= \left[\frac{\left(x-x_1\right)^2}{2\left(x_0-x_1\right)}f\left(x_0\right)+\frac{\left(x-x_0\right)^2}{2\left(x_1-x_0\right)}f\left(x_1\right)\right]_{x_0}^{x_1} + \frac{1}{2}f''(\xi)\int\limits_{x_0}^{x_1}\left(x-x_0\right)\left(x-x_1\right)\mathrm{d}x \\
&= -\frac{\left(x_0-x_1\right)^2}{2\left(x_0-x_1\right)}f\left(x_0\right)+\frac{\left(x_1-x_0\right)^2}{2\left(x_1-x_0\right)}f\left(x_1\right)+\frac{1}{2}f''(\xi)\left(-\frac{h^3}{6}\right) \\
&= \frac{h}{2}\left[f\left(x_0\right)+f\left(x_1\right)\right]-\frac{h^3}{12}f''(\xi)
\end{aligned} \tag{14.1.1241}$$

Thus, the Trapezoidal rule is:

$$\boxed{\int\limits_a^b f(x)\mathrm{d}x = \frac{h}{2}[f(a)+f(b)]-\frac{h^3}{12}f''(\xi) \approx \frac{b-a}{2}[f(a)+f(b)]} \tag{14.1.1242}$$

We fall back here on the relation that we have proved earlier but with another approach (a more analytic one...!).

Since the error term for the Trapezoidal rule involves f'', the rule gives the exact result when applied to any function whose second derivative is identically zero. That is, the Trapezoidal rule gives the exact result for polynomials of degree up to or equal to one.

Now we are home free. To get the Riemann sum for:

$$\int_a^b f(x)dx \tag{14.1.1243}$$

using the trapezoidal local approximation, assuming $f(x)$ is any integrable function.

Therefore on a long non-local interval splitted in n value such that $h = (b-a)/n$ we use:

$$\int_a^b f(x)\mathrm{d}x = \frac{h}{2}[f(a)+f(b)] \approx \frac{b-a}{2}[f(a)+f(b)] \tag{14.1.1244}$$

Here is the trivial associated pseudocode:

Algorithm 11: Trapezoidal's rule

```
Input: $a$,$b$,$n$,$f$
Output: Area
Area := 0
$h := (b-a)/n$
for $i = 1, 2, \ldots$ to $n$ do
    $\text{Area} = \text{Area} + \dfrac{(a+i\cdot h)-(a+(i-1)\cdot h)}{2}\left(f(a+i\cdot h)+f(a+(i-1)\cdot h)\right)$
return Area
```

14.1.16.3.2 Composite Trapezoidal Rule

When the trapezoidal rule is applied on the subintervals it is named a "composite trapezoidal rule".

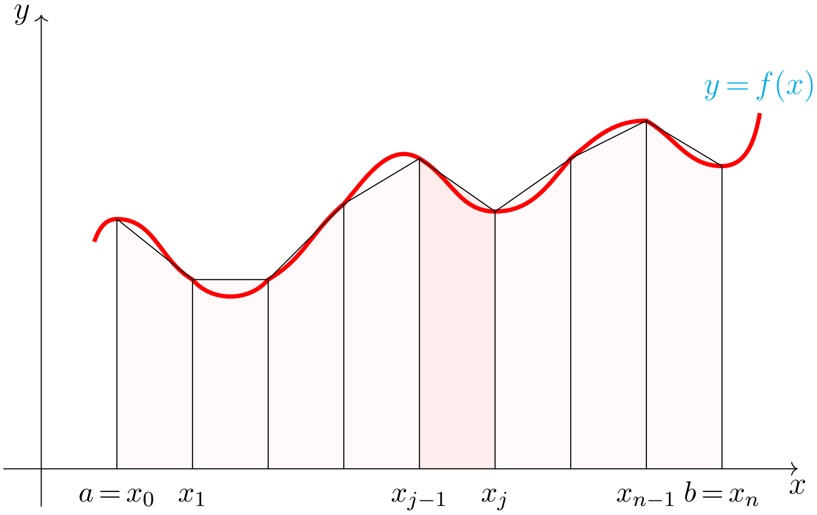

Figure 14.77: **Composite trapezoidal rule illustration**

To see this, let us define:

$$h = x_j - x_{j-1} \tag{14.1.1245}$$

Then:

$$\begin{aligned}\int\limits_{a=x_0}^{b=x_n} f(x)\mathrm{d}x &= \sum_{j=1}^{n}\int\limits_{x_{j-1}}^{x_j} f(x)\mathrm{d}x = \sum_{j=1}^{n}\left(\frac{h}{2}\left[f\left(x_{j-1}\right)+f\left(x_j\right)\right]-\frac{h^3}{12}f''\left(\xi_j\right)\right)\\ &= \sum_{j=1}^{n}\frac{h}{2}\left[f\left(x_{j-1}\right)+f\left(x_j\right)\right]-\frac{h^3}{12}\sum_{j=1}^{n}f''\left(\xi_j\right)\\ &= \sum_{j=1}^{n}\frac{h}{2}\left[f\left(x_{j-1}\right)+f\left(x_j\right)\right]-\frac{h^2}{12}(b-a)f''(\xi), \quad (\text{ since } nh = b-a)\end{aligned} \tag{14.1.1246}$$

Thus, the Composite Trapezoidal rule is:

$$\boxed{\int\limits_a^b f(x)\mathrm{d}x = \sum_{j=1}^{n} \frac{x_j - x_{j-1}}{2}\left[f\left(x_{j-1}\right) + f\left(x_j\right)\right] - \frac{h^2}{12}(b-a)f''(\xi)} \tag{14.1.1247}$$

14.1.16.3.3 Simpson's Rule

Simpson's rule can be derived by integrating the second Lagrange polynomial (see page 6594). However, this derivation gives only an $\mathcal{O}\left(h^4\right)$ error term involving $f^{(3)}$. To get a better error term, we use Taylor polynomial to derive the Simpson's rule.

Let $x_0 = a, x_2 = b$, and $x_1 = \dfrac{a+b}{2} = a + \dfrac{b-a}{2} = a + h$. That is, $x_1 - x_0 = h$ and $x_2 - x_1 = h$. Then:

$$\begin{aligned}
\int\limits_{a=x_0}^{b=x_2} f(x)\mathrm{d}x &= \int\limits_{x_0}^{x_2} \left[f\left(x_1\right) + f'\left(x_1\right)\left(x - x_1\right) + \frac{f''\left(x_1\right)}{2}\left(x - x_1\right)^2 + \frac{f'''\left(x_1\right)}{6}\left(x - x_1\right)^3 + \frac{f^{(4)}(\xi)}{24}\left(x - x_1\right)^4\right]\mathrm{d}x \\
&= \left[f\left(x_1\right)x + \frac{f'\left(x_1\right)}{2}\left(x - x_1\right)^2 + \frac{f''\left(x_1\right)}{6}\left(x - x_1\right)^3 + \frac{f'''\left(x_1\right)}{24}\left(x - x_1\right)^4 + \frac{f^{(4)}(\xi)}{120}\left(x - x_1\right)^5\right]_{x_0}^{x_2} \\
&= f\left(x_1\right)\left(x_2 - x_0\right) + \frac{f'\left(x_1\right)}{2}\left[\left(x_2 - x_1\right)^2 - \left(x_0 - x_1\right)^2\right] + \frac{f''\left(x_1\right)}{6}\left[\left(x_2 - x_1\right)^3 - \left(x_0 - x_1\right)^3\right] \\
&+ \frac{f'''\left(x_1\right)}{24}\left[\left(x_2 - x_1\right)^4 - \left(x_0 - x_1\right)^4\right] + \frac{f^{(4)}(\xi)}{120}\left[\left(x_2 - x_1\right)^5 - \left(x_0 - x_1\right)^5\right] \\
&= 2hf\left(x_1\right) + \frac{f'\left(x_1\right)}{2}\left[h^2 - h^2\right] + \frac{f''\left(x_1\right)}{6}\left[h^3 + h^3\right] + \frac{f'''\left(x_1\right)}{24}\left[h^4 - h^4\right] + \frac{f^{(4)}(\xi)}{120}\left[h^5 + h^5\right] \\
&= 2hf\left(x_1\right) + h^3\frac{f''\left(x_1\right)}{3} + h^5\frac{f^{(4)}(\xi)}{60} \\
&= 2hf\left(x_1\right) + \frac{h^3}{3}\left[\frac{f\left(x_0\right) - 2f\left(x_1\right) + f\left(x_2\right)}{h^2} - \frac{h^2}{12}f^{(4)}(\xi)\right] + \frac{h^5}{60}f^{(4)}(\xi) \\
&= \frac{h}{3}\left[f\left(x_0\right) + 4f\left(x_1\right) + f\left(x_2\right)\right] - \frac{h^5}{90}f^{(4)}(\xi)
\end{aligned} \tag{14.1.1248}$$

Thus, the Simpson's rule is:

$$\boxed{\int\limits_a^b f(x)\mathrm{d}x = \frac{h}{3}\left[f\left(x_0\right) + 4f\left(x_1\right) + f\left(x_2\right)\right] - \frac{h^5}{90}f^{(4)}(\xi) \approx \frac{b-a}{6}\left[f(a) + 4f\left(\frac{a+b}{2}\right) + f(b)\right]} \tag{14.1.1249}$$

There are plenty of other possible derivations with plenty of different final formulation that the reader can find in the literature!

Now we are home free. To get the Riemann sum for:

$$\int_a^b f(x)dx \tag{14.1.1250}$$

using the quadratic local approximation, assuming $f(x)$ is any integrable function.

Therefore on a long non-local interval splitted in n value such that $h=(b-a)/n$ we use:

$$\int_a^b f(x)\mathrm{d}x=\sum_{i=0}^{n-1}\frac{h}{3}\left[f\left(x_i\right)+4f\left(\frac{x_i+x_{i+1}}{2}\right)+f\left(x_{i+1}\right)\right] \tag{14.1.1251}$$

Here is the trivial associated pseudocode:

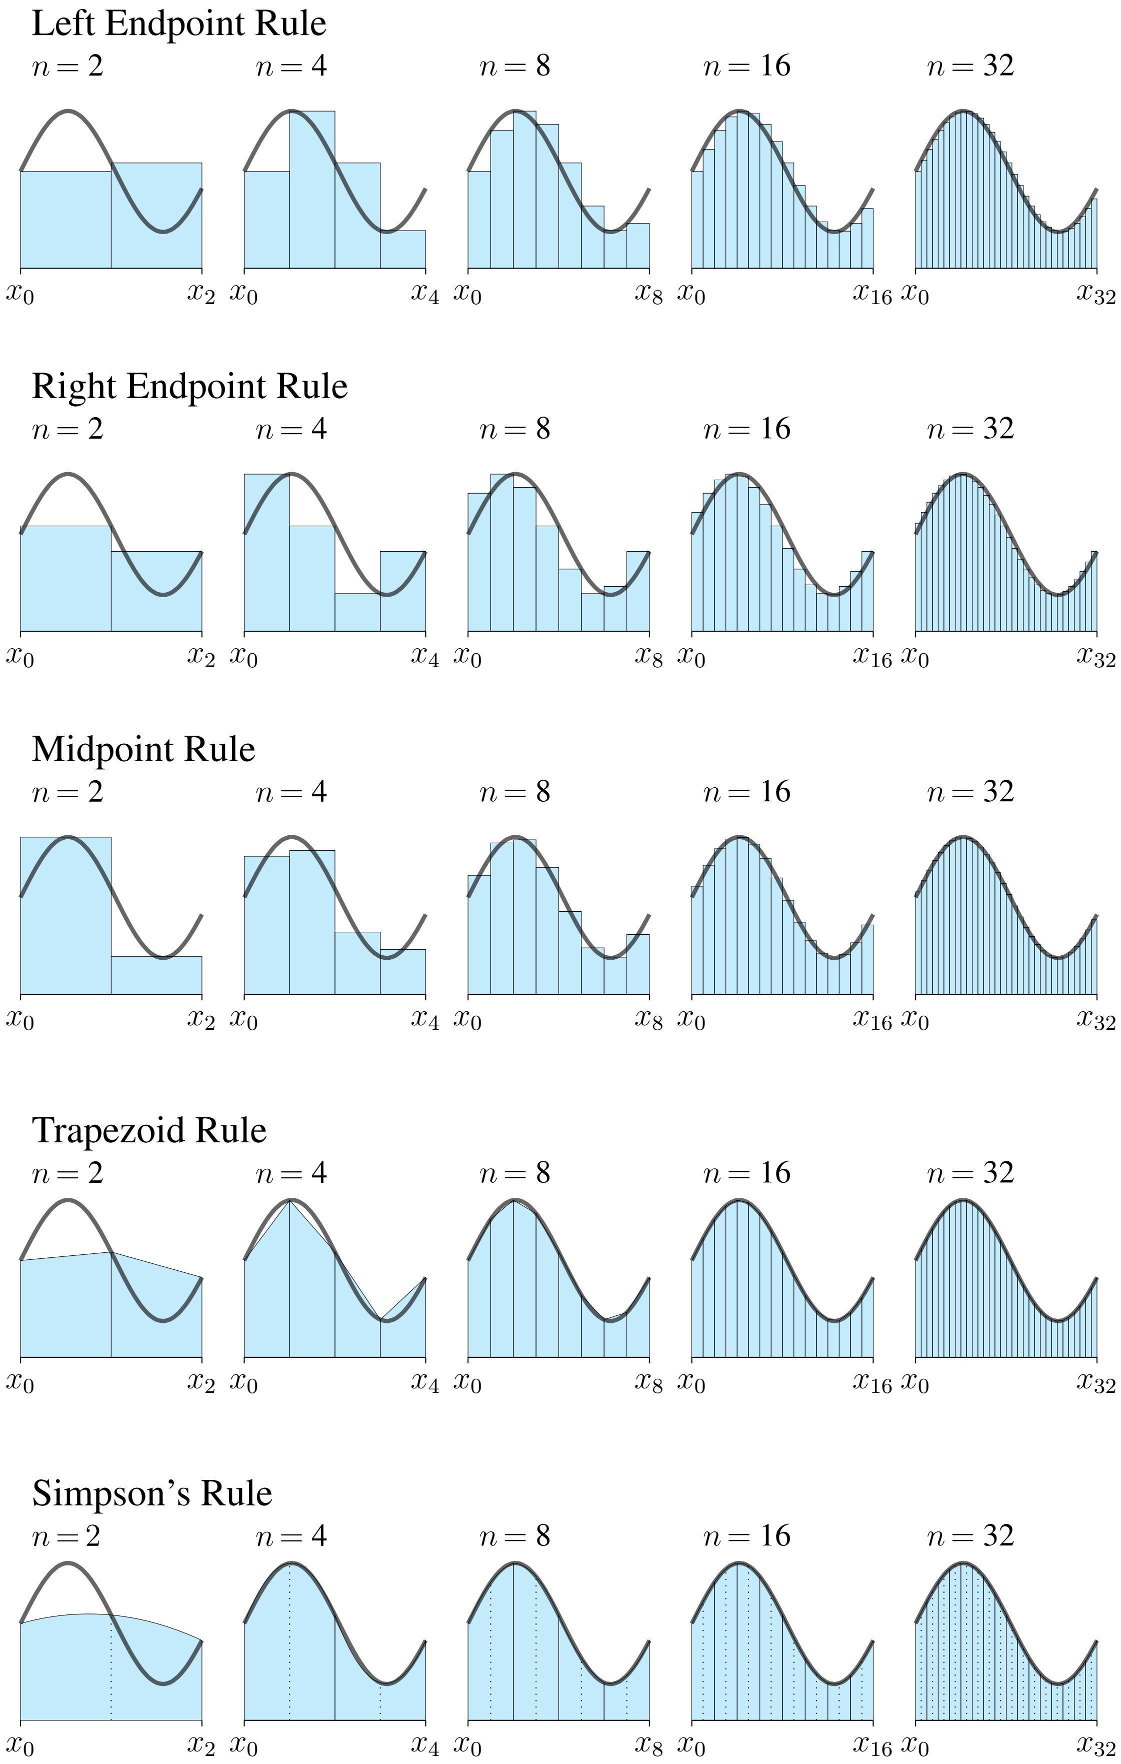
Algorithm 12: Simpson's rule

```
Input: $a$,$b$,$n$,$f$
Output: Area
Area := 0
$h:=(b-a)/n$
for $i=0,1,\ldots$ to $n-1$ do
    Area = Area + $\frac{h}{3}\left[f\left(a+i\cdot h\right)+4f\left(\frac{(a+i\cdot h)+(a+(i+1)\cdot h)}{2}\right)+f\left(a+(i+1)h\right)\right]$
return Area
```

Remark

When Simpson's rule is applied on two subintervals it is named a "composite Simpson's rule".

All what we have seen so far can be summarized by the following figure:



Left Endpoint Rule
Right Endpoint Rule
Midpoint Rule

14.1.16.4 Multidimensional integrals

Integrals of functions of several variables, over regions with dimension greater than one, are not easy. There are two reasons for this. First, the number of function evaluations needed to sample an N-dimensional space increases as the Nth power of the number needed to do a one-dimensional integral. If you need 30 function evaluations to do a one-dimensional integral crudely, then you will likely need on the order of $30 \times 30 \times 30 = 27000$ evaluations to reach the same crude level for a three-dimensional integral. Second, the region of integration in N-dimensional space is defined by an $N-1$ dimensional boundary which can itself be terribly complicated: It need not be convex or simply connected, for example. By contrast, the boundary of a one-dimensional integral consists of two numbers, its upper and lower limits.

The first question to be asked, when faced with a multidimensional integral is if can it be reduced analytically to a lower dimensionality one?

Alternatively, the function may have some special symmetry in the way it depends on its independent variables. If the boundary also has this symmetry, then the dimension can be reduced. In three dimensions, for example, the integration of a spherically symmetric function over a spherical region reduces, in polar coordinates, to a one-dimensional integral.

The next questions to be asked will guide your choice between two entirely different approaches to doing the problem. The questions are: Is the shape of the boundary of the region of integration simple or complicated? Inside the region, is the integrand smooth and simple, or complicated, or locally strongly peaked? Does the problem require high accuracy, or does it require an answer accurate only to a percent, or a few percent?

If your answers are that the boundary is complicated, the integrand is not strongly peaked in very small regions, and relatively low accuracy is tolerable, then your problem is a good candidate for Monte Carlo integration. This method is very straightforward to program, in its cruder forms. One needs only to know a region with simple boundaries that includes the complicated region of integration, plus a method of determining whether a random point is inside or outside the region of integration. Monte Carlo integration evaluates the function at a random sample of points, and estimates its integral based on that random sample.

If the boundary is simple, and the function is very smooth, then the remaining approaches, breaking up the problem into repeated one-dimensional integrals, or multidimensional Gaussian quadratures, will be effective and relatively fast. If you require high accuracy, these approaches are in any case the only ones available to you, since Monte Carlo methods are by nature asymptotically slow to converge.

For low accuracy, use repeated one-dimensional integration or Gaussian quadratures when the integrand is slowly varying and smooth in the region of integration, Monte Carlo when the integrand is oscillatory or discontinuous, but not strongly peaked in small regions.

If the integrand is strongly peaked in small regions, and you know where those regions are, break the integral up into several regions so that the integrand is smooth in each, and do each separately. If you don't know where the strongly peaked regions are, you might as well (at the level of sophistication of this textbook) quit: It is hopeless to expect an integration routine to search out unknown pockets of large contribution in a huge N-dimensional space.

If, on the basis of the above guidelines, we decide to pursue the repeated one-dimensional integration approach, here is how it works (the text below about the repeated one-dimensions approach is a bit a small summary of multivariate integral that we have already study in-deep in the section of Differential and Integral Calculus page 1518). For definiteness, we will consider the case of a three-dimensional integral in x, y, z-space. Two dimensions, or more than three dimensions, are entirely analogous.

The first step is to specify the region of integration by:

1. Its lower and upper limits in x, which we will denote x_1 and x_2
2. Its lower and upper limits in y at a specified value of x, denoted $y_1(x)$ and $y_2(x)$
3. Its lower and upper limits in z at specified x and y, denoted $z_1(x,y)$ and $z_2(x,y)$.

In other words, find the numbers x_1 and x_2, and the functions $y_1(x)$, $y_2(x)$, $z_1(x,y)$, and $z_2(x,y)$ such that:

$$I=\iiint f(x,y,z)\mathrm{d}x\mathrm{d}y\mathrm{d}z=\int\limits_{x_1}^{x_2}\mathrm{d}x\int\limits_{y_1(x)}^{y_2(x)}\mathrm{d}y\int\limits_{z_1(x,y)}^{z_2(x,y)}f(x,y,z)\mathrm{d}z \qquad (14.1.1252)$$

Now we can define a function $G(x,y)$ that does the innermost integral:

$$G(x,y)=\int\limits_{z_1(x,y)}^{z_2(x,y)}f(x,y,z)\mathrm{d}z \qquad (14.1.1253)$$

and a function $H(x)$ that does the integral of $G(x,y)$:

$$H(x)=\int\limits_{y_1(x)}^{y_2(x)}G(x,y)\mathrm{d}y \qquad (14.1.1254)$$

and finally our answer as an integral over $H(x)$:

$$I=\int\limits_{x_1}^{x_2}H(x)\mathrm{d}x \qquad (14.1.1255)$$

The methods that we have introduced earlier to calculate simple integrals can be generalized to multiple integrals. Les us consider first the following integral:

$$\iint_{\mathcal{R}}f(x,y)\mathrm{d}A \qquad (14.1.1256)$$

where $\mathcal{R}$ is a rectangular area of the plane, that is of the type:

$$\mathcal{R}=\{(x,y)|A\leq x\leq b,c\leq y\leq d\} \qquad (14.1.1257)$$

the limits of integration a,b,c and d being (for the moment...) constants.

To determine an approximated value of this integral, let us write it under the form:

$$\iint_{\mathcal{R}} f(x,y)\mathrm{d}A=\int\limits_a^b\left(\int\limits_c^d f(x,y)\mathrm{d}y\right)\mathrm{d}x \tag{14.1.1258}$$

and let us use the Simpson's method that we have proved earlier (see page 6629):

$$\int\limits_a^b f(x)\mathrm{d}x=\frac{h}{3}\left[f\left(x_0\right)+4f\left(x_1\right)+f\left(x_2\right)\right]-\frac{h^5}{90}f^{(4)}(\xi) \tag{14.1.1259}$$

for each of the integrals. Notice that every Newton-Cotes method can be used and that it is not necessary to use the same method for the two variables.

Let us choose two integers m and n to subdivide the interval $[a,b]$ into $2m$ sub-intervals with the step:

$$h=\frac{b-a}{2m} \tag{14.1.1260}$$

and $[c,d]$ into $2n$ sub-intervals with the step:

$$k=\frac{d-c}{2n} \tag{14.1.1261}$$

That is $y_0=c$, $y_1=c+k$, $y_{2n}=d$.

The first step has for purpose to calculate the integral:

$$\int\limits_c^d f(x,y)\mathrm{d}y \tag{14.1.1262}$$

with the Simpson's method by keeping x constant! We put $y_j=c+jk$, with $j=0,1,\ldots,2n$, therefore $y_0=c$ and $y_{2n}=d$. We then get (without the error term):

$$\int\limits_c^d f(x,y)\mathrm{d}y\cong\frac{k}{3}\left[f(x,y_0)+\sum_{j=1}^{n}f(x,y_{2j-1})+f(x,y_{2n})\right] \tag{14.1.1263}$$

and for the double integral:

$$\int\limits_a^b\left(\int\limits_c^d f(x,y)\mathrm{d}y\right)\mathrm{d}x\cong\frac{k}{3}\int\limits_a^b f(x,y_0)\mathrm{d}x+\frac{4k}{3}\sum_{j=1}^{n}\int\limits_a^b f(x,y_{2j-1})\mathrm{d}x+\frac{k}{3}f(x,y_{2n})\mathrm{d}x \tag{14.1.1264}$$

The Simpson's method can now be used to calculate each integral that leads on the variables x. Let us put for this purpose $x_i=a+ih$ with $i=0,1,\ldots,2m$, therefore $x_0=a$ and $x_{2m}=b$. For each value of the index j ($j=0,1,2,\ldots,2n$), that is by $y=y_j$, we then get without error term:

$$\int\limits_a^b f(x,y_j)\mathrm{d}x=\frac{h}{3}\left[f(x_0,y_j)+4\sum_{i=1}^{m}f(x_{2i-1},y_j)+f(x_{2m},y_j)\right] \tag{14.1.1265}$$

By substituting the latter in the first integral, we get:

$$\begin{aligned}\int_a^b\int_c^d f(x,y)\mathrm{d}y\mathrm{d}x \cong \frac{hk}{9}\Bigg[&f(x_0,y_0)+4\sum_{i=1}^{m}f(x_{2i-1},y_0)+f(x_{2m},y_0)+4\sum_{j=1}^{n}f(x_0,y_{2j-1})\\&+16\sum_{j=1}^{n}\sum_{i=1}^{m}f(x_{2i-1},y_{2j-1})+4\sum_{j=1}^{n}f(x_{2m},y_{2j-1})+f(x_0,y_{2n})\\&+4\sum_{i=1}^{m}f(x_{2i-1},y_{2n})+f(x_{2m},y_{2n})\Bigg]\end{aligned} \tag{14.1.1266}$$

This can be written also in matrix form:

$$\int_a^b\int_c^d f(x,y)\mathrm{d}y\mathrm{d}x \cong \frac{hk}{9}(1\,4\,\ldots\,4\,1)\begin{bmatrix}f_{0,0} & f_{0,1} & \ldots & f_{0,2n}\\ f_{1,0} & f_{1,1} & \ldots & f_{1,2n}\\ \vdots & \vdots & \ldots & \vdots\\ f_{2m,0} & f_{2m,1} & \ldots & f_{2m,2n}\end{bmatrix}\begin{pmatrix}1\\4\\2\\ \vdots\\2\\4\\1\end{pmatrix} \tag{14.1.1267}$$

The use of numerical approximation methods for double integrals is not limited to rectangular areas. The integrals of the shape:

$$\int_a^b\int_{c(x)}^{d(x)} f(x,y)\mathrm{d}x\mathrm{d}y \quad\text{or}\quad \int_c^d\int_{a(y)}^{b(y)} f(x,y)\mathrm{d}x\mathrm{d}y \tag{14.1.1268}$$

can be computed by modifying a bit the previous described method.

As example, let us use the Simpson's method to determine an approximation of the following double integral:

$$\int_a^b\int_{c(x)}^{d(x)} f(x,y)\mathrm{d}x\mathrm{d}y \tag{14.1.1269}$$

in the simplest case with $m=n=1$. Therefore the integration step of the variables x is then:

$$h=\frac{b-a}{2m}=\frac{b-a}{2} \tag{14.1.1270}$$

when that of the step of y varies with x:

$$k(x)=\frac{d(x)-c(x)}{2n}=\frac{d(x)-c(x)}{2} \tag{14.1.1271}$$

The estimation of the integral then takes the following shape (without the error term):

$$\begin{aligned}\int\limits_a^b\int\limits_{c(x)}^{d(x)} f(x,y)\mathrm{d}x\mathrm{d}y &\cong \int\limits_a^b \frac{k(x)}{3}\left[f(x,c(x))+4f(x,c(x)+k(x))+f(x,d(x))\right]\mathrm{d}x\\ &\cong \frac{h}{3}\left(\frac{k(a)}{3}\left[f(a,c(a))+4f(a,c(a)+k(a))+f(a,d(a))\right]\right.\\ &+\frac{4k(x_1)}{3}\left[f(x_1,c(x_1))+4f(x_1,c(x_1)+k(x_1))+f(x_1,d(x_1))\right]\\ &\left.+\frac{k(b)}{3}\left[f(b,c(b))+4f(b,c(b)+k(b))+f(b,d(b))\right]\right)\end{aligned} \tag{14.1.1272}$$

14.1.16.5 Numerical solution of ordinary differential equations

Numerical integration of ordinary differential equations is a frequent task of numerical analysis. Numerical integration of differential equations is used if the equations are non-linear or if we have a large system of linear equations with constant coefficients, where the analytical solution can be found, but it is in the form of long and complicated expressions containing exponential functions. Numerical integration of such systems is more efficient both in human time and in computer time.

Numerical integration of linear equations with non-constant coefficients is also more efficient than the analytical solution; in the case of inner diffusion in porous catalyst with a chemical reaction of the first order the analytical solution contains Bessel functions, which can be evaluated more conveniently when we use numerical integration of the original equations than to evaluate Bessel functions.

We have already seen how to use Euler's method and the method of Taylor's expansion at the page 6587, let us see more elaborated techniques.

14.1.16.5.1 Runge-Kutta methods

In numerical analysis, the Runge–Kutta methods are a family of implicit and explicit iterative methods, which include the well-known "Euler's method" (we will prove that further below), used in temporal discretization for the approximate solutions of ordinary differential equations. These methods were developed around 11900 (holocene calendar) by the German mathematicians Carl Runge and Wilhelm Kutta.

The techniques discussed in these pages approximate the solution of first order ordinary differential equations (with initial conditions) of the form ("Cauchy's problem" type):

$$\frac{\mathrm{d}y(t)}{\mathrm{d}t}=y'(t)=f(y(t),t) \quad \text{with} \quad y(t_0)=y_0 \tag{14.1.1273}$$

In the following developments you will understand why we say sometimes that Runge-Kutta methods "simulate" the Taylor's method!

14.1.16.5.1.1 1st order Runge-Kutta method

The first order Runge-Kutta method is already known to us. It's simply the "Euler's method" already derived earlier before.

Let us review that latter introducing a notation that is really mainstream and will be useful to understand the higher Runge-Kutta order methods.

For this we start again from:

$$\frac{\mathrm{d}y(t)}{\mathrm{d}t}=y'(t)=f(y(t),t) \quad \text{with} \quad y(t_0)=y_0 \tag{14.1.1274}$$

and we write the approximation to the derivative as:

$$k_1 = y'(t) = f(y^*(t), t) \tag{14.1.1275}$$

We expand $y(t)$ around t_0 assuming a time step h using Taylor expansion given for recall by:

$$P_n(x) = \sum_{k=0}^{n} \frac{1}{k!} \frac{\mathrm{d}^k P(x_0)}{\mathrm{d}x^k} (x - x_0)^k \tag{14.1.1276}$$

This give us:

$$y(t_0 + h) = y(t_0) + y'(t_0)h + y''(t_0)\frac{h^2}{2} + \ldots \tag{14.1.1277}$$

and drop all terms after the linear term. Because all of the dropped terms are multiplied by h^2 or greater, we say that the algorithm is accurate to order h^2 locally, or $\mathcal{O}(h^2)$ (if h is small the other terms that are multiplied by h^3, h^4... which will be even smaller, and can be dropped as well):

$$y(t_0 + h) \cong y(t_0) + y'(t_0)h \tag{14.1.1278}$$

This gives us our approximate Euler's method solution at the next time step:

$$y^*(t_0 + h) \cong y^*(t_0) + k_1 h \tag{14.1.1279}$$

Since the number of steps over the whole interval is proportional to $1/h$ (or $\mathcal{O}(h^{-1})$) we might expect the overall accuracy to be the $\mathcal{O}(h^2) \cdot \mathcal{O}(h^{-1}) = \mathcal{O}(h)$. A rigorous analysis proves that this is true.

With a little more work we can develop a method that is accurate to higher order than $\mathcal{O}(h)$. And this is the second order Runge-Kutta method.

14.1.16.5.1.2 2nd order Runge-Kutta method

In the following derivation we will use two math facts that are reviewed here. You should be familiar with this from a course in multivariate calculus.

First, let us recall the relation we have derived in the section of Sequences and Series on bivariate Taylor series (see page 1714):

$$\begin{aligned} f(x_0 + h, y_0 + k) \cong f(x_0, y_0) &+ \frac{1}{1!}\frac{\partial f}{\partial x}(x_0, y_0)h + \frac{1}{1!}\frac{\partial f}{\partial y}(x_0, y_0)k \\ &+ \frac{1}{2!}\left[\frac{\partial^2 f}{\partial x^2}(x_0, y_0)h^2 + 2\frac{\partial^2 f}{\partial x \partial y}(x_0, y_0)hk + \frac{\partial^2 f}{\partial y^2}(x_0, y_0)k^2\right] \end{aligned} \tag{14.1.1280}$$

Hence:

$$\begin{aligned} f(x_0 + \Delta x, y_0 + \Delta y) &= f(x_0, y_0) + \left.\frac{\partial f(x,y)}{\partial x}\right|_{x_o, y_0} \Delta x + \left.\frac{\partial f(x,y)}{\partial y}\right|_{x_o, y_0} \Delta y + \ldots \\ &= f + f_x \Delta x + f_y \Delta y + \ldots \end{aligned} \tag{14.1.1281}$$

If f is a function of two variables $f(x,y)$, where $x=r(t)$ and $y=s(t)$, then by the chain rule for partial derivatives:

$$\frac{\mathrm{d}f}{\mathrm{d}t}=\frac{\partial f}{\partial r}\frac{\mathrm{d}r}{\mathrm{d}t}+\frac{\partial f}{\partial s}\frac{\mathrm{d}s}{\mathrm{d}t} \tag{14.1.1282}$$

In particular if:

$$y'(t)=\frac{\mathrm{d}y(t)}{\mathrm{d}t}=f(y(t),t)=f \tag{14.1.1283}$$

then:

$$y''(t)=\frac{\mathrm{d}f(y(t),t)}{\mathrm{d}t}=\frac{\partial f}{\partial t}\frac{\mathrm{d}t}{\mathrm{d}t}+\frac{\partial f}{\partial y}\frac{\mathrm{d}y}{\mathrm{d}t}=\frac{\partial f}{\partial t}+\frac{\partial f}{\partial y}\frac{\mathrm{d}y}{\mathrm{d}t}=f_t+f_yf \tag{14.1.1284}$$

To start, recall that we are expressing our differential equation as

$$\frac{\mathrm{d}y(t)}{\mathrm{d}t}=y'(t)=f(y(t),t) \quad \text{with}\, y(t_0)=y_0 \tag{14.1.1285}$$

Now we define two approximations to the derivative:

$$\begin{aligned} k_1&=f(y^*(t_0),t_0)\\ k_2&=f(y^*(t_0)+\beta hk_1,t_0+\alpha h) \end{aligned} \tag{14.1.1286}$$

In all cases α and β will represent fractional values between 0 and 1. These equation state that k_1 is the approximation to the derivative based on the estimated value of $y(t)$ at $t=t_0$ (i.e., $y^*(t_0)$) and the time at t_0. The value of k_2 is based upon the estimated value, $y^*(t_0)$, plus some fraction of the step size, βh, times the slope k_1, and the time at $t_0+\alpha h$ (i.e., some time between t_0 and t_0+h).

To update our solution with the next estimate of $y(t)$ at t_0+h we use then the relation:

$$\begin{aligned} y^*(t_0+h)&\cong y^*(t_0)+h(ak_1+bk_2)\\ &=y^*(t_0)+h\left[af(y^*(t_0),t_0)+bf(y^*(t_0)+\beta hk_1,t_0+\alpha h)\right] \end{aligned} \tag{14.1.1287}$$

That latter relation can be found in some textbooks under the form:

$$y^*_{k+1}\cong y^*_k+h\left[af(t_k,y_k)+bf\left(t_k+\alpha h,y_k+\beta hf(t_k,y_k)\right)\right] \tag{14.1.1288}$$

This equation states that we get the value of $y^*(t_0+h)$ from the value of $y^*(t_0)$ plus the time step, h, multiplied by a slope that is a weighted sum of k_1 and k_2. In the method described previously $a=0$ and $b=1$, so we used only the second estimate for the slope.

Note that Euler's Method (first order Runge-Kutta) is a special case of this method with $a=1$, $b=0$, and α and β don't matter because k_2 is not used in the update equation!

Remark

In general a Runge-Kutta method of order s will be written as:

$$y^*_{t_0+h} \cong y^*_{t_0} + h\sum_{i=1}^{s} a_i k_i + \mathcal{O}(h^{s+1}) \tag{14.1.1289}$$

where:

$$k_i = f\left(y_{t_0} + h\sum_{j=1}^{s} \beta_{ij} k_j,\ t_n + \alpha_i h\right) \tag{14.1.1290}$$

Our goal now is to determine, from first principles, how to find the values a, b, α and β that result in low error. Starting with the update equation above:

$$y^*(t_0+h) \cong y^*(t_0) + h\left[af(y^*(t_0),t_0) + bf\left(y^*(t_0) + \beta h k_1, t_0 + \alpha h\right)\right] \tag{14.1.1291}$$

We can use now the bivariate-dimensional Taylor series (where the increment in the first dimension is $\beta h k_1$, and the increment in the second dimension is αh) to expand the rightmost term:

$$\begin{aligned} f\left(y^*(t_0) + \beta h k_1,\ t_0 + \alpha h\right) &= f + f_y \beta h k_1 + f_t \alpha h + \mathcal{O}(h^2) \\ &= f + f_y f \beta h + f_t \alpha h + \mathcal{O}(h^2) \end{aligned} \tag{14.1.1292}$$

In the last line we used the fact the $k_1 = f$. Now we substitute this in the update equation:

$$\begin{aligned} y^*(t_0+h) &= y^*(t_0) + h\left[af(y^*(t_0),t_0) + bf\left(y^*(t_0) + \beta h k_1, t_0 + \alpha h\right)\right] \\ &= y^*(t_0) + h\left[af(y^*(t_0),t_0) + b\left(f + f_y f \beta h + f_t \alpha h + h\mathcal{O}(h^2)\right)\right] \\ &= y^*(t_0) + h(a+b)f + h^2 f_t b\alpha + h^2 b\beta f_y f + \mathcal{O}(h^3) \end{aligned} \tag{14.1.1293}$$

To finish we compare this approximation with the expression for a Taylor expansion of the exact solution (going from the first line to the second we used the chain rule for partial derivatives):

$$\begin{aligned} y(t_0+h) &= y(t_0) + h y'(t)\big|_{t_0} + \frac{h^2}{2} y''(t)\big|_{t_0} + \ldots \\ &= y(t_0) + hf + \frac{h^2}{2}\left(f_t + f_y f\right) + \ldots \\ &= y(t_0) + hf + \frac{h^2}{2} f_t + \frac{h^2}{2} f_y f + \ldots \end{aligned} \tag{14.1.1294}$$

Comparing this expression with our final expression for the approximation:

$$y^*(t_0+h) = y^*(t_0) + hf(a+b) + h^2 f_t b\alpha + h^2 b\beta f_y f + \ldots \tag{14.1.1295}$$

we see that they agree up to the error terms (third order and higher) if we define the constants, a, b, α and β such that:

$$\begin{aligned} a + b &= 1 \\ b\alpha &= \frac{1}{2} \\ b\beta &= \frac{1}{2} \end{aligned} \tag{14.1.1296}$$

Also written:

$$\begin{aligned} a+b-1&=0\\ b\alpha-\frac{1}{2}&=0\\ b\beta-\frac{1}{2}&=0 \end{aligned} \tag{14.1.1297}$$

This system is underspecified, there are four unknowns, and only three equations, so more than one solution is possible.

The following choices are the most common one:

- $a=0$, $b=1$ and $\alpha=\beta=1/2$, we get:

  $$\begin{aligned} y^*(t_0+h)&\cong y^*(t_0)+h\left[af(y^*(t_0),t_0)+bf\left(y^*(t_0)+\beta hk_1,t_0+\alpha h\right)\right]\\ &=y^*(t_0)+h\left[f(y^*(t_0),t_0)+f\left(y^*(t_0)+\frac{1}{2}hk_1,t_0+\frac{1}{2}h\right)\right] \end{aligned} \tag{14.1.1298}$$

  This is named the "middle-point method".

- $a=b=1/2$ and $\alpha=\beta=1$, we get:

  $$\begin{aligned} y^*(t_0+h)&\cong y^*(t_0)+h\left[af(y^*(t_0),t_0)+bf\left(y^*(t_0)+\beta hk_1,t_0+\alpha h\right)\right]\\ &=y^*(t_0)+h\left[\frac{1}{2}f(y^*(t_0),t_0)+\frac{1}{2}f\left(y^*(t_0)+hk_1,t_0+h\right)\right]\\ &=y^*(t_0)+\frac{h}{2}\left[f(y^*(t_0),t_0)+f\left(y^*(t_0)+hk_1,t_0+h\right)\right] \end{aligned} \tag{14.1.1299}$$

  This is named the "improved Euler's method" or "modified Euler's method". Notice that the term:

  $$\frac{h}{2}\left[f(y^*(t_0),t_0)+f\left(y^*(t_0)+hk_1,t_0+h\right)\right] \tag{14.1.1300}$$

  is equivalent to the trapezoidal approximation of an integral of $y^*(y(t),t)$.

- $a=1/4$, $b=3/4$ and $\alpha=\beta=2/3$, we get:

  $$\begin{aligned} y^*(t_0+h)&\cong y^*(t_0)+h\left[af(y^*(t_0),t_0)+bf\left(y^*(t_0)+\beta hk_1,t_0+\alpha h\right)\right]\\ &=y^*(t_0)+h\left[\frac{1}{4}f(y^*(t_0),t_0)+\frac{3}{4}f\left(y^*(t_0)+\frac{2}{3}hk_1,t_0+\frac{2}{3}h\right)\right] \end{aligned} \tag{14.1.1301}$$

  This is named the "Heun's method".

More complicated and more accurate methods can be derived by a similar approach and this can be the subject of a whole book.

14.1.16.5.1.3 4th order Runge-Kutta method

It is the most widely known member of the Runge–Kutta family and generally referred to as "RK4", the "classic Runge–Kutta method" or simply as the "Runge–Kutta method".

To derive it, let us recall that general a Runge–Kutta (empirical) method of order s can be written as:

$$y_{t+h} \cong y_t + h\sum_{i=1}^{s} a_i k_i + \mathcal{O}(h^{s+1}) \tag{14.1.1302}$$

where:

$$k_i = f\left(y_t + h\sum_{j=1}^{s}\beta_{ij}k_j,\ t_n+\alpha_i h\right) \tag{14.1.1303}$$

are increments obtained evaluating the derivatives of y_t at the i-th order.

We develop the derivation for the Runge–Kutta fourth-order method using the general formula with $s=4$ evaluated, at the starting point, the midpoint and the end point of any interval $(t,\ t+h)$. Thus, we choose:

$$\begin{array}{cc} \alpha_i & \beta_{ij} \\ \alpha_1=0 & \beta_{21}=\dfrac{1}{2} \\ \alpha_2=\dfrac{1}{2} & \beta_{32}=\dfrac{1}{2} \\ \alpha_3=\dfrac{1}{2} & \beta_{43}=1 \\ \alpha_4=1 & \end{array} \tag{14.1.1304}$$

and $\beta_{ij}=0$ otherwise. We begin by defining the following quantities:

$$\begin{aligned} y_{t+h}^1 &= y_t + hf\left(y_t,\ t\right) \\ y_{t+h}^2 &= y_t + hf\left(y_{t+h/2}^1,\ t+\frac{h}{2}\right) \\ y_{t+h}^3 &= y_t + hf\left(y_{t+h/2}^2,\ t+\frac{h}{2}\right) \end{aligned} \tag{14.1.1305}$$

where:

$$y_{t+h/2}^1 = \frac{y_t+y_{t+h}^1}{2} \qquad \text{and} \qquad y_{t+h/2}^2 = \frac{y_t+y_{t+h}^2}{2} \tag{14.1.1306}$$

If we define:

$$\begin{aligned} k_1 &= f(y_t,\ t) \\ k_2 &= f\left(y_{t+h/2}^1,\ t+\frac{h}{2}\right) = f\left(y_t+\frac{h}{2}k_1,\ t+\frac{h}{2}\right) \\ k_3 &= f\left(y_{t+h/2}^2,\ t+\frac{h}{2}\right) = f\left(y_t+\frac{h}{2}k_2,\ t+\frac{h}{2}\right) \\ k_4 &= f\left(y_{t+h}^3,\ t+h\right) = f\left(y_t+hk_3,\ t+h\right) \end{aligned} \tag{14.1.1307}$$

and for the previous relations we can show that the following equalities hold up to $\mathcal{O}(h^2)$:

$$\begin{aligned}
k_2 &= f\left(y^1_{t+h/2},\ t+\frac{h}{2}\right) = f\left(y_t+\frac{h}{2}k_1,\ t+\frac{h}{2}\right)\\
&= f\left(y_t,\ t\right)+\frac{h}{2}\frac{\mathrm{d}}{\mathrm{d}t}f\left(y_t,\ t\right)\\
k_3 &= f\left(y^2_{t+h/2},\ t+\frac{h}{2}\right) = f\left(y_t+\frac{h}{2}f\left(y_t+\frac{h}{2}k_1,\ t+\frac{h}{2}\right),\ t+\frac{h}{2}\right)\\
&= f\left(y_t,\ t\right)+\frac{h}{2}\frac{\mathrm{d}}{\mathrm{d}t}\left[f\left(y_t,\ t\right)+\frac{h}{2}\frac{\mathrm{d}}{\mathrm{d}t}f\left(y_t,\ t\right)\right]\\
k_4 &= f\left(y^3_{t+h},\ t+h\right) = f\left(y_t+hf\left(y_t+\frac{h}{2}k_2,\ t+\frac{h}{2}\right),\ t+h\right)\\
&= f\left(y_t+hf\left(y_t+\frac{h}{2}f\left(y_t+\frac{h}{2}f\left(y_t,\ t\right),\ t+\frac{h}{2}\right),\ t+\frac{h}{2}\right),\ t+h\right)\\
&= f\left(y_t,\ t\right)+h\frac{\mathrm{d}}{\mathrm{d}t}\left[f\left(y_t,\ t\right)+\frac{h}{2}\frac{\mathrm{d}}{\mathrm{d}t}\left[f\left(y_t,\ t\right)+\frac{h}{2}\frac{\mathrm{d}}{\mathrm{d}t}f\left(y_t,\ t\right)\right]\right]
\end{aligned}\tag{14.1.1308}$$

where:

$$\frac{\mathrm{d}}{\mathrm{d}t}f(y_t,\ t)=\frac{\partial}{\partial y}f(y_t,\ t)\dot{y}_t+\frac{\partial}{\partial t}f(y_t,\ t)=f_y(y_t,\ t)\dot{y}+f_t(y_t,\ t):=\ddot{y}_t\tag{14.1.1309}$$

is the total exact differential of f with respect to time.

If we now express the general formula using what we just derived we get:

$$\begin{aligned}
y_{t+h} \cong y_t+h\Bigg\{&a\cdot f(y_t,\ t)+b\cdot\left[f(y_t,\ t)+\frac{h}{2}\frac{\mathrm{d}}{\mathrm{d}t}f(y_t,\ t)\right]+\\
&+c\cdot\left[f(y_t,\ t)+\frac{h}{2}\frac{\mathrm{d}}{\mathrm{d}t}\left[f\left(y_t,\ t\right)+\frac{h}{2}\frac{\mathrm{d}}{\mathrm{d}t}f(y_t,\ t)\right]\right]+\\
&+d\cdot\left[f(y_t,\ t)+h\frac{\mathrm{d}}{\mathrm{d}t}\left[f(y_t,\ t)+\frac{h}{2}\frac{\mathrm{d}}{\mathrm{d}t}\left[f(y_t,\ t)+\frac{h}{2}\frac{\mathrm{d}}{\mathrm{d}t}f(y_t,\ t)\right]\right]\right]\Bigg\}+\mathcal{O}(h^5)\\
=y_t+a\cdot hf_t&+b\cdot hf_t+b\cdot\frac{h^2}{2}\frac{\mathrm{d}f_t}{\mathrm{d}t}+c\cdot hf_t+c\cdot\frac{h^2}{2}\frac{\mathrm{d}f_t}{\mathrm{d}t}+\\
&+c\cdot\frac{h^3}{4}\frac{\mathrm{d}^2f_t}{\mathrm{d}t^2}+d\cdot hf_t+d\cdot h^2\frac{\mathrm{d}f_t}{\mathrm{d}t}+d\cdot\frac{h^3}{2}\frac{\mathrm{d}^2f_t}{\mathrm{d}t^2}+d\cdot\frac{h^4}{4}\frac{\mathrm{d}^3f_t}{\mathrm{d}t^3}+\mathcal{O}(h^5)
\end{aligned}\tag{14.1.1310}$$

and comparing this with the Taylor series of y_{t+h} around y_t:

$$\begin{aligned}
y_{t+h}&=y_t+h\dot{y}_t+\frac{h^2}{2}\ddot{y}_t+\frac{h^3}{6}y_t^{(3)}+\frac{h^4}{24}y_t^{(4)}+\mathcal{O}(h^5)=\\
&\cong y_t+hf(y_t,\ t)+\frac{h^2}{2}\frac{\mathrm{d}}{\mathrm{d}t}f(y_t,\ t)+\frac{h^3}{6}\frac{\mathrm{d}^2}{\mathrm{d}t^2}f(y_t,\ t)+\frac{h^4}{24}\frac{\mathrm{d}^3}{\mathrm{d}t^3}f(y_t,\ t)
\end{aligned}\tag{14.1.1311}$$

we get a system of constraints on the coefficients:

$$\begin{cases} a+b+c+d=1 \\ \tfrac{1}{2}b+\dfrac{1}{2}c+d=\dfrac{1}{2} \\ \dfrac{1}{4}c+\dfrac{1}{2}d=\dfrac{1}{6} \\ \dfrac{1}{4}d=\dfrac{1}{24} \end{cases} \tag{14.1.1312}$$

which when solved gives:

$$a=\frac{1}{6},b=\frac{1}{3},c=\frac{1}{3},d=\frac{1}{6} \tag{14.1.1313}$$

as stated above.

14.1.17 Optimization

In mathematics, computer science and operations research, mathematical optimization (alternatively "mathematical programming") is the selection of a best element (with regard to some criteria) from some set of available alternatives.

In the simplest case, an optimization problem consists of maximizing or minimizing a real function by systematically choosing input values from within an allowed set and computing the value of the function. The generalization of optimization theory and techniques to other formulations comprises a large area of applied mathematics. More generally, optimization includes finding best available values of some objective function given a defined domain (or a set of constraints), including a variety of different types of objective functions and different types of domains.

In mathematics, conventional optimization problems are usually stated in terms of minimization (or changed to be as!). A large number of algorithms proposed for solving optimization problems are not capable of making a distinction between local optimal solutions and rigorous optimal solutions. The branch of applied mathematics and numerical analysis that is concerned with the development of deterministic algorithms that are capable of guaranteeing convergence in finite time to the actual optimal solution is named "global optimization".

Remark

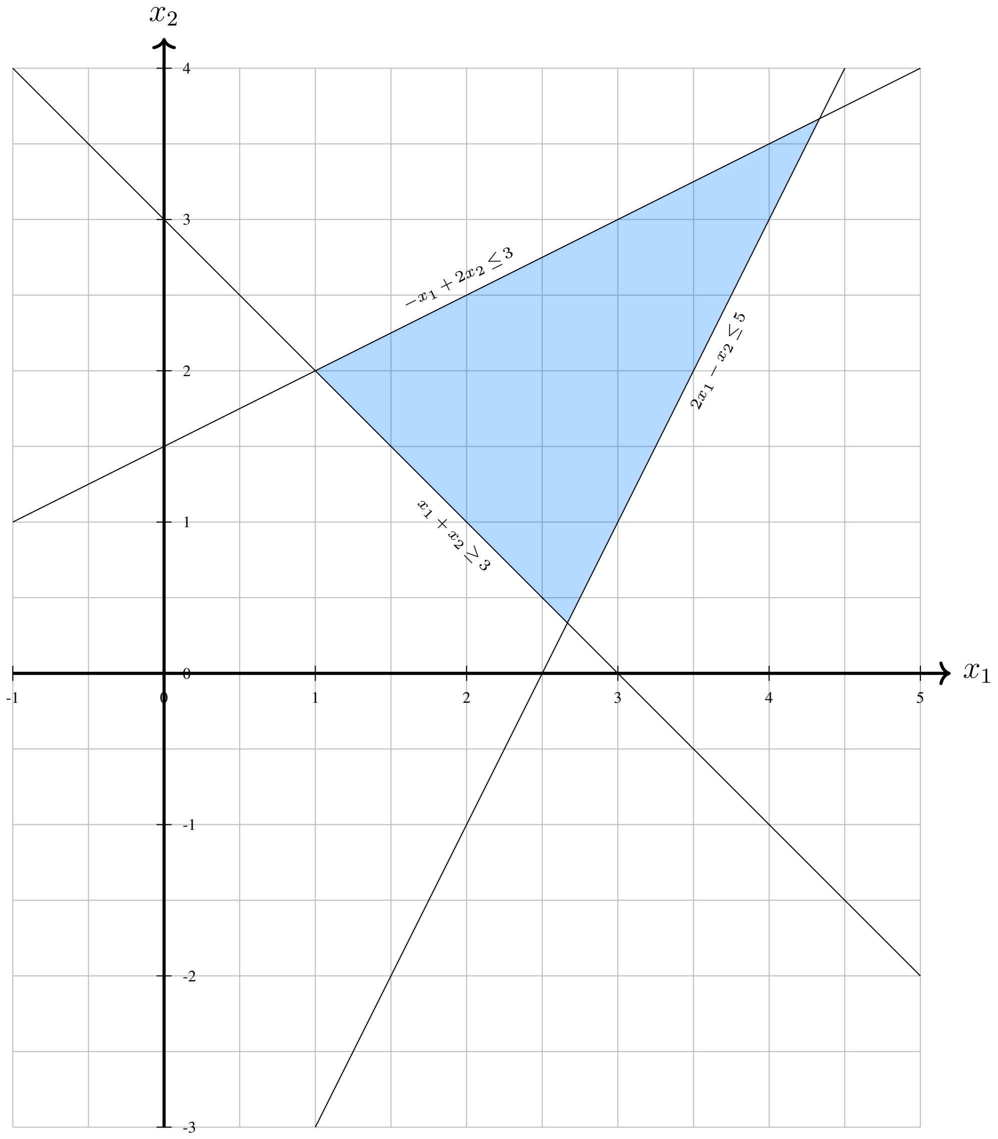
We speak of "convex optimization" when any local minimum must be a global minimum. In other word there is only one unique solution.

In the context of problem solving which involves two variables and their products, we then speak logically "quadratic programming (QP)" or simply "non-linear programming". This is typically the case in financial engineering in portfolios modelling (see section Economy page 7699) or in forecasting. We will study in details also further below simplified and particular version of the corresponding models that are the: Newton's method, quasi-Newton's method, conjugate gradient method and non-linear GRG.

14.1.17.1 Linear programming (Linear Optimization)

The objective of the linear programming (LP-programming) is to find the optimum value of a linear function subject to a system of equations consisting in inequalities constraints that are also linear. The objective function is named "economic function" (because used a lot in Economy) and we solve this type of system using typically, among others, a method named "simplex method" (see below), the corresponding graph is a "polygon constraints" (when the number of variable is obviously equal to 2).

The reader can remember the following diagram (convex polytope) that we saw in the section Calculus:

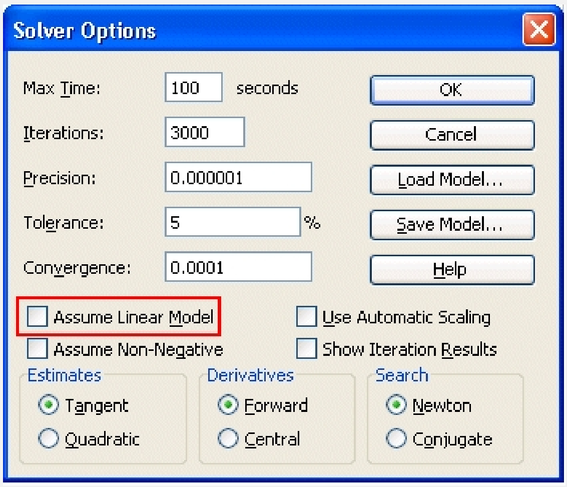


Corresponding to the following system of inequalities:

$$\begin{aligned}-x_1+2x_2&\leq 3\\ 2x_1-x_2&\leq 5\\ x_1+x_2&\geq 3\end{aligned} \tag{14.1.1314}$$

Remark

Linear programming is widely used (to name only the most famous case) in Supply Chain (maximal flow problem also named "transport problem"), in Corporate Finance or also in Decision Theory when we solve a mixed strategy game (see the section of Game and Decision Theory for a practical example). That's why Microsoft® Excel® 12.0 and earlier includes a tool named the "solver" in which there is an option named "Assume Linear Model" which then requires the use of the simplex model that we will study below:



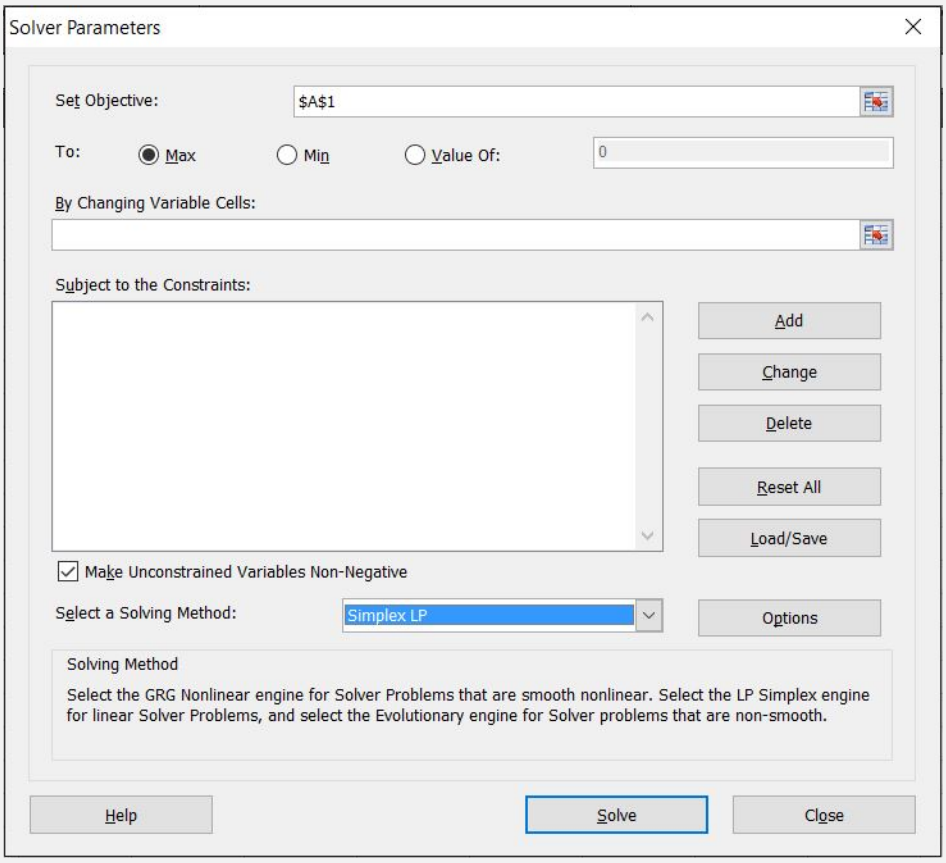
Solver Options

Max Time: 100 seconds
Iterations: 3000
Precision: 0.000001
Tolerance: 5 %
Convergence: 0.0001

☐ Assume Linear Model
☐ Use Automatic Scaling
☐ Assume Non-Negative
☐ Show Iteration Results

Estimates: ● Tangent ○ Quadratic
Derivatives: ● Forward ○ Central
Search: ● Newton ○ Conjugate

or since the 2010 version of the software (the user interface has completely changed):



Solver Parameters

Set Objective: $A$1

By Changing Variable Cells:

Subject to the Constraints:

☑ Make Unconstrained Variables Non-Negative

Select a Solving Method: Simplex LP

Solving Method

Select the GRG Nonlinear engine for Solver Problems that are smooth nonlinear. Select the LP Simplex engine for linear Solver Problems, and select the Evolutionary engine for Solver problems that are non-smooth.

We will focus especially in this section on the most widely used algorithm for linear optimization named the "simplex algorithm".

When a problem can be modelled as an economic function to be maximized with respect to certain constraints that are purely additive, we are typically in the context of linear programming!

So an economic function Z is defined as:

$$Z=c_1x_1+c_2x_2+\ldots+c_nx_n=\sum_{i=1}^{n}c_ix_i \tag{14.1.1315}$$

where the x_i are variables that affect the value of Z, and the c_i the weights of these variables modelling the relative importance of each of them on the value of the economic function.

The constraints related to the variables are expressed by the following linear system:

$$\begin{aligned}&a_{11}x_1+a_{12}x_2+\ldots+a_{1n}x_n\leq B_1\\&a_{21}x_1+a_{22}x_2+\ldots+a_{2n}x_n\leq B_2\\&\ldots\\&a_{m1}x_1+a_{m2}x_2+\ldots+a_{mn}x_n\leq B_n\end{aligned} \tag{14.1.1316}$$

Under general and matrix form this problem is written as:

$$\boxed{\begin{aligned}\underset{\vec{x}}{\text{minimize}}\quad & Z(\vec{x})=\sum_{j=1}^{n}c_ix_i\\ \text{subject to}\quad & \sum_{i=1}^{m}a_{ij}x_j=b_i \quad i=1\ldots m\\ & x_j\geq 0\quad j=1\ldots n\end{aligned}} \tag{14.1.1317}$$

To see the different methods of resolution let us use an example as theoretical introduction:

A factory produces two types of pieces $P1$ and $P2$ machined in two workshops $A1$ and $A2$. Machining times are for $P1$ or 3 hours in the workshop $A1$ and 6 hours in the workshop $A2$ and of for 4 hours for $P2$ in the workshop $A1$ and 3 hours in the workshop $A2$.

Weekly up-time of human resources (workers) of the $A1$ workshop is 160 hours and that of the workshop $A2$ is 180 hours.

The profit margin is of $1,200.-$ for the pieces $P1$ and $1,000.-$ for pieces $P2$.

The question is how much of each kind of piece should we make to maximize weekly margin?

This will be formalized as follows (canonical formulation):

$$\boxed{\begin{aligned}\underset{\vec{x}}{\text{maximize}}\quad & Z(\vec{x})=1,200x_1+1,000x_2\\ \text{subject to}\quad & \text{A1: }3x_1+4x_2\leq 160\\ & \text{A2: }6x_1+3x_2\leq 180\\ & x_1,x_2\geq 0\end{aligned}} \tag{14.1.1318}$$

14.1.17.1.1 Graphical LP resolution

The graphical method is will adapted for problem with 2 or 3 variables but not more as our perception of hyper-volume is quite limited for humans.

When translate our optimization problem into graphical form, we speak also of "polygon of constraints". Indeed, the economical constraints are represented by half planes. The solutions, if they exists, belongs to the intersection set name "set of admissible solutions" and is quite trivially represented in our case by:

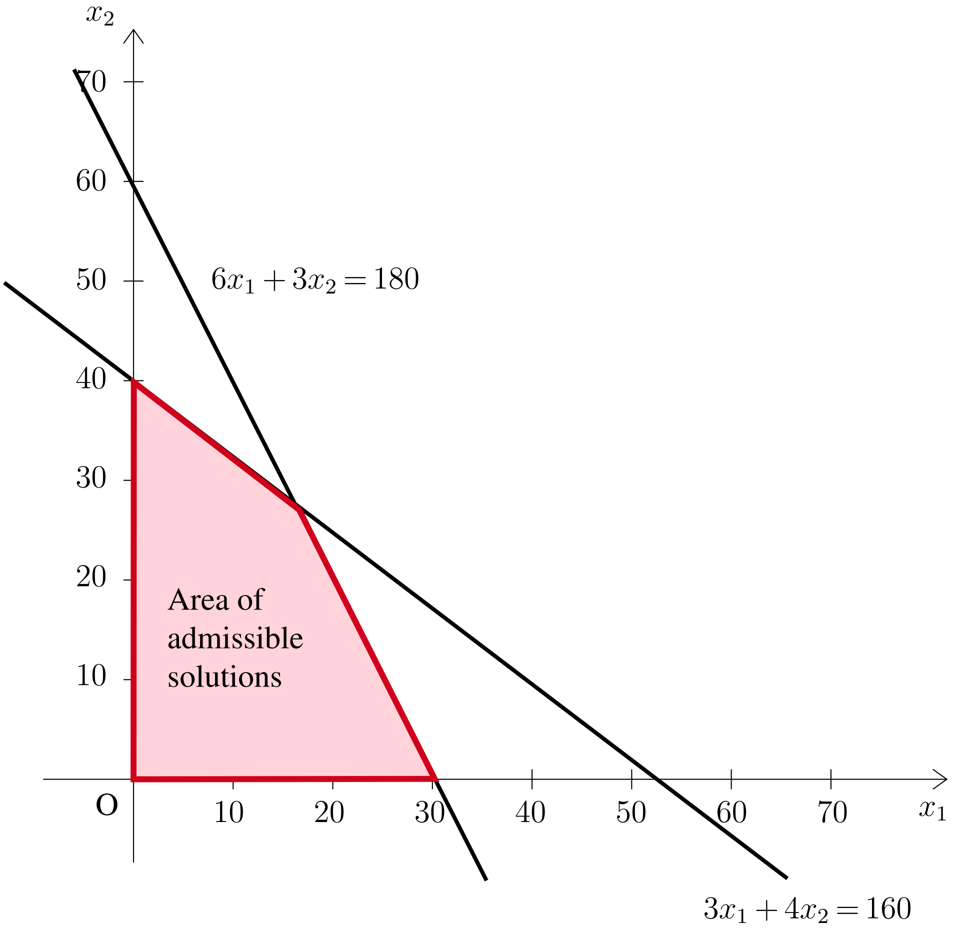

Figure 14.79: **Illustration of a simple operational research problem with area of feasible solutions (convex polytope)**

Remark

In the general case, for those who love the language of mathematicians ..., the information of a linear constraint geometrically problem corresponds to a half space of n-dimensional space (n being the number of variables). In the elementary case, all the points in space that satisfy all constraints are limited by a convex portion of a hyperplane (see the case with 2 variables, easy more to illustrate...), that is why this type of problems are also named "convex optimization". If the cost function is linear, the extreme point is a vertices (easy to see in a two dimensional case). The basic algorithm simplex algorithm (see further below) start from one vertices and goes to the next vertices which locally maximizes the cost, and restarts the procedure as long as necessary.

To find the coordinates of the vertices, we can use the graph if the points are easy to determine.

It is therefore to seek inside this area (connex), the pair (x_1, x_2) maximizing the economic function.

However, the equation Z is represented by a constant line of constant slope (-1.2) which all points (x_1, x_2) provide the same Z value for the objective function.

In particular, the straight line $1200x_1 + 1000x_2$ pass trough the origin and it provides a zero value to the economic function. To increase the value of Z and therefore of the economic function, we have to take away from the origin (in the quarter $x_1 \geq 0, x_2 \geq 0$ that is to say in the `Ist` quadrant) the line of slope -1.2. Obviously then we see very quickly that the simplex method will not work if the constraints of the polygon does not contain the origin point!

To meet the constraints, this straight line will be moved until the limit where it will not have a point of intersection anymore in common with the area of admissible solutions (eventually a segment).

$1200x_1 + 1000x_2 = z_0$

Figure 14.80: **Finding solutions graphically with the economic function**

The optimal solution is therefore necessarily located on the periphery of the region of admissible solutions and the parallel formed by translating the economic function are named "isoquants lines" or "isocost lines"...

14.1.17.1.2 Algebraic LP resolution

Let us now see how to solve this problem analytically before moving to the theoretical part.

So we have the "canonical system":

$$\begin{aligned}\text{A1: } & 3x_1+4x_2\leq 160\\ \text{A2: } & 6x_1+3x_2\leq 180\\ & x_1,x_2\geq 0\end{aligned} \tag{14.1.1319}$$

with:

$$Z=1200x_1+1000x_2 \tag{14.1.1320}$$

We first introduce the "slack variables" to transform the 2 inequalities in equalities. The system of equations takes then "standard form":

$$\begin{aligned}3x_1+4x_2+ax_3&=160\\ 6x_1+3x_2+bx_4&=180\\ 1200x_1+1000x_2&=Z\end{aligned} \tag{14.1.1321}$$

Therefore, for $x_1,x_2\geq 0$ fixed, the slack variable whose coefficients are always unit, measure the distance to travel to reach the vertices.

It goes without saying that the technique of slack variables may be used for linear (or non-linear) systems. Therefore, a constraint optimization system with inequalities, can always be reduced to an optimization system with equalities.

Remark

Obviously there is as much slack variable as inequalities.

For the remaining part, we have noticed, after a review of this section, that the technique using tables (that we will see later) often presented in textbooks and websites finally brought nothing to a deep understanding of the resolution mechanism. Since the purpose of the present book is to always prove with a maximum of details the operating principle of a process, it goes without saying that we will opt first for a purely algebraic approach! Let us see it by returning to the system with the slack variables and the economic function but slightly rearranged:

$$\begin{aligned}x_3&=160-(3x_1+4x_2)\\ x_4&=180-(6x_1+3x_2)\\ Z&=1200x_1+1000x_2\end{aligned} \tag{14.1.1322}$$

The $A1$ constraint then becomes:

$$x_3\geq 0 \tag{14.1.1323}$$

and the constraint $A2$ respectively becomes:

$$x_4\geq 0 \tag{14.1.1324}$$

Therefore, the problem consist to maximize Z with the constraints:

$$x_1, x_2, x_3, x_4 \geq 0 \tag{14.1.1325}$$

Let us start with an obvious feasible solution given the constraints that is trivially:

$$x_1 = x_2 = 0 \tag{14.1.1326}$$

Therefore with the system:

$$\begin{aligned} x_3 &= 160 - (3x_1 + 4x_2) \\ x_4 &= 180 - (6x_1 + 3x_2) \\ Z &= 1200x_1 + 1000x_2 \end{aligned} \tag{14.1.1327}$$

we find immediately:

$$\begin{aligned} x_3 &= 160 \\ x_4 &= 180 \\ Z &= 0 \end{aligned} \tag{14.1.1328}$$

The parameters in the actual state can be summarized as:

$$x_1 = 0, x_2 = 0, x_3 = 160, x_4 = 180 \tag{14.1.1329}$$

To go forward, the goal will be to make Z grow and for this purpose we will increase only one single variable, choosing the one with the largest coefficient (weight) in:

$$Z = 1200x_1 + 1000x_2 \tag{14.1.1330}$$

that is to say x_1 (because implicitly we think this is how the Z will increase the faster). We speak then of x_1 as the "pivot direction". We keep then $x_2 = 0$ and we increase x_1 with the system which then reduces to:

$$\begin{aligned} x_3 &= 160 - 3x_1 \\ x_4 &= 180 - 6x_1 \\ Z &= 1200x_1 \end{aligned} \tag{14.1.1331}$$

Therefore with $x_2 = 0$ and to begin $x_1 = 1$, we have:

$$\begin{aligned} x_3 &= 160 - 3 = 157 \\ x_4 &= 180 - 6 = 154 \\ Z &= 1200 \end{aligned} \tag{14.1.1332}$$

and we see that the constraints $x_1, x_2, x_3, x_4 \geq 0$ are still respected, it is the same if x_1 is equal to 2, 3, 4, 5, ... and this until 31, because after:

$$\begin{aligned} x_3 &= 160 - 3 \cdot 31 = 67 \\ x_4 &= 180 - 6 \cdot 31 = -6 \\ Z &= 1200 \cdot 31 = 37200 \end{aligned} \tag{14.1.1333}$$

and one of the slack variable has become negative, the constraints $x_1, x_2, x_3, x_4 \geq 0$ are not all met and therefore this solution is not feasible.

The question in the general case is to ask ourselves until what value (the most constraint value, verbatim the smallest) we can increase x_1 while maintaining the condition $x_1, x_2, x_3, x_4 \geq 0$ when $x_2 = 0$? And the answer is quite simple:

$$\begin{aligned} x_3 &= 160 - 3x_1 \Rightarrow x_1 = \frac{160}{3} \\ x_4 &= 180 - 6x_1 \Rightarrow x_1 = \frac{180}{6} = 30 \end{aligned} \tag{14.1.1334}$$

and therefore it is:

$$x_1 = 30 \tag{14.1.1335}$$

then we speak sometimes of the "pivot step". We then have the actual solution:

$$x_1 = 30, x_2 = 0, x_3 = 70, x_4 = 0 \tag{14.1.1336}$$

Which gives:

$$Z = 1200 \cdot 30 = 36000 \tag{14.1.1337}$$

Graphically, this is what we have just done:

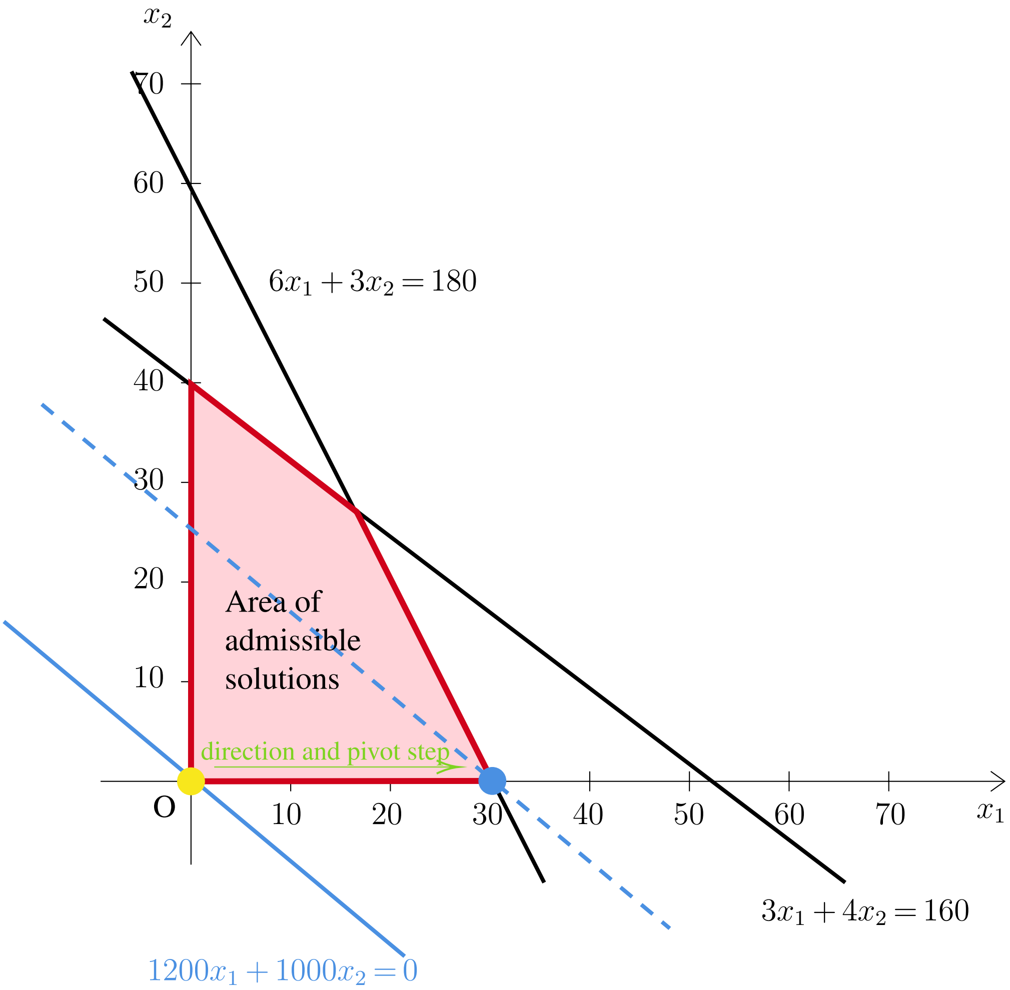

Figure 14.81: Direction of the pivot head and arrival at point $(30, 0)$

To continue to increase Z such simply (by increasing only one variable), we need a new system of equations similar to the original system:

$$\begin{aligned} x_3 &= 160-(3x_1+4x_2)\\ x_4 &= 180-(6x_1+3x_2)\\ Z &= 1200x_1+1000x_2 \end{aligned} \tag{14.1.1338}$$

where we have expressed the variables that takes non-zero value depending on others who take a zero value! That is to say x_3,x_4, in function of x_1,x_2 since we had for recall:

$$x_1=0, x_2=0, x_3=160, x_4=180 \tag{14.1.1339}$$

For the remaining part, we must express x_1,x_3 and also Z in function of x_2,x_4 since we just get for reminder:

$$x_1=30, x_2=0, x_3=70, x_4=0 \tag{14.1.1340}$$

Before getting the new system reaction function, making some algebraic manipulations:

$$\left.\begin{aligned} x_3 &= 160-(3x_1+4x_2)\\ x_4 &= 180-(6x_1+3x_2) \end{aligned}\right\} \Rightarrow 2x_3-x_4=(320-(6x_1+8x_2))-(180-(6x_1+3x_2)) \tag{14.1.1341}$$

which gives after simplification:

$$2x_3-x_4=140-5x_2 \Rightarrow 70-2.5x_2+0.5x_4 \tag{14.1.1342}$$

and therefore it comes:

$$\left.\begin{aligned} x_3 &= 160-(3x_1+4x_2)\\ x_3 &= 70-2.5x_2+0.5x_4 \end{aligned}\right\} \Rightarrow x_3-x_3=(160-(3x_1+4x_2))-(70-2.5x_2+0.5x_4) \tag{14.1.1343}$$

which gives after simplification:

$$x_1=30-0.5x_2-\frac{1}{6}x_4 \tag{14.1.1344}$$

and we have identically:

$$Z=1200x_1+1000x_2=1200\left(30-0.5x_2-\frac{1}{6}x_4\right)+1000x_2=36000+400x_2-200x_4 \tag{14.1.1345}$$

So finally the system is:

$$\begin{aligned} x_1 &= 30-0.5x_2-\frac{1}{6}x_4\\ x_3 &= 70-2.5x_2+0.5x_4\\ Z &= 36000+400x_2-200x_4 \end{aligned} \tag{14.1.1346}$$

from which we reiterate the process (we increase only one variable in Z keeping the other to 0). When we can not increase Z as all coefficients are negative, well it is that we are at a maximum (thank you convexity...). Let us see this...

In Z the biggest coefficient is now x_2 and so it leads us to put $x_4 = 0$. The most constraint value of x_2 that allows to always respect the constraints $x_1, x_2, x_3, x_4 \geq 0$ is therefore:

$$x_2 = 28 \tag{14.1.1347}$$

And for this value, we have:

$$x_1 = 30 - 0.5x_2 = 30 - 0.5 \cdot 28 = 16 \tag{14.1.1348}$$

The original economic function then takes the value:

$$1200x_1 + 1000x_2 = Z \Rightarrow 1200 \cdot 16 + 1000 \cdot 28 = 47200 \tag{14.1.1349}$$

which therefore corresponds graphically to:

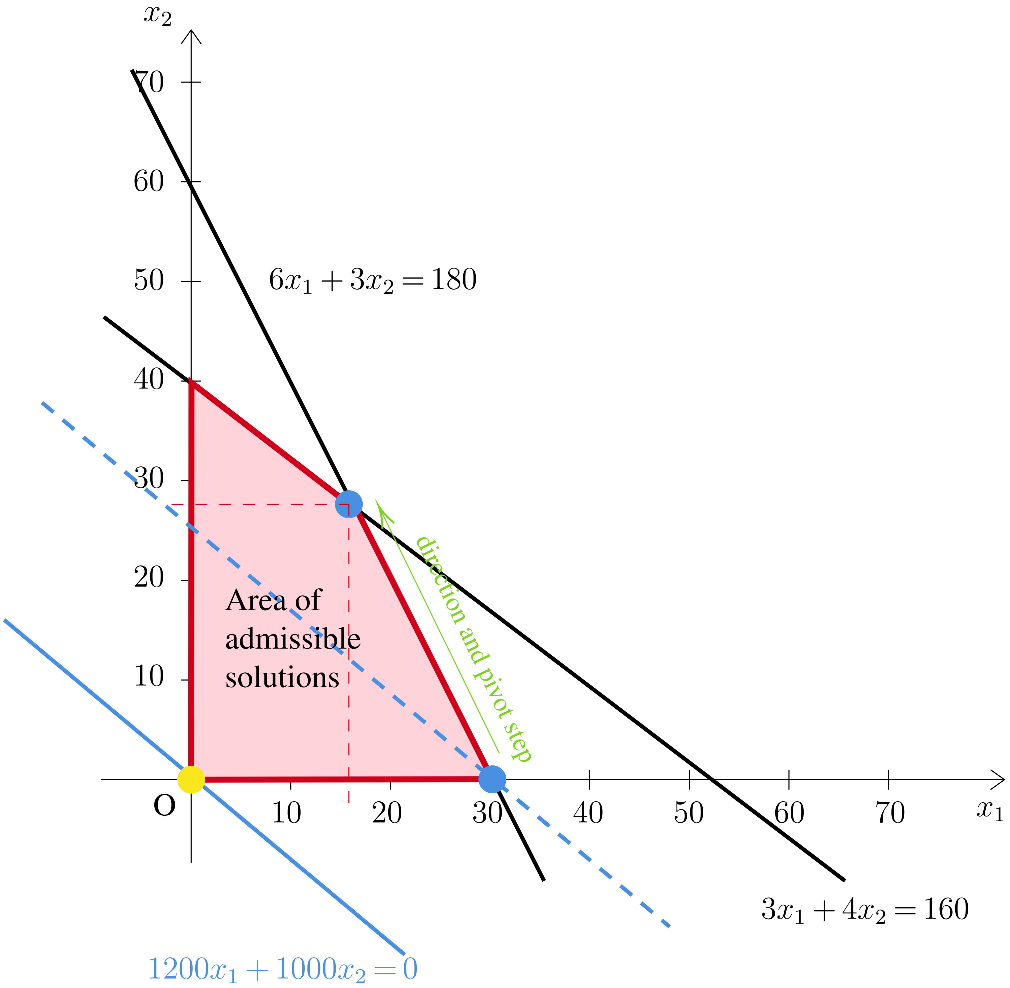

Figure 14.82: **Pivot direction with arrival point at** $(16, 28)$ **for the second iteration**

So we see above that we arrived at the optimum value visible on the graph given at the beginning of this example. But how do we know that we arrived at the final point if we do not have plots or if we work in higher dimensions?

In fact, the process is terminated either when all the coefficients of the economic function are negative or that the most constraint value that respects the constraints is equal to zero !!! Let's see if this is the case! We therefore have in our example:

$$x_1=16, x_2=28, x_3=0, x_4=0 \tag{14.1.1350}$$

So we will rewrite the system:

$$\begin{aligned}x_1&=30-0.5x_2-\frac{1}{6}x_4\\x_3&=70-2.5x_2+0.5x_4\\Z&=36000+400x_2-200x_4\end{aligned} \tag{14.1.1351}$$

with this time x_1,x_2 and Z dependant to x_3,x_4. We then have first:

$$x_1=30-0.5\left(\frac{70-x_3+0.5x_4}{2.5}\right)-\frac{1}{6}x_4=16+\frac{1}{5}x_3-\frac{4}{15}x_4 \tag{14.1.1352}$$

and we have:

$$\begin{aligned}x_1=30-0.5x_2-\frac{1}{6}x_4\Rightarrow x_2=60-2x_1-\frac{1}{3}x_4&=60-2\left(16+\frac{1}{5}-\frac{4}{15}x_4\right)-\frac{1}{3}x_4\\&=28-\frac{2}{5}x_3+\frac{1}{5}x_4\end{aligned} \tag{14.1.1353}$$

Therefore for Z we have (the coefficients are all negative so we guess what comes ...):

$$Z=3600+400\left(28-\frac{2}{5}x_3+\frac{1}{5}x_4\right)-200x_4=47200-160x_3-120x_2 \tag{14.1.1354}$$

We then have the new system:

$$\begin{aligned}x_1&=16+\frac{1}{5}x_3-\frac{4}{15}x_4\\x_2&=28-\frac{2}{5}x_3+\frac{1}{5}x_4\\Z&=47200-160x_3-120x_4\end{aligned} \tag{14.1.1355}$$

As all coefficients of Z are now negative, we're blocked because we would go in the wrong direction if we continue. We must therefore stop here and we adopt finally the solution:

$$\begin{aligned}x_1&=16\\x_2&=28\end{aligned} \tag{14.1.1356}$$

The method of resolution using tables that is often presented in the literature is only useful to write the coefficients of the variables of the system a table, but the changes that we made are exactly those we just made algebraically before (but a the opposite of the tables the method we used don't hide the logic of the method).

14.1.17.1.3 Simplex algorithm LP resolution

To implement the simplex algorithm, we must write the problem in a "standard" form and introduce the concept of "base program" that is the algebraic expression corresponding to the notion of "extreme point of the polyhedron of eligible programs" presented earlier above. Indeed, we will see that the solution of a problem of the linear programming type it exists, can still be obtained with a base program. The simplex method will therefore be to find a first base program and to build a following base programs constantly improving the economic function and thus leading to the optimum (this is what we name "dynamic programming").

An LP problem is said to be placed in its "standard form" if it involves the search for the minimum of the objective function, the latter being subject to constraints in the form of linear equations and conditions of non-negativity of the variables, that is, we can write it in the form seen earlier before:

$$\boxed{\begin{aligned} &\underset{\vec{x}}{\text{minimize}} \quad Z(\vec{x})=\sum_{j=1}^{n} c_i x_i \\ &\text{subject to} \quad \sum_{i=1}^{n} a_{ij}x_j=b_i \quad i=1\ldots m \\ &\qquad\qquad\qquad\qquad x_j\geq 0 \quad j=1\ldots n \end{aligned}} \tag{14.1.1357}$$

Or using matrix notation:

$$\boxed{\begin{aligned} &\underset{\vec{x}}{\text{minimize}} \quad \vec{c}^T\vec{x}=z \\ &\text{subject to} \quad A\vec{x}=\vec{b} \\ &\qquad\qquad\quad\; \vec{x}\geq\vec{0} \end{aligned}} \tag{14.1.1358}$$

where the matrices $C:n\times 1, A:m\times n, b:m\times 1$ respectively correspond to the activity coefficients of objective function, to the technical coefficients of activities and to second members of the constraints.

We will now see how a LP general problem can always be reduced to a standard form. As we guess it the concept of "slack variable" will be essential to perform this "reduction".

Find the maximum of a function $f(x)$ is equivalent to find the minimum of the opposite sign function $f(x)$. Moreover, a constraint which is presented as an inequality:

$$\sum_{j=1}^{p} a_{ij}x_j\leq b_i \tag{14.1.1359}$$

can be replaced by the following system:

$$\sum_{j=1}^{p} a_{ij}x_j+s_i=b_i \tag{14.1.1360}$$

where as we already know s_i is the slack variable constraint such that $s_i\geq 0$.

Of course, if the system is such that:

$$\sum_{j=1}^{p} a_{ij}x_j \geq b_i \tag{14.1.1361}$$

can be replaced by the system:

$$\sum_{j=1}^{p} a_{ij}x_j - e_i = b_i \tag{14.1.1362}$$

implying again to add a slack variable and always with the constraint that $e_i \geq 0$.

This work of putting in standard form work us to find a system of linear equations to solve system (we saw previously at the beginning of this section how to solve this kind of system with the pivot algorithm).

The matrix A representing the components of the system of equations can be, as we know, expressed in different ways depending on the chosen vector basis (see section Vector Calculus page 1809). We will introduce now the concept of "canonical associated usable form" by choosing a special base and show that this reformulation of constraint system will enable us to move towards the optimum.

The matrix A can, after introduction of the slack variables be decomposed into two sub-matrices $[D|B]$, one containing the initial variables D and the other with the slack variables B such that:

$$A = [D|B] \tag{14.1.1363}$$

Remark

The slack variables are... variable and not constant!! In a system where the variables are in quantity n and the equations in quantity m written as:

$$a_{i1}x_1 + a_{i2}x_2 + \ldots + a_{in}x_n \leq b_i \tag{14.1.1364}$$

We add a slack variable to change the latter into:

$$a_{i1}x_1 + a_{i2}x_2 + \ldots + a_{in}x_n + x_{n+1} = b_i \tag{14.1.1365}$$

where $x_{n+1} = e_i$ on each row m. The added slack variable being different of all variables already existing in the system! This is why we can decompose the initial matrix in two sub matrices.

The columns of the matrix B are obviously, by definition of the method, units columns, linearly independent. These columns form a basis of the vector space of columns of m elements (or dimensions) - the number of lines of the system. We name B the "base matrix".

Right now it can seem a little bit confusing. So let us continue the theory with a companion example as we have for habit to do it in this textbook.

The text below describing the simplex algorithm has been taken to Marcel Oliver (April 12, 12012 according to holocene calendar) and formalized by our own work.

1. Step 1: Write the linear programming problem in standard form

   Turning a problem into standard form involves the following steps.

   (a) Turn Maximization into minimization and write inequalities in standard order.

   This step is obvious. Multiply expressions, where appropriate, by -1.

   (b) Introduce slack variables to turn inequality constraints into equality constraints with non-negative unknowns.

   Any inequality of the form

$$a_1\,x_1+\cdots+a_n\,x_n\leq b \tag{14.1.1366}$$

   can be replaced by:

$$a_1\,x_1+\cdots+a_n\,x_n+s=b \tag{14.1.1367}$$

   with $s\geq 0$.

   (c) Replace variables which are not sign-constrained by differences.

   Any real number x can be written as the difference of non-negative numbers $x=u-v$ with $u,v\geq 0$.

   Consider the following example.

$$\max Z=x_1+2\,x_2+3\,x_3 \tag{14.1.1368}$$

   subject to:

$$\begin{aligned}x_1+x_2-x_3&=1\\-2\,x_1+x_2+2\,x_3&\geq -5\\x_1-x_2&\leq 4\\x_2+x_3&\leq 5\\x_1&\geq 0\\x_2&\geq 0\end{aligned} \tag{14.1.1369}$$

   Written in standard form, the problem becomes:

$$\min Z=-x_1-2\,x_2-3\,u+3\,v \tag{14.1.1370}$$

   subject to:

$$\begin{aligned}x_1+x_2-u+v&=1\\2\,x_1-x_2-2\,u+2\,v+s_1&=5\\x_1-x_2+s_2&=4\\x_2+u-v+s_3&=5\\x_1,x_2,u,v,s_1,s_2,s_3&\geq 0\end{aligned} \tag{14.1.1371}$$

2. Step 2: Write the coefficients of the problem into a "simplex tableau".

   The coefficients of the linear system are collected in an augmented matrix as known from Gaussian elimination for systems of linear equations; the coefficients of the objective function are written in a separate bottom row with a zero in the right hand column.

   For our example, the initial tableau reads:

x_1	x_2	u	v	s_1	s_2	s_3	
1	1	-1	1	0	0	0	1
2	-1	-2	2	1	0	0	5
1	-1	0	0	0	1	0	4
0	1	1	-1	0	0	1	5
-1	-2	-3	3	0	0	0	0

So following what we have above, we get for:

$$A=[X|S] \tag{14.1.1372}$$

that:

$$D=\begin{bmatrix}1 & 1 & -1 & 1\\ 2 & -1 & -2 & 2\\ 1 & -1 & 0 & 0\\ 0 & 1 & 1 & -1\end{bmatrix} \quad \text{and} \quad B=\begin{bmatrix}0 & 0 & 0\\ 1 & 0 & 0\\ 0 & 1 & 0\\ 0 & 0 & 1\end{bmatrix} \tag{14.1.1373}$$

The variables associated to the column components of the matrix S will now be named "bases variables". In our case the bases variables are then essentially the slack variables that we will write now $x_{n+1},x_{n+2},\ldots,x_{n+m}$. The variables associates to the column of the matrix X are named "off-base variables", these are the variables $x_1,x_2,\ldots,x_n$.

Remark

Let us recall that in the expression of the economic function, only the off-base variables appear.

In the following steps, we will act on the tableau by the rules of Gaussian elimination, where the pivots are always chosen from the columns corresponding to the bases variables.

Before proceeding, we need to choose an initial set of basic variables which corresponds to a point in the feasible region of the linear programming problem. Such a choice may be non-obvious, but we shall defer this discussion for now. In our example, x_1 and $s_1,\ldots,s_3$ shall be chosen as the initial bases variables, indicated by gray columns in the tableau above.

3. Step 3: Gaussian elimination

   For a given set of basic variables, we use Gaussian elimination (see page 6305) to reduce the corresponding columns to a permutation of the identity matrix. This amounts to solving $A\vec{x}=\vec{b}$ in such a way that the values of the non-basic variables are zero and the values for the basic variables are explicitly given by the entries in the right hand column of the fully reduced matrix. In addition, we eliminate the coefficients of the objective function below each pivot.

   Our initial tableau is thus reduced to:

x_1	x_2	$\boldsymbol{u}$	v	s_1	s_2	s_3	
1	1	$\mathbf{-1}$	1	0	0	0	1
0	-3	$\mathbf{0}$	0	1	0	0	3
0	-2	***1***	*– 1*	*0*	*1*	*0*	*3*
0	1	$\mathbf{1}$	-1	0	0	1	5
0	-1	$\mathbf{-4}$	4	0	0	0	1

The solution expressed by the tableau is only admissible if all basic variables are non-negative, i.e., if the right hand column of the reduced tableau is free of negative entries. This is the case in this example. At the initial stage, however, negative entries may come up; this indicates that different initial basic variables should have been chosen. At later stages in the process, the selection rules for the basic variables will guarantee that an initially feasible tableau will remain feasible throughout the process.

4. Step 4: Choose new basic variables

   If, at this stage, the objective function row has at least one negative entry, the cost can be lowered by making the corresponding variable basic. This new basic variable is named the "entering variable". Correspondingly, one formerly basic variable has then to become non-basic, this variable is named the "leaving variable". We use the following standard selection rules.

   (a) The entering variable shall correspond to the column which has the most negative entry in the cost function row. If all cost function coefficients are non-negative, the cost cannot be lowered and we have reached an optimum. The algorithm then terminates.

   (b) Once the entering variable is determined, the leaving variable shall be chosen as follows. Compute for each row the ratio of its right hand coefficient to the corresponding coefficient in the entering variable column. Select the row with the smallest finite positive ratio. The leaving variable is then determined by the column which currently owns the pivot in this row. If all coefficients in the entering variable column are non-positive, the cost can be lowered indefinitely, i.e., the linear programming problem does not have a finite solution. The algorithm then also terminates.

If entering and leaving variable can be found, go to Step 3 and iterate.

Note that choosing the most negative coefficient in rule (i) is only a heuristic for choosing a direction of fast decrease of the objective function. Rule (ii) ensures that the new set of basic variables remains feasible.

Let us see how this applies to our problem. The previous tableau holds the most negative cost function coefficient in column 3, thus u shall be the entering variable (marked in boldface). The smallest positive ratio of right hand column to entering variable column is in row 3, as $\frac{3}{1} < \frac{5}{1}$. The pivot in this row points to s_2 as the leaving variable. Thus, after going through the Gaussian elimination once more, we arrive at:

x_1	$\boldsymbol{x_2}$	u	v	s_1	s_2	s_3	
1	**−1**	0	0	0	1	0	4
0	**−3**	0	0	1	0	0	3
0	**−2**	1	−1	0	1	0	3
0	***3***	***0***	*0*	*0*	*−1*	*1*	*2*
0	**−9**	0	0	0	4	0	13

At this point, the new entering variable is x_2 corresponding to the only negative entry in the last row, the leaving variable is s_3. After Gaussian elimination, we find:

x_1	x_2	u	v	s_1	s_2	s_3	
1	0	0	0	0	$\frac{2}{3}$	$\frac{1}{3}$	$\frac{14}{3}$
0	0	0	0	1	-1	1	5
0	0	1	-1	0	$\frac{1}{3}$	$\frac{2}{3}$	$\frac{13}{3}$
0	1	0	0	0	$-\frac{1}{3}$	$\frac{1}{3}$	$\frac{2}{3}$
0	0	0	0	0	1	3	19

Since there is no more negative entry in the last row, the cost cannot be lowered by choosing a different set of basic variables; the termination condition applies.

5. Step 5: Read off the solution

   The solution represented by the final tableau has all non-basic variables set to zero, while the values for the basic variables can be can be read off the right hand column. The bottom right corner gives the negative of the objective function.

   In our example, the solution reads $x_1=\frac{14}{3}$, $x_2=\frac{2}{3}$, $x_3=u=\frac{13}{3}$, $s_1=5$, $v=s_2=s_3=0$, which corresponds to $\zeta=-19$, which can be independently checked by plugging the solution back into the objective function.

   As a further check, we notice that the solution must satisfy the initial equation and inequations. This can obviously be checked by direct computation.

In summary, any LP once put in standard form is such that:

- There is a square sub-matrix of matrix A, which is named the "base matrix" and is equal to the square unit matrix $\mathbb{1}$ of size m (indeed there are as many slack variables that lines in the original equations - at the number of m - and as many columns as each slack variable has a different index).
- The basic variables involved does not appear in the expression of the economic function.
- The second member of the constraints consists of non-negative values.

We say then that the problem is put under a "a canonical form associated with the basis B, corresponding to the basis variables $x_{n+1},x_{n+2},\ldots,x_{n+m}$".

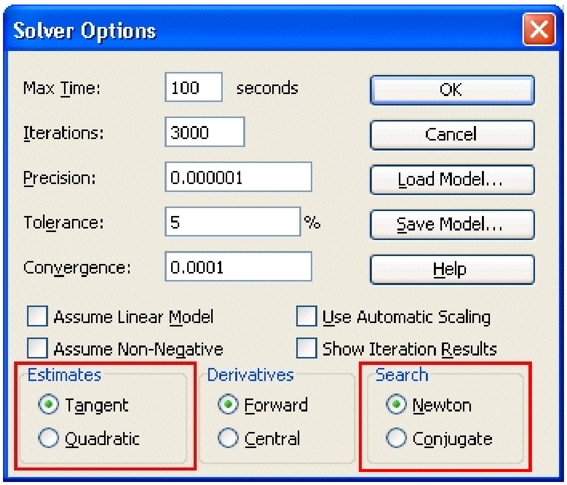
14.1.17.2 Nonlinear programming (Nonlinear optimization)

Nonlinear programming is the process of solving an optimization problem defined by a system of equalities and inequalities, collectively termed constraints, over a set of unknown real variables, along with an objective function to be maximized or minimized, where some of the constraints or the objective function are non-linear.

A non-linear optimization program (NLOP) is a generalization of linear programming (simplex algorithm) but about non-linear functions and can also include non-linear constraints and non-linear economic functions.

The purpose of what follows is to understand in outline but with an acceptable level of rigour the optimization tools that offer many spreadsheets softwares like the previous versions of

Microsoft® Excel® to the version 2007 (since the version 2007 we cannot make a fine-tuning of these options anymore):



Max Time: 100 seconds

Iterations: 3000

Precision: 0.000001

Tolerance: 5 %

Convergence: 0.0001

☐ Assume Linear Model ☐ Use Automatic Scaling

☐ Assume Non-Negative ☐ Show Iteration Results

Estimates: ● Tangent ○ Quadratic

Derivatives: ● Forward ○ Central

Search: ● Newton ○ Conjugate

Figure 14.83: **Microsoft® Excel® 2003 Solver options**

We will especially see now in what consist the *Newton* Search (meaning implicitly: "Gauss-Newton's method") with the *Tangent* and *Quadratic* estimates. After which we will study also the Conjugate Gradients Search also with the tangent and quadratic methods respectively.

Remark

We will stop at the study of the above cited models because there is an excessive quantity of empirical models such as for example the best known models (algorithms): substitution method, method of Lagrange multipliers, Nelder-Mead algorithm, Broyden-Fletcher-Goldfarb-Shanno (BFGS) algorithm, algorithm of simultaneous annihilation (SA), methods of interior points... and see Wikipedia for a more complete list (there are over a dozen of methods without taking into account the variations including empirical adjustments).

We will see it further below, but we already guess that the choice *Tangent* use a linear approximation (tangent) of the function to be optimized at the point considered when at the opposite the *Quadratic* option will make an estimation of a function of the second degree at the considered point (typically a parabola). If at the considered point, the function is well modelled by a quadric, then the *Quadratic* option can save time by choosing a better starting point that will require fewer steps on each additional research. If you have no idea of the behaviour of the a priori function, then the *Tangent* option is slower but safer.

A well known example in the literature to introduce the search of optimums of non-linear functions, before moving on to the part taking into account constraints on the system, is the "hump-back whale function" of that consist to find the minimum of:

$$x_1^2\left(4-2.1x^2+\frac{1}{3}x_1^4\right)+x_1x_2+x_2^2(-4+4x_2^2) \qquad (14.1.1374)$$

With the range constraints:

$$\begin{gathered}-2\geq x_1\geq 2\\ -1\geq x_2\geq 1\end{gathered} \qquad (14.1.1375)$$

what we can indeed check visually:

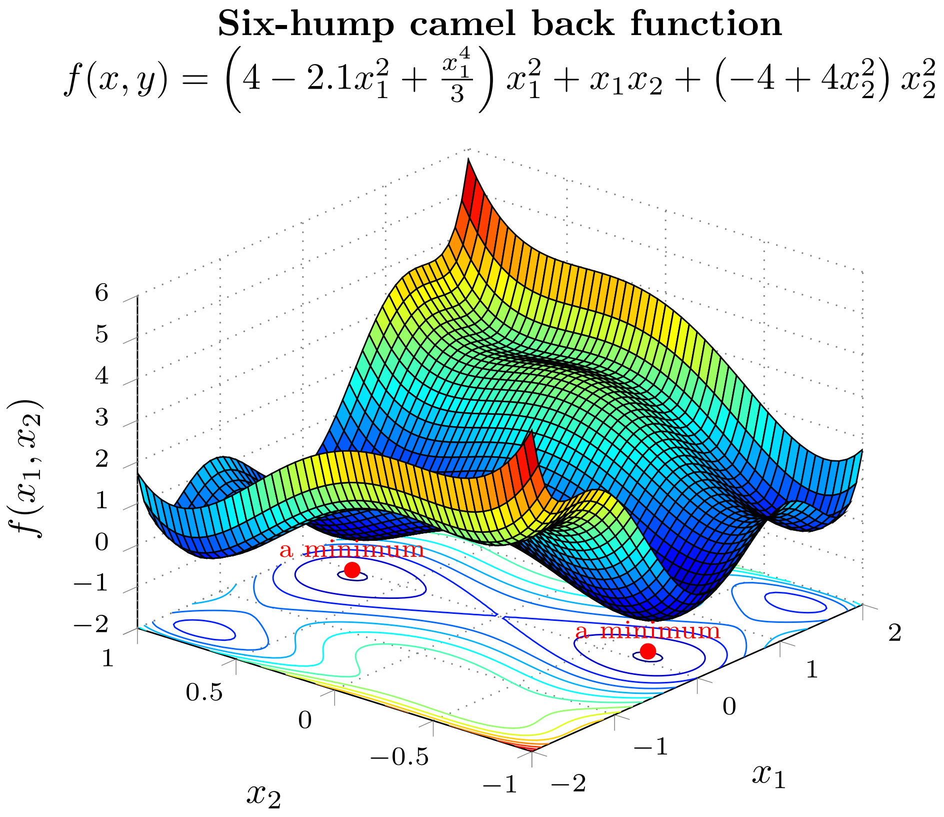


Figure 14.84: Plot of the humpback whale function with minima already visible made with TikZ/pgfplot/gnulplot (authors: Vincent Isoz, Jasper Habicht)

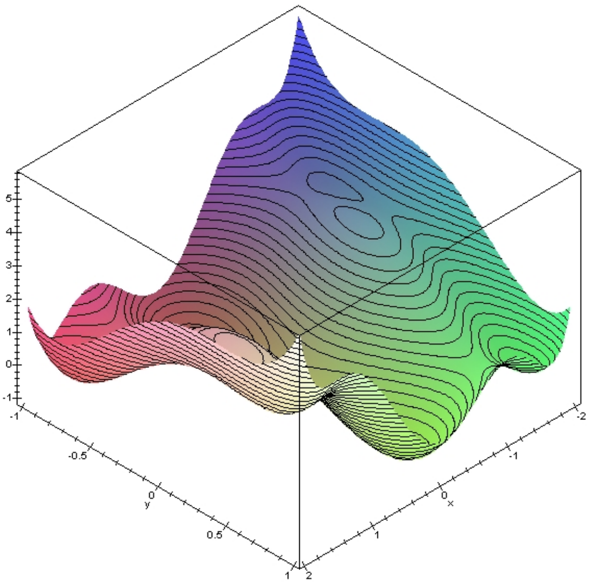
Either with Maple™ 4.00b:

```
>plot3d(x^2*(4-2.1*x^2+1/3*x^4)+x*y+y^2*(-4+4*y^2),
x=-2..2,y=-1..1,contours=20,style=patchcontour,axes=boxed);
```

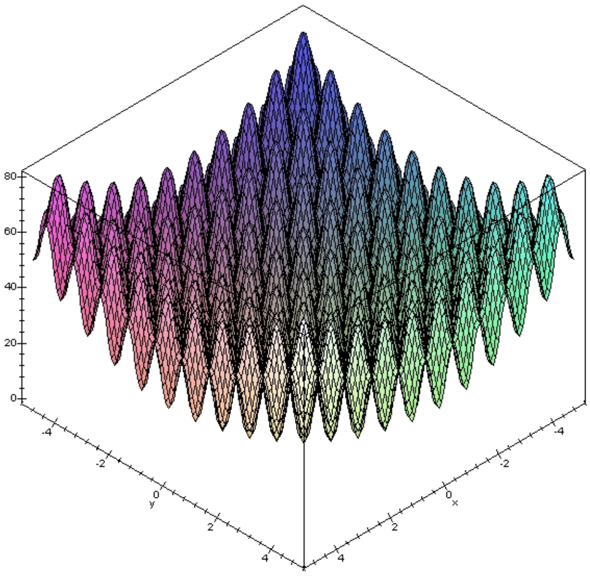
That gives:



As we can see, this function is a great example of multiple local minimum but there is also a must more vicious one that we will refer to when we will study evolutionary algorithms, the "Rastgrini's function":

```
>plot3d(20+x^2+y^2-10*(cos(2*Pi*x)+cos(2*Pi*y)),
x=-5..5,y=-5..5,contours=20,style=patch,axes=boxed,numpoints=10000);
```

That gives:



14.1.17.2.1 Substitution Method

The least complex method for solving a non-linear programming problem is named the "substitution method".

This method is restricted to models containing a single constraint and must be in addition to the equality type.

Let us consider a companion example by considering the following economic function to maximize:

$$\max Z = 4x_1 - 0.1x_1^2 + 5x_2 - 0.2x_2^2 \qquad (14.1.1376)$$

with the constraint (remember that it must be an equality !!!):

$$x_1 + 2x_2 = 40 \qquad (14.1.1377)$$

The first step is then to arbitrarily substitute:

$$x_1 = 40 - 2x_2 \qquad (14.1.1378)$$

into the economic function to get:

$$\begin{aligned}Z &= 4(40-2x_2) - 0.1(40-2x_2)^2 + 5x_2 - 0.2x_2^2\\ &= 160 - 8x_2 - 0.1(1600 - 160x_2 + 4x_2^2) + 5x_2 - 0.2x_2^2\\ &= 160 - 8x_2 - 160 + 16x_2 - 0.4x_2^2 + 5x_2 - 0.2x_2^2\\ &= 13x_2 - 0.6x_2^2\end{aligned} \qquad (14.1.1379)$$

This therefore brings us back to a function to be maximized which is unconstrained, so we can differentiate it and put it as zero. Then it comes:

$$\frac{\partial Z}{\partial x_2} = 13 - 1.2x_2 = 0 \qquad (14.1.1380)$$

that gives:

$$x_2 = 10.8 \qquad (14.1.1381)$$

From this we can deduce immediately that:

$$x_1 = 18.4 \qquad (14.1.1382)$$

By injecting those two values in the economic function, we then have:

$$Z = 4x_1 - 0.1x_1^2 + 5x_2 - 0.2x_2^2 = 70.42 \qquad (14.1.1383)$$

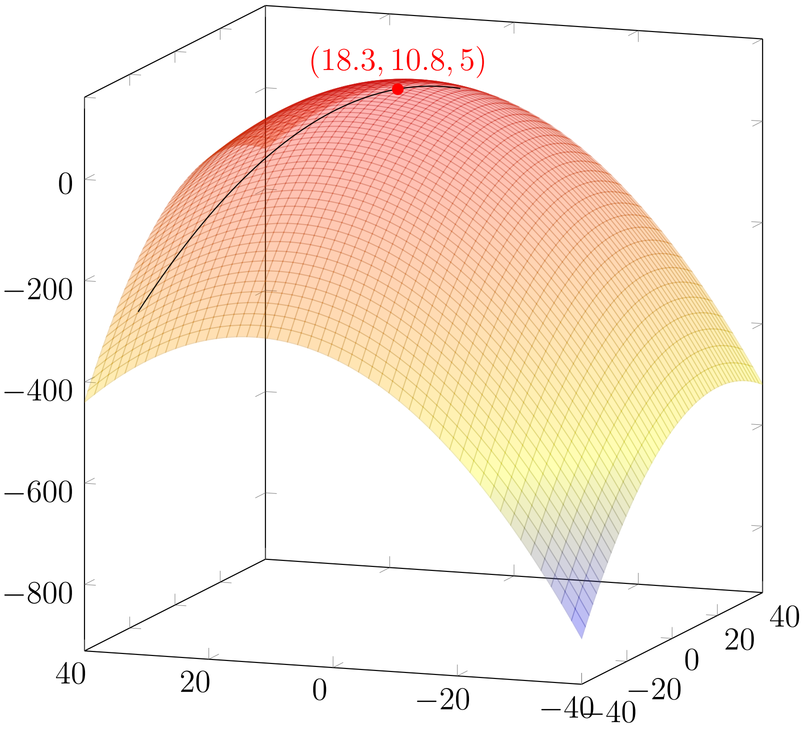


Figure 14.85: **Substitution method example plotted**

We see by this example very quickly the limitations of this technique. The first being that the economic function was not too complex, the final equation to solve was therefore not a problem, the second being that there were only two variables, the third being that the constraint must be an equality as we have already mentioned.

14.1.17.2.2 Lagrange Multipliers Method

The "Lagrange multipliers method" is a rather general technique for solving non-linear programming problems with one or more constraints with linear or non linear economic function with inequalities (rather than strict equations only) and with more than two variables (for other examples than those presented here the reader can go to the corresponding page of Wikipedia).

We will begin to introduce this technique with a simple case which consists of taking again the example used during our study of the method of substitution:

$$\begin{aligned} \underset{\vec{x}}{\text{maximise}} \quad & Z = 4x_1 - 0.1x_1^2 + 5x_2 - 0.2x_2^2 \\ \text{subject to} \quad & x_1 + 2x_2 = 40 \end{aligned} \tag{14.1.1384}$$

The first step is to write the constraint function in Lagrangian form as we do in Analytical Mechanics (see section Analytical Mechanics page 3162) at the difference that there are no general variables depending on the time:

$$\frac{\partial L}{\partial q_i} - \underbrace{\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{q}_i}}_{=0} = 0 \tag{14.1.1385}$$

For this, we write first:

$$x_1+2x_2-40=0 \tag{14.1.1386}$$

Then the idea is that since this expression is null, nothing prevents us from summing it or subtracting it from the economic function with why not an empirical multiplier that we will denote λ and which we will name the "Lagrange multiplier".

It comes then if we choose to subtract for example (in fact the choice of the subtraction is made by anticipation of an interpretation of the Lagrange multiplier that we will see immediately after):

$$L=4x_1-0.1x_1^2+5x_2-0.2x_2^2-\lambda(x_1+2x_2-40)=0 \tag{14.1.1387}$$

Which gives us our Lagrangian function. In generic form the latter is often written as following:

$$\boxed{L(\vec{x},\lambda)=f(\vec{x})+\lambda(g(\vec{x})-c)} \tag{14.1.1388}$$

Now the idea is to determine the values of the variables where the partial derivatives of the Lagrangian with respect to the variables vanish at the same time (corresponding in Analytical Mechanics as the sum of all the Lagrangians relatively to one variable to be equal to zero):

$$\begin{aligned}\frac{\partial L}{\partial x_1}&=4-0.2x_1-\lambda=0\\ \frac{\partial L}{\partial x_2}&=5-0.4x_2-2\lambda=0\\ \frac{\partial L}{\partial \lambda}&=-x_1-2x_2+40=0\end{aligned} \tag{14.1.1389}$$

What is generally written as:

$$\boxed{\vec{\nabla}_{\vec{x},\lambda}(L(\vec{x},\lambda))=\vec{0}} \tag{14.1.1390}$$

We therefore have a system of three equations with three unknowns which we know trivially how to solve (see section Linear Algebra page 1929). We then get as solutions:

$$\begin{aligned}x_1&=18.3\\ x_2&=10.8\\ \lambda&=0.33\end{aligned} \tag{14.1.1391}$$

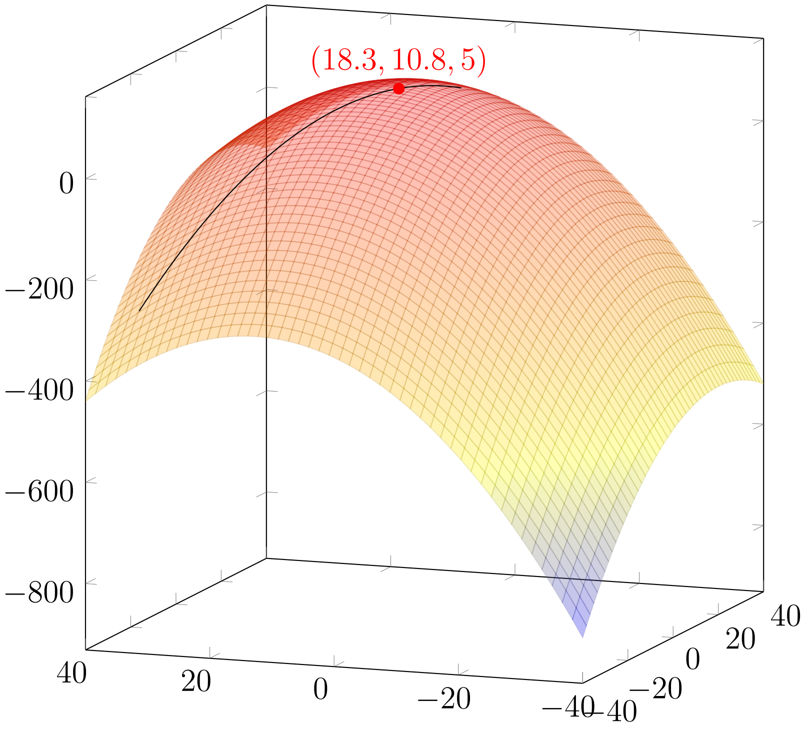

Figure 14.86: Lagrange multiplier example plotted

Notice that if we had not taken into consideration λ and therefore that implicitly that latter had been equal to 1 since the beginning, we would have had the following system of equations:

$$\begin{aligned}\frac{\partial L}{\partial x_1}&=4-0.2x_1^2-1=0\\ \frac{\partial L}{\partial x_2}&=5-0.4x_2-2=0\end{aligned}\tag{14.1.1392}$$

and therefore we would not have obtained the results of the substitution method seen previously ... hence the multiplicative factor!

The final value of Z is then the same as for the substitution method taking into account λ!!!

Although the Lagrange multiplier method is powerful, its increasing complexity with a large number of variables makes it a difficult tool to manipulate in practice.

We will now focus on the interpretation of λ. As we shall see, the latter represents the local variation rate per unit of positive variation of the constant of the constraint function. Thus, if the constraint function becomes (we have changed the 40 into a 41):

$$\begin{aligned}\underset{\vec{x}}{\text{maximise}}\quad & Z=4x_1-0.1x_1^2+5x_2-0.2x_2^2\\ \text{subject to}\quad & x_1+2x_2=41\end{aligned}\tag{14.1.1393}$$

By doing again the same calculations as before, we then get:

$$x_1=18.7\qquad x_2=11.2\qquad \lambda=0.27\qquad Z=70.75\tag{14.1.1394}$$

Therefore, by having increased of one unit the constant of the constrained function, we have:

$$\Delta Z = 0.33 = \lambda \tag{14.1.1395}$$

In general, if the Lagrange multiplier is positive, then the economic function will increase if the constant of the constraint is also incremented positively and vice versa.

Let us now consider a case much more elaborated and useful for our study of Economics (especial Portfolio Optimization). We want to solve by the method of the Lagrange multipliers the Markowitz portfolio problem (see section Economy page 7699) but without the risk free asset (we will do that later case in the section of Economy!):

$$\begin{aligned} \underset{\mathrm{V}(R_P)}{\text{minimize}} \quad & \mathrm{E}(R_P) = c^{te} \\ \text{subject to} \quad & \sum X_i = 1 \end{aligned} \tag{14.1.1396}$$

with for recall:

$$\mathrm{V}(R_P) = X^T c_{ij} X = \sum_{i=1}^{n} \sum_{j=1}^{n} X_i X_j \operatorname{cov}(R_i, R_j) \tag{14.1.1397}$$

To facilitate the developments that will follow we will write this system with the following quite ugly traditional notation (for the details on the notations see the section Economy):

$$\begin{gathered} \min \sigma_P = \sum_{i,j}^{n} w_i w_j \sigma_{ij} = \vec{w}^T \Sigma \vec{w} \\ \sum_{i=1}^{n} w_i \mu_i - \mu_P = \vec{w}^T \vec{\mu} - \mu_P = 0 \\ \sum_{i=1}^{n} w_i - 1 = \vec{w} \cdot \vec{1} - 1 = \vec{w} 1 - 1 = 0 \end{gathered} \tag{14.1.1398}$$

The Lagrangian function will therefore be written by adding the three constraints above:

$$L(\vec{w}, \lambda_1, \lambda_2) = \vec{w}^T \Sigma \vec{w} - \lambda_1 (\vec{w}^T \vec{\mu} - \mu_P) - \lambda_2 (\vec{w}^T 1 - 1) \tag{14.1.1399}$$

Therefore:

$$L(\vec{w}, \lambda_1, \lambda_2) = \vec{w}^T \Sigma \vec{w} + \lambda_1 (\mu_P - \vec{w}^T \vec{\mu}) - \lambda_2 (1 - \vec{w}^T 1) \tag{14.1.1400}$$

Now we calculate:

$$\vec{\nabla}_{\vec{w}, \lambda_1, \lambda_2} (L(\vec{w}, \lambda_1, \lambda_2)) = \vec{0} \tag{14.1.1401}$$

This gives us the system of three equations:

$$\begin{aligned} \frac{\partial L}{\partial \vec{w}} &= 2\Sigma \vec{w} - \lambda_1 \vec{\mu} - \lambda_2 1 = 0 \\ \frac{\partial L}{\partial \lambda_1} &= \mu_P = \vec{w}^T \vec{\mu} = 0 \\ \frac{\partial L}{\partial \lambda_2} &= 1 - \vec{w}^T 1 = 0 \end{aligned} \tag{14.1.1402}$$

By rearranging the first equation:

$$2\Sigma\vec{w}-\lambda_1\vec{\mu}-\lambda_1\vec{\mu}-\lambda_2 1=0 \tag{14.1.1403}$$

We have:

$$\vec{w}=\frac{1}{2}\left(\lambda_1\Sigma^{-1}\vec{\mu}+\lambda_2\Sigma^{-1}1\right) \tag{14.1.1404}$$

Let us now take the two equations:

$$\begin{gathered}\mu_P-\vec{w}^T\vec{\mu}=0\Leftrightarrow\vec{w}^T\vec{\mu}=\mu_P\\ 1-\vec{w}^T1=0\Leftrightarrow\vec{w}^T1=1\end{gathered} \tag{14.1.1405}$$

Thus in an equivalent way:

$$\begin{gathered}\vec{\mu}^T\vec{w}=\mu_P\\ 1^T\vec{w}=1\end{gathered} \tag{14.1.1406}$$

By injecting in it the explicit relation of the weights of the portfolio, we have:

$$\begin{gathered}\vec{\mu}^T\vec{w}=\vec{\mu}^T\left(\frac{1}{2}(\lambda_1\Sigma^{-1}\vec{\mu}+\lambda_2\Sigma^{-1}1)\right)=\frac{1}{2}\left(\lambda_1(\vec{\mu}^T\Sigma^{-1}\vec{\mu})+\lambda_2(\vec{\mu}^T\Sigma^{-1}1)\right)=\mu_P\\ 1^T\vec{w}=1^T\left(\frac{1}{2}(\lambda_1\Sigma^{-1}\vec{\mu}+\lambda_2\Sigma^{-1}1)\right)=\frac{1}{2}\left(\lambda_1(1^T\Sigma^{-1}\vec{\mu})+\lambda_2(1^T\Sigma^{-1}1)\right)=1\end{gathered} \tag{14.1.1407}$$

We can put this system in matrix form:

$$\frac{1}{2}\begin{bmatrix}\vec{\mu}^T\Sigma^{-1}\vec{\mu} & \vec{\mu}^T\Sigma^{-1}1\\ 1^T\Sigma^{-1}\vec{\mu} & 1^T\Sigma^{-1}1\end{bmatrix}\begin{pmatrix}\lambda_1\\ \lambda_2\end{pmatrix}=\begin{pmatrix}\mu_P\\ 1\end{pmatrix} \tag{14.1.1408}$$

Which gives us:

$$\begin{aligned}\begin{pmatrix}\lambda_1\\ \lambda_2\end{pmatrix}&=2\begin{bmatrix}\vec{\mu}^T\Sigma^{-1}\vec{\mu} & \vec{\mu}^T\Sigma^{-1}1\\ 1^T\Sigma^{-1}\vec{\mu} & 1^T\Sigma^{-1}1\end{bmatrix}^{-1}\begin{pmatrix}\mu_P\\ 1\end{pmatrix}\\ &=2\frac{1}{(\vec{\mu}^T\Sigma^{-1}1)-(\vec{\mu}\Sigma^{-1}1)^2)}\begin{bmatrix}\vec{\mu}^T\Sigma^{-1}1 & -1^T\Sigma^{-1}1\\ -1^T\Sigma^{-1}1 & \vec{\mu}\Sigma^{-1}\vec{\mu}\end{bmatrix}\begin{pmatrix}\mu_P\\ 1\end{pmatrix}\end{aligned} \tag{14.1.1409}$$

Therefore:

$$\begin{aligned}\lambda_1&=2\frac{\vec{\mu}^T\Sigma^{-1}1\mu_P-1^T\Sigma^{-1}1}{(\vec{\mu}^T\Sigma^{-1}\vec{\mu})(1^T\Sigma^{-1}1)-(\vec{\mu}^T\Sigma^{-1}1)^2}\\ \lambda_2&=2\frac{-1^T\Sigma^{-1}1\mu_P+\vec{\mu}^T\Sigma^{-1}\vec{\mu}}{(\vec{\mu}^T\Sigma^{-1}\vec{\mu})(1^T\Sigma^{-1}1)-(\vec{\mu}^T\Sigma^{-1}1)^2}\end{aligned} \tag{14.1.1410}$$

So once we have the values of these two Lagrange multipliers, we just have to inject them into:

$$\vec{w}=\frac{1}{2}\left(\lambda_1\Sigma^{-1}\vec{\mu}+\lambda_2\Sigma^{-1}1\right) \tag{14.1.1411}$$

to get the weights that minimize the portfolio variance:

$$\boxed{\vec{w}=\frac{\left(\left(\vec{\mu}^T\Sigma^{-1}1\mu_P-1^T\Sigma^{-1}1\right)\Sigma^{-1}\vec{\mu}+\left(-1^T\Sigma^{-1}1\mu_P+\vec{\mu}^T\Sigma^{-1}\vec{\mu}\right)\Sigma^{-1}1\right)}{(\vec{\mu}^T\Sigma^{-1}\vec{\mu})(1^T\Sigma^{-1}1)-(\vec{\mu}^T\Sigma^{-1}1)^2}} \tag{14.1.1412}$$

So the reader will see during our study of Modern Portfolio management that getting the optimal weights (see page 7699) is much more easy using the Lagrange multiplier method (and less time consuming) than using a software optimizer!

Remark

By the way the attentive reader will perhaps have noticed that finally making all the development with the factor $1/2$ is useless since during the final substitution, the latter is neutralized with itself since 2 is multiplied by $1/2$.

14.1.17.2.3 Newton-Raphson Method (Quadratic Newton)

The "Newton-Raphson method", also named "Newton's method for unconstrained optimization", is a technique for searching the extremum of a function or also, as we will see it when we will compare with a special example the difference between the Gauss-Newton's method with that of Newton, for non-linear regression.

The Newton-Raphson, who in earlier versions to Microsoft® Excel® 2007 was activated in the solver by selecting Newton and Quadratic option uses the second order Taylor approximation (i.e. with second order derivatives) to have a quadratic function (parabola) which converges if the origin point of the research is close to the optimum. This approximation is repeated to each iteration.

To start the formal approach let us recall that we have proved in the section Sequences and Series that a Taylor expansion for a function of two variables could be written in quadratic approximation by:

$$f(x_0+h,y_0+k)=f(x_0,y_0)+\frac{\partial f}{\partial x}(x_0,y_0)h+\frac{\partial f}{\partial y}(x_0,y_0)k+\frac{1}{2}(h \quad k)H\begin{pmatrix}h\\k\end{pmatrix} \tag{14.1.1413}$$

where for recall h and k are variables and x_0, y_0 are fixed and where we have the Hessian matrix (see section Sequences and Series page 1715):

$$\begin{pmatrix}\dfrac{\partial^2 f}{\partial x^2} & \dfrac{\partial^2 f}{\partial x\partial y}\\ \dfrac{\partial^2 f}{\partial x\partial y} & \dfrac{\partial^2 f}{\partial y^2}\end{pmatrix} \tag{14.1.1414}$$

that USA experts in the field have the habit (unfortunate in my opinion ...) to denote:

$$H=\left[\frac{\partial^2 f}{\partial x_i\partial x_j}\right]_{ij}=\left[\vec{\nabla}\right]=\vec{\nabla}^2 f \tag{14.1.1415}$$

the latter expression being the most common can be very misleading with the notation of the Laplacian...

In the field of numerical methods it is customary to write the Taylor series above with few notations changes by putting first:

$$\begin{aligned}&x_0+h=x\Rightarrow h=x-x_0\\&y_0+k=y\Rightarrow k=y-y_0\\&\begin{pmatrix}x_0\\y_0\end{pmatrix}+\begin{pmatrix}h\\k\end{pmatrix}=\begin{pmatrix}x_0+h\\y_0+k\end{pmatrix}=\vec{x}_0+\begin{pmatrix}h\\k\end{pmatrix}=\vec{x}\Rightarrow\begin{pmatrix}j\\k\end{pmatrix}=\vec{x}-\vec{x}_0\\&=\vec{\nabla}=\begin{pmatrix}\partial_x\\\partial_y\end{pmatrix}\end{aligned} \tag{14.1.1416}$$

This gives us a more condensed and technical form of the Taylor series around $\vec{x}$:

$$f(\vec{x})\cong f(\vec{x}_0)+\vec{\nabla}(f(\vec{x}_0))(\vec{x}-\vec{x}_0)+\frac{1}{2}(\vec{x}-\vec{x}_0)^T H(\vec{x}_0)(\vec{x}-\vec{x}_0) \tag{14.1.1417}$$

By changing again a little bit the notations:

$$f(\vec{x}) \cong f(\vec{x}_i) + \vec{\nabla}(f(\vec{x}_i))(\vec{x} - \vec{x}_i) + \frac{1}{2}(\vec{x} - \vec{x}_i)^T H(\vec{x}_i)(\vec{x} - \vec{x}_i) \qquad (14.1.1418)$$

We thus fall back on the usual expression of a function of $\mathbb{R}^2 \rightarrow \mathbb{R}$ evaluated in Taylor series centered on $\vec{x}$.

But if we seek for a local extrema (also sometimes named "critical point"), we will need in first time that the derivative of the whole Taylor series be equal to zero. That is to say:

$$\vec{\nabla}\left(f(\vec{x})\right) = \begin{pmatrix} \partial_x f(\vec{x}) \\ \partial_y f(\vec{x}) \end{pmatrix} \cong \vec{\nabla}\left(f(\vec{x}_i) + \vec{\nabla}(f(\vec{x}_i))(\vec{x} - \vec{x}_i) + \frac{1}{2}(\vec{x} - \vec{x}_i)^T H(\vec{x}_i)(\vec{x} - \vec{x}_i)\right) = \vec{0} \qquad (14.1.1419)$$

and that the determinant of the Hessian matrix is positive (see section Sequences and Series page 1715). And to know if we are on a local maximum or local minimum, we must look at the sign of $\partial_x^2 f(\vec{x})$.

Let us rewrite the above relation explicitly as we proved it in the section of Sequences and Series for pedagogical reasons:

$$\begin{aligned} f(x_0+h, y_0+k) = f(x_0, y_0) &+ \frac{1}{1!}\frac{\partial f}{\partial x}(x_0, y_0)h + \frac{1}{1!}\frac{\partial f}{\partial y}(x_0, y_0)k \\ &+ \frac{1}{2!}\left[\frac{\partial^2 f}{\partial x^2}(x_0, y_0)h^2 + 2\frac{\partial^2 f}{\partial x \partial y}(x_0, y_h)hk + \frac{\partial^2 f}{\partial y^2}(x_0, y_0)k^2\right] \end{aligned} \qquad (14.1.1420)$$

And let us recall that all terms x_0, y_0 are constants because it is either the function f evaluated the particular point (x_0, y_0), or the partial derivative evaluated at the same point, either the partial second derivative always evaluated at the same point, etc.

So finally the gradient will give:

$$\begin{aligned} \vec{\nabla}\left(f(x_0+h, y_0+h)\right) &= \begin{pmatrix} \partial_h f(x_0+h, y_0+h) \\ \partial_k f(x_0+h, y_0+h) \end{pmatrix} \\ &= \begin{pmatrix} \underbrace{\partial_h f(x_0, y_0)}_{=0} + \underbrace{\partial_h(\partial_x f(x_0, y_0)h)}_{=\partial_x f(x_0,y_0)} + \underbrace{\partial_h(\partial_y f(x_0, y_0)k)}_{=0} + \underbrace{\frac{1}{2}\partial_h(\partial_x^2 f(x_0, y_0)h^2)}_{=\partial_x^2 f(x_0,y_0)h} \\ + \underbrace{\frac{1}{2}\partial_h\left(\partial_{xy}^2 f(x_0, y_0)hk\right)}_{=\frac{1}{2}\partial_{xy}^2 f(x_0,y_0)k} + \underbrace{\frac{1}{2}\partial_h\left(\partial_y^2 f(x_0, y_0)k^2\right)}_{=0} \\ \underbrace{\partial_k f(x_0, y_0)}_{=0} + \underbrace{\partial_k(\partial_x f(x_0, y_0)h)}_{=0} + \underbrace{\partial_k(\partial_y f(x_0, y_0)k)}_{=\partial_y f(x_0,y_0)} + \underbrace{\frac{1}{2}\partial_k(\partial_x^2 f(x_0, y_0)h^2)}_{=0} \\ + \underbrace{\frac{1}{2}\partial_k\left(\partial_{xy}^2 f(x_0, y_0)hk\right)}_{=\frac{1}{2}\partial_{xy}^2 f(x_0,y_0)h} + \underbrace{\frac{1}{2}\partial_k\left(\partial_y^2 f(x_0, y_0)k^2\right)}_{=\partial_y^2 f(x_0,y_0)k} \end{pmatrix} \\ &= \begin{pmatrix} \partial_x f(x_0, y_0) + \partial_x^2 f(x_0, y_0)h + \frac{1}{2}\partial_{xy}^2 f(x_0, y_0)k \\ \partial_y f(x_0, y_0) + \partial_y^2 f(x_0, y_0)k + \frac{1}{2}\partial_{xy}^2 f(x_0, y_0)h \end{pmatrix} = \vec{\nabla}\left(f(x_0, y_0)\right) + H\begin{pmatrix} h \\ h \end{pmatrix} \end{aligned} \qquad (14.1.1421)$$

and returning traditional notations in the field of numerical methods, we have then:

$$\vec{\nabla}\left(f(\vec{x})\right)=\vec{\nabla}\left(f(\vec{x}_i)\right)+H(\vec{x}_i)(\vec{x}-\vec{x}_i) \tag{14.1.1422}$$

And so as the gradient has to be equal zero, we have:

$$\vec{\nabla}\left(f(\vec{x}_i)\right)+H(\vec{x}_i)(\vec{x}-\vec{x}_i)=\vec{0} \tag{14.1.1423}$$

and after a first rearrangement:

$$H^{-1}(\vec{x}_i)\vec{\nabla}\left(f(\vec{x}_i)\right)+\vec{x}-\vec{x}_i=\vec{0} \tag{14.1.1424}$$

and a second rearrangement:

$$\boxed{\vec{x}=\vec{x}_i-H^{-1}(\vec{x}_i)\vec{\nabla}\left(f(\vec{x}_i)\right)} \tag{14.1.1425}$$

which is often written:

$$\vec{x}_{i+1}=\vec{x}_i-H^{-1}(\vec{x}_i)\vec{\nabla}\left(f(\vec{x}_i)\right) \tag{14.1.1426}$$

and by USA specialists in the field:

$$\vec{x}_{i+1}=\vec{x}_i-\left[\vec{\nabla}^2 f(\vec{x}_i)\right]^{-1}(\vec{x}_i)\vec{\nabla}\left(f(\vec{x}_i)\right) \tag{14.1.1427}$$

Finally, before moving on to a concrete example it is important that the reader remembers the relation just seen above:

$$\vec{\nabla}\left(f(\vec{x}_i)\right)+H(\vec{x}_i)(\vec{x}-\vec{x}_i)=\vec{0}\Rightarrow-\vec{\nabla}\left(f(\vec{x}_i)\right)=H(\vec{x}_i)(\vec{x}-\vec{x}_i) \tag{14.1.1428}$$

✍**Example:**

We are seeking a local extremum of the "humpback whale" function shown earlier above:

$$f(x,y)=x^2\left(4-2.1x^2+\frac{1}{3}x^4\right)+xy+y^2\left(-4+4y^2\right) \tag{14.1.1429}$$

with the starting point (arbitrary):

$$\vec{x}_0=\begin{pmatrix}1\\1\end{pmatrix} \tag{14.1.1430}$$

To do the search, we calculate the gradient:

$$\vec{\nabla}(f(\vec{x}_i))=\begin{pmatrix}\partial_x f(\vec{x}_i)\\ \partial_y f(\vec{x}_i)\end{pmatrix}=\begin{pmatrix}8x_1-8.4x_i^3+2x_i^5+y_i\\ x_i-8y_i+16y_i^3\end{pmatrix} \tag{14.1.1431}$$

and the Hessian matrix:

$$H(\vec{x}_i)=\begin{bmatrix}\partial_x^2 f(x_i,y_i) & \partial_{xy}^2 f(x_i,y_i)\\ \partial_{xy}^2 f(x_i,y_i) & \partial_y^2 f(x_i,y_i)\end{bmatrix}=\begin{bmatrix}8-25.2x_i^2+10x_i^4 & 0\\ 0 & -8+48y_i^2\end{bmatrix} \tag{14.1.1432}$$

We then have:

$$\vec{\nabla}(f(\vec{x}_0))=\begin{pmatrix}\partial_x f(x_0)\\ \partial_y f(y_0)\end{pmatrix}=\begin{pmatrix}\partial_x f(1)\\ \partial_y f(1)\end{pmatrix}=\begin{pmatrix}9x_0-8.4x_0^3+2x_0^5+y_0\\ x_0-8y_0+16y_0^3\end{pmatrix}=\begin{pmatrix}2.60\\ 9.00\end{pmatrix} \tag{14.1.1433}$$

and:

$$H(\vec{x}_0)=\begin{bmatrix}\partial_x^2 f(x_0,y_0) & \partial_{xy}^2 f(x_0,y_0)\\ \partial_{xy}^2 f(x_0,y_0) & \partial_y^2 f(x_0,y_0)\end{bmatrix}=\begin{bmatrix}8-25.2x_0^2+10x_0^4 & 0\\ 0 & -8+48y_0^2\end{bmatrix}= \begin{bmatrix}-7.20 & 0\\ 0 & 40.00\end{bmatrix} \tag{14.1.1434}$$

and:

$$H^{-1}(\vec{x}_0)=\begin{bmatrix}-7.20 & 0\\ 0 & 40.00\end{bmatrix}^{-1}=\begin{bmatrix}-0.138 & 0\\ 0 & 0.025\end{bmatrix} \tag{14.1.1435}$$

and therefore:

$$\vec{x}_1=\vec{x}_0-H^{-1}\vec{\nabla}(f(\vec{x}_0))=\begin{pmatrix}1\\1\end{pmatrix}\begin{bmatrix}-0.138 & 0\\ 0 & 0.025\end{bmatrix}\begin{pmatrix}2.60\\ 9.00\end{pmatrix}=\begin{pmatrix}1.361\\ 0.775\end{pmatrix} \tag{14.1.1436}$$

and we start again (with less detail):

$$\vec{\nabla}(f(\vec{x}_2))=\begin{pmatrix}-0.01\\ 0.51\end{pmatrix} \tag{14.1.1437}$$

and:

$$\begin{aligned} H(\vec{x}_2) &= \begin{pmatrix} -5.52 & 0 \\ 0 & 12.26 \end{pmatrix} \\ H^{-1}(\vec{x}_2) &= \begin{pmatrix} -0.181 & 0 \\ 0 & 0.081 \end{pmatrix} \end{aligned} \tag{14.1.1438}$$

Therefore:

$$\vec{x}_3 = \vec{x}_2 - H^{-1}(\vec{x}_2)\vec{\nabla}(f(\vec{x}_2)) = \begin{pmatrix} 1.303 \\ 0.608 \end{pmatrix} \tag{14.1.1439}$$

and once again (with again less details):

$$\begin{aligned} \vec{\nabla}(f(\vec{x}_3)) &= \begin{pmatrix} -0.04 \\ 0.03 \end{pmatrix} \\ H^{-1}(\vec{x}_3) &= \begin{bmatrix} -0.167 & 0 \\ 0 & 0.102 \end{bmatrix} \end{aligned} \tag{14.1.1440}$$

and therefore:

$$\vec{x}_4 = \vec{x}_3 - H^{-1}(\vec{x}_3)\vec{\nabla}(f(\vec{x}_3)) = \begin{pmatrix} 1.296 \\ 0.604 \end{pmatrix} \tag{14.1.1441}$$

and again (with even less detail):

$$\vec{x}_5 = \vec{x}_4 - H^{-1}(\vec{x}_4)\vec{\nabla}(f(\vec{x}_4)) = \begin{pmatrix} 1.296 \\ 0.605 \end{pmatrix} \tag{14.1.1442}$$

and values will not move anymore. But if we look at the original graphic where we highlighted the convergence point by a red point:

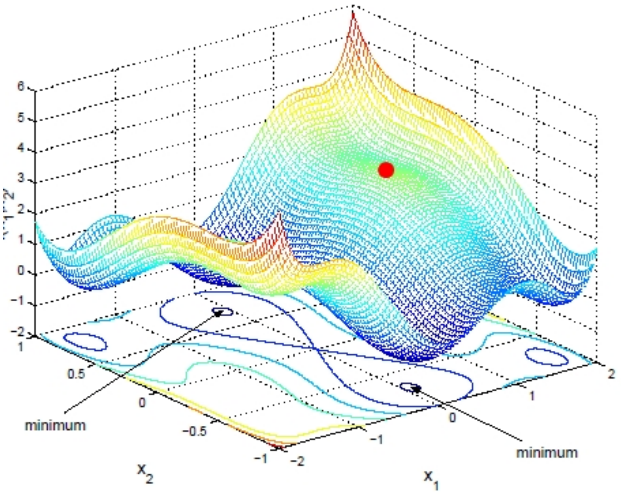

Figure 14.87: **Highlight of the convergence point in the humpback whale function**

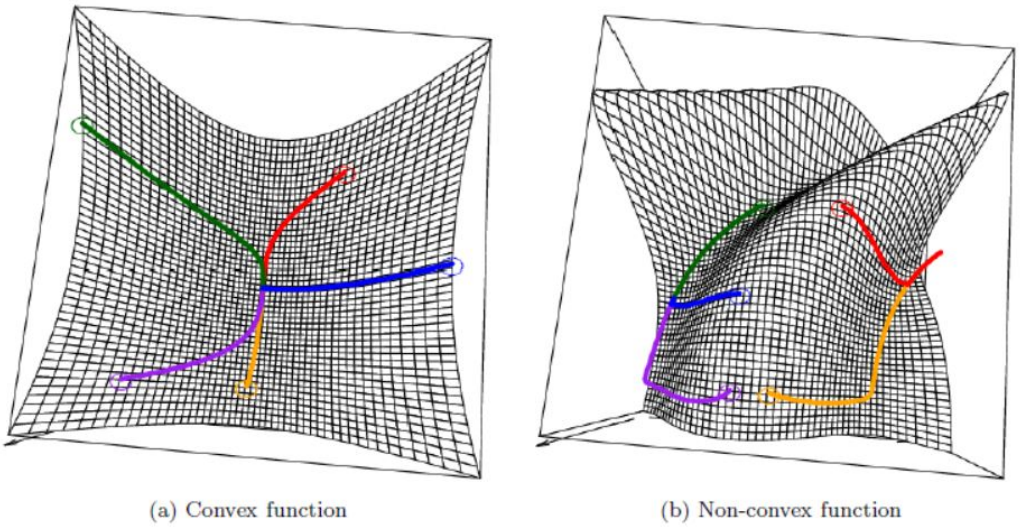
we see that this system does not search a global extremum but a local extremum as we already specified it. In fact, as the reader may test itself, convergence is very sensitive to initial starting point.

Keep really in mind that this method (and also the next one) works well only for smooth convex optimization problem (obviously twice differentiable and the opposite of the next method that need to be only once differentiable):



(a) Convex function (b) Non-convex function

Figure 14.88: Optimization paths with different starting points are illustrated in different colours. In the case of strictly convex function (Figure a.), the paths starting from any points all lead to the global optimum. Conversely, in the case of non-convex function, different paths may end up at different local optima!

Here is the corresponding pseudocode:

```
Algorithm 13: Newton-Raphson method (quadratic Newton)
Input: $f:\mathbb{R}^n \rightarrow \mathbb{R}$ a twice-differentiable function
       $\vec{x}_0 \in \mathbb{R}^n$ an initial solution
       $\varepsilon$ is a tolerance value
for $k$ to maxiter do
    Compute $\vec{\nabla} f\left(\vec{x}_k\right)$;
    Compute $H^{-1}\left(\vec{x}_k\right)$;
    Update $\vec{x}_{k+1} \leftarrow \vec{x}_k - H^{-1}\left(\vec{x}_k\right) \vec{\nabla} f\left(\vec{x}_k\right)$;
    if $\left\|f\left(\vec{x}_{k+1}\right) - f\left(\vec{x}_k\right)\right\| < \varepsilon$ or $\left\|\vec{\nabla} f\left(\vec{x}_k\right)\right\| < \varepsilon$ then
        Converged. Print $\vec{x}^* \leftarrow \vec{x}_{k+1}$ and $f\left(\vec{x}^*\right) \leftarrow f\left(\vec{x}_{k+1}\right)$;
```

14.1.17.2.4 Gauss-Newton method's (Tangent Newton)

The Gauss-Newton's method is a powerful approximation without the derivatives of the second order of the Newton-Raphson method that in the prior versions of Microsoft® Excel® 2007 was activated in the solver by selecting the option *Newton* and *Tangent*.

To study this method, let us do use a companion concrete example! Suppose we obtained the following data:

t_i	y_i
1	3.2939
2	4.2699
4	7.1749
5	9.3008
8	20.259

and we suppose "a priori" that the data follow the following theoretical model (we could also try any other function):

$$y_i \cong x_1 e^{x_2 t_i} \qquad (14.1.1443)$$

We look then for x_1, x_2 that minimize the sum of squares (the square of the euclidean distance - L^2 - that is obviously not the only choice of distance in practice!) between the experimental and theoretical values such that:

$$\min_{x_1,x_2} f(x_1,x_2) = \sum_{i=1}^{5} (x_1 e^{x_2 t_i} - y_i)^2 = \sum_{i=1}^{5} (y_i - x_1 e^{x_2 t_i})^2 \qquad (14.1.1444)$$

with therefore:

$$f_i(x_1,x_2) = f_i(\vec{x}) = x_1 e^{x_2 t_i} - y_i \qquad (14.1.1445)$$

The previous relation is also sometimes (especially in the field of Machine Learning) denoted as following (but with a notation quite generalized):

$$\boxed{J(\vec{\omega}) = \frac{1}{2}\sum_i \left(y_i(\vec{x}) - \phi_i(\vec{\omega},\vec{x})\right)^2} \qquad (14.1.1446)$$

and named the "cost function". The $1/2$ is here by anticipation to eliminate a useless factor 2 that will appear later below (as it change nothing to the result of minimization anyway!). The way to put a problem in this form and minimize the cost function is generally named a "least square optimization problem" or in finance and ecology a "model calibration" (that will result to a "calibrated model"...).

Remark

We can also use this method to just minimize a function:

$$\min_{\vec{x}} f(\vec{x}) \qquad (14.1.1447)$$

without using any sum of square. This depends on the problem! The methods remains exactly the same.

Let us write (following the tradition in the field of optimization):

$$F(\vec{x}) = \begin{pmatrix} f_1 \\ f_2 \\ \vdots \\ f_n \end{pmatrix} \qquad (14.1.1448)$$

We then have the following common notation:

$$\min_{x_1,x_2} f(x_1,x_2)=\sum_i f_i^2 \Rightarrow \min_{\vec{x}} f(\vec{x})=F(\vec{x})^T F(\vec{x}) \qquad (14.1.1449)$$

Now, imagine that we found a bipoint $(x_1,x_2)=(\vec{x})$ that gives this minimum and let us denote it $(\vec{x}_*)$ and without forgetting that it will remain a local minimum and with luck a global one...!

Let us consider a special case that we will name "compatible solution" and define by the fact the bi-point that minimize the sum of squares of errors is also such that for all i we have:

$$f_i(\vec{x}_*)=0 \qquad (14.1.1450)$$

Therefore it is immediate that:

$$F(\vec{x}_*)=\vec{0} \qquad (14.1.1451)$$

Before going further, let us notice for example that for a component j (which corresponds in our case to each variable of the a priori supposed theoretical function of our model):

$$\begin{aligned}\vec{\nabla}\left(F(\vec{x})^T F(\vec{x})\right)_j &= \frac{\partial}{\partial x_j}\sum_i f_i^2=\sum_i f_i^2=\sum_i \frac{\partial f_i^2}{\partial x_j}=\sum_i 2 f_i \frac{\partial f_i}{\partial x_j}=2\sum_i f_i \frac{\partial f_i}{\partial x_j}\\ &=2\sum_i \frac{\partial f_i}{\partial x_j} f_i=2\left(\vec{\nabla}\left(F(\vec{x})^T\right)F(\vec{x})\right)_j\end{aligned} \qquad (14.1.1452)$$

where the last condensed equality is many times less obvious as it makes usage of the gradient of a vector field (see section Vector Calculus page 1878) that we see rarely in practice (note the factor 2 that we were speaking about earlier!). The reader that should be destabilized can refer directly to the numerical example further below to makes things more crystal clear.

✍**Example:**

In the field of Machine Learning, considering (this a liner weighted input of a neural network as we will see later during our study of these objects):

$$z=\omega_0 x_0+\omega_1 x_1+\omega_m x_m=\sum_{j=0}^{m} x_j\omega_j=\vec{\omega}^T\vec{x} \qquad (14.1.1453)$$

where x_0 refers something named a "bias unit" such that $x_0=1$.

Here, our cost function is also the following sum of squared errors (SSE) with the traditional notation of Machine Learning field that fits more when we do detailed developments:

$$J(\vec{w})=\frac{1}{2}\sum_i\left(y^{(i)}-\phi(z)^{(i)}\right)^2 \qquad (14.1.1454)$$

We then have for one component j:

$$\begin{aligned}\frac{\partial J}{\partial \omega_j}&=\frac{\partial}{\partial \omega_j}\frac{1}{2}\sum_i\left(y^{(i)}-\phi(z)^{(i)}\right)^2=\frac{1}{2}\frac{\partial}{\partial \omega_j}\sum_i\left(y^{(i)}-\phi(z)^{(i)}\right)^2\\&=\frac{1}{2}\sum_i 2\left(y^{(i)}-\phi(z)^{(i)}\right)\frac{\partial}{\partial \omega_j}\left(y^{(i)}-\phi(z)^{(i)}\right)=\sum_i\left(y^{(i)}-\phi(z)^{(i)}\right)\frac{\partial}{\partial \omega_j}\left(y^{(i)}-\sum_j(\omega_j^{(i)}x_j^{(i)})\right)\\&=\sum_i\left(y^{(i)}-\phi(z)^{(i)}\right)(-x_j^{(i)})=-\sum_i\left(y^{(i)}-\phi(z)^{(i)}\right)x_j^{(i)}\end{aligned} \tag{14.1.1455}$$

So we have the correspondence for this special (famous) case:

$$\vec{\nabla}\left(J(\vec{\omega})^T J(\vec{\omega})\right)_j=\frac{\partial J}{\partial \omega_j}=-\sum_i\left(y^{(i)}-\phi(z)^{(i)}\right)x_j^{(i)} \tag{14.1.1456}$$

So to continue... we deduce that:

$$\vec{\nabla}\left(\sum_i f_i^2\right)=\vec{\nabla}(f(\vec{x}))=2\vec{\nabla}\left(F(\vec{x})^T\right)F(\vec{x}) \tag{14.1.1457}$$

and the "compatible solution" brings us obviously to:

$$\vec{\nabla}\left(f(\vec{x}_*)\right)=2\vec{\nabla}\left(F(\vec{x}_*)^T\right)F(\vec{x}_*) \tag{14.1.1458}$$

Following the same step, we have:

$$\begin{aligned}\vec{\nabla}^2\left(F(\vec{x}^T)F(\vec{x})\right)=\vec{\nabla}\left(2\sum_i f_i\frac{\partial f_i}{\partial x_j}\right)&=2\vec{\nabla}\left(\sum_i f_i\frac{\partial f_i}{\partial x_j}\right)\\&=2\sum_{i,k}\left(\frac{\partial f_i}{\partial x_k}\frac{\partial f_i}{\partial x_j}+f_i\frac{\partial f_i}{\partial x_k\partial x_j}\right)=2\left(\sum_{i,k}\frac{\partial f_i}{\partial x_k}\frac{\partial f_i}{\partial x_j}+\sum_{i,k}f_i\frac{\partial f_i}{\partial x_k\partial x_j}\right)\\&=2\left(\vec{\nabla}\left(F(\vec{x})^T\right)\left(\vec{\nabla}F(\vec{x})\right)+\sum_i f_i\vec{\nabla}^2 f_i(\vec{x})\right)_j\end{aligned} \tag{14.1.1459}$$

So finally we have the following two relations:

$$\vec{\nabla}\left(f(\vec{x})\right)=2\vec{\nabla}\left(F(\vec{x})^T\right)F(\vec{x})\vec{\nabla}^2\left(F(\vec{x}^T F(\vec{x})\right)=2\left(\vec{\nabla}\left(F(\vec{x})^T\right)\left(\vec{\nabla}F(\vec{x})\right)+\sum_i f_i\vec{\nabla}^2 f_i(\vec{x})\right)_j \tag{14.1.1460}$$

Given that for the "compatible solution" we have:

$$f_i(\vec{x}_*)=0 \tag{14.1.1461}$$

it follows that in this case the second relation becomes:

$$\begin{aligned}\vec{\nabla}^2\left(F(\vec{x}_*)^T F(\vec{x}_*)\right)&\cong 2\left(\vec{\nabla}\left(F(\vec{x}_*)^T\right)\vec{\nabla}(F(\vec{x}_*)+\sum_i\underbrace{f_i(\vec{x}_*)}_{=0}\vec{\nabla}^2 f_i(\vec{x}_x)\right)\\&=2\vec{\nabla}\left(F(\vec{x}_*)^T\right)\vec{\nabla}\left(F(\vec{x}_*)\right)=2[1\quad 1]H\begin{bmatrix}1\\1\end{bmatrix}\end{aligned} \tag{14.1.1462}$$

where H is the Hessian matrix (see section Sequences and Series page 1715) what practitioners in the USA write simply:

$$\vec{\nabla}\left(F(\vec{x}_*)^T\right)\vec{\nabla}\left(F(\vec{x}_*)\right)\cong H(\vec{x}_*) \tag{14.1.1463}$$

So we can approximate in the case of the compatible solution, the Hessian that contains derivatives of the second order by derivatives of the first order and that the main difference between the Gauss-Newton and Newton-Raphson method!!!!

So we have finally in this special case the two relations that are the pillar of the Gauss-Newton's method:

$$\boxed{\begin{gathered}\vec{\nabla}(f(\vec{x}_*)=2\vec{\nabla}(F(\vec{x}_*)^T)F(\vec{x}_*)\\ \vec{\nabla}\left(F(\vec{x}_*)^T\right)\vec{\nabla}(F(\vec{x}_*)\cong H(\vec{x}_*)\end{gathered}} \tag{14.1.1464}$$

Now let us recall the basic relation of the Newton-Raphson method obtained earlier above:

$$-\vec{\nabla}(f(\vec{x}_i))=H(\vec{x}_i)(\vec{x}-\vec{x}_i) \tag{14.1.1465}$$

and for information, any mathematical technique (because they are many of them!) that simplifies the Hessian matrix (see section Sequences and Series page 1715) to the right of equality becomes part of the family named "quasi-Newton's methods".

Well the Gauss-Newton's method that interest us here and is therefore one of the techniques of the family of the "quasi-Newton's methods" consists simply in a first step in getting rid of the second derivatives of the Hessian (see section Sequences and Series page 1715) of the Newton-Raphson method at the right of the equality thanks to the previously established relations such that (attention to remember the abuse of writing!):

$$-\vec{\nabla}\left(f(\vec{x}_i)\right)\cong\vec{\nabla}\left(F(\vec{x}_{i*})^T\right)\vec{\nabla}\left(F(\vec{x}_{i*})\right)(\vec{x}-\vec{x}_{i*}) \tag{14.1.1466}$$

and in a second time rewrite the gradient on the left of the equality thanks also to the previously established relation. Which gives us:

$$\boxed{-2\vec{\nabla}\left(F(\vec{}_*)^T\right)F(\vec{x}_*)\cong\vec{\nabla}\left(F(\vec{x}_{i*})^T\right)\vec{\nabla}\left(F(\vec{x}_{i*})\right)(\vec{x}-\vec{x}_{i*})} \tag{14.1.1467}$$

The factor 2 above being not very aesthetic, almost all textbooks simplify such optimization problem with the following type of notation:

$$\min_{x_1,x_2} f(x_1,x_2)=\frac{1}{2}\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)^2 \tag{14.1.1468}$$

So by simply multiplying by a factor $1/2$ (which does not change the result as we already know!) we have then:

$$\vec{\nabla}\left(F(\vec{}_*)^T\right)F(\vec{x}_*)\cong\vec{\nabla}\left(F(\vec{x}_{i*})^T\right)\vec{\nabla}\left(F(\vec{x}_{i*})\right)(\vec{x}-\vec{x}_{i*}) \tag{14.1.1469}$$

Let us recall again that a spreadsheet software like Microsoft® Excel® can not determine the derivatives it will calculate them using the numerical methods of right or centered derivatives as we have presented a earlier above.

Now let us come back to our example of the beginning! So we have:

$$t=\begin{pmatrix}1\\2\\4\\5\\8\end{pmatrix}\qquad y=\begin{pmatrix}3.2939\\4.2699\\7.1749\\9.3008\\20.259\end{pmatrix}\tag{14.1.1470}$$

We start with a bipoint that seems the closest to the desired solution:

$$x=\begin{pmatrix}x_1\\x_2\end{pmatrix}=\begin{pmatrix}x_{1,0*}\\x_{2,0*}\end{pmatrix}=\begin{pmatrix}2.5\\0.25\end{pmatrix}\tag{14.1.1471}$$

Then we have:

$$F(\vec{x})=\begin{pmatrix}f_1\\f_2\\f_3\\f_4\\f_5\end{pmatrix}=\begin{pmatrix}x_1e^{x_2t_1}-y_1\\x_1e^{x_2t_2}-y_2\\x_1e^{x_2t_3}-y_3\\x_1e^{x_2t_4}-y_4\\x_1e^{x_2t_5}-y_5\end{pmatrix}=\begin{pmatrix}2.5e^{0.25\cdot 1}-3.2939\\2.5e^{0.25\cdot 2}-4.2699\\2.5e^{0.25\cdot 4}-7.17149\\2.5e^{0.25\cdot 5}-9.3008\\2.5e^{0.25\cdot 8}-20.259\end{pmatrix}=\begin{pmatrix}-0.0838\\-0.1481\\-0.3792\\-0.5749\\-1.7864\end{pmatrix}\tag{14.1.1472}$$

and therefore we have:

$$\min_{x_1,x_2} f(x_1,x_2)=\frac{1}{2}\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)^2=1.847\cong 2\tag{14.1.1473}$$

Then it comes:

$$\vec{\nabla}(f(\vec{x}))=\frac{1}{2}\begin{pmatrix}\displaystyle\sum_{i=1}^{5}2\left(x_1e^{x_2t_i}-y_i\right)e^{x_2t_i}\\\displaystyle\sum_{i=1}^{5}2\left(x_1e^{x_2t_i}-y_i\right)x_1t_ie^{x_2t_i}\end{pmatrix}=\begin{pmatrix}\displaystyle\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)e^{x_2t_i}\\\displaystyle\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)x_1t_ie^{x_2t_i}\end{pmatrix}\tag{14.1.1474}$$

What we can therefore rewrite as:

$$\begin{aligned}\vec{\nabla}(f(\vec{x}))&=\vec{\nabla}\left(F(\vec{x})^T\right)F(\vec{x})\\&=\begin{bmatrix}e^{x_2t_1}&e^{x_2t_2}&e^{x_2t_3}&e^{x_2t_4}&e^{x_2t_5}\\x_1t_1e^{x_2t_1}&x_1t_2e^{x_2t_2}&x_1t_3e^{x_2t_3}&x_1t_4e^{x_2t_4}&x_1t_5e^{x_2t_5}\end{bmatrix}\begin{pmatrix}x_1e^{x_2t_1}-y_1\\x_1e^{x_2t_2}-y_2\\x_1e^{x_2t_3}-y_3\\x_1e^{x_2t_4}-y_4\\x_1e^{x_2t_5}-y_5\end{pmatrix}\\&=\begin{bmatrix}1.2840&1.6847&2.718&3.4903&7.3891\\3.2101&8.2435&27.1828&43.6293&147.7811\end{bmatrix}\begin{pmatrix}-0.0383\\-0.1481\\-0.3792\\-0.5749\\-1.7864\end{pmatrix}=\begin{bmatrix}-16.5888\\-300.8722\end{bmatrix}\end{aligned}\tag{14.1.1475}$$

We also have by extension:

$$\begin{aligned}&\vec{\nabla}\left(F(\vec{x})^T\right)\vec{\nabla}(F(\vec{x}))\\&=\begin{bmatrix}e^{x_2t_1} & e^{x_2t_2} & e^{x_2t_3} & e^{x_2t_4} & e^{x_2t_5}\\ x_1t_1e^{x_2t_1} & x_1t_2e^{x_2t_2} & x_1t_3e^{x_2t_3} & x_1t_4e^{x_2t_4} & x_1t_5e^{x_2t_5}\end{bmatrix}\begin{pmatrix}e^{x_2t_1} & x_1t_1e^{x_2t_1}\\ e^{x_2t_2} & x_1t_2e^{x_2t_2}\\ e^{x_2t_3} & x_1t_3e^{x_2t_3}\\ e^{x_2t_4} & x_1t_4e^{x_2t_4}\\ e^{x_2t_5} & x_1t_5e^{x_2t_5}\end{pmatrix}\\&=\begin{bmatrix}78.5367 & 1335.8479\\ 1335.8479 & 24559.9419\end{bmatrix}\end{aligned}\tag{14.1.1476}$$

Then we apply the relation proved earlier above:

$$-\vec{\nabla}\left(F(\vec{x}_*)^T\right)F(\vec{x}_*)\cong\vec{\nabla}\left(F(\vec{x}_{i*})^T\right)(\vec{x}-\vec{x}_{i*})\tag{14.1.1477}$$

Therefore:

$$-\begin{pmatrix}-16.5888\\-300.8722\end{pmatrix}=\begin{bmatrix}78.5367 & 1335.8479\\ 1335.8479 & 24559.9419\end{bmatrix}\begin{pmatrix}x_1-x_{1,0*}\\ x_2-x_{2,0*}\end{pmatrix}\tag{14.1.1478}$$

After a minor simplification:

$$\begin{pmatrix}16.5888\\300.8722\end{pmatrix}=\begin{bmatrix}78.5367 & 1335.8479\\ 1335.8479 & 24559.9419\end{bmatrix}\begin{pmatrix}x_1-x_{1,0*}\\ x_2-x_{2,0*}\end{pmatrix}\tag{14.1.1479}$$

Therefore:

$$\begin{pmatrix}x_1-x_{1,0*}\\ x_2-x_{2,0*}\end{pmatrix}=\begin{pmatrix}x_1\\ x_2\end{pmatrix}-\begin{pmatrix}x_{1,0*}\\ x_{2,0*}\end{pmatrix}=\begin{bmatrix}78.5367 & 1335.8479\\ 1335.8379 & 24559.9419\end{bmatrix}^{-1}\begin{pmatrix}16.5888\\300.8722\end{pmatrix}=\begin{pmatrix}0.0381\\0.0120\end{pmatrix}\tag{14.1.1480}$$

and therefore the next bipoint for the iteration will be:

$$\begin{pmatrix}x_1\\ x_2\end{pmatrix}=\begin{pmatrix}x_{1,1*}\\ x_{2,1*}\end{pmatrix}=\begin{pmatrix}0.0381\\0.0102\end{pmatrix}+\begin{pmatrix}x_{1,0*}\\ x_{2,0*}\end{pmatrix}=\begin{pmatrix}0.0381\\0.0102\end{pmatrix}+\begin{pmatrix}2.5\\0.25\end{pmatrix}=\begin{pmatrix}0.0381\\0.0102\end{pmatrix}+\begin{pmatrix}2.5381\\0.2602\end{pmatrix}\tag{14.1.1481}$$

Hence formally:

$$\boxed{\begin{pmatrix}x_{1,1*}\\ x_{2,1*}\end{pmatrix}=\begin{pmatrix}x_{1,0*}\\ x_{2,0*}\end{pmatrix}-\left[\vec{\nabla}\left(F(\vec{x}_{i*})^T\right)\vec{\nabla}\left(F(\vec{x}_{i*})\right)\right]^{-1}\left(\vec{\nabla}\left(F(\vec{x}_*)^T\right)F(\vec{x}_*)\right)}\tag{14.1.1482}$$

Remark

In the field of Machine Learning, that latter relation is written as following:

$$\boxed{\vec{\omega}^+=\vec{\omega}+\Delta\omega=\vec{\omega}-\eta\vec{\nabla}\left(J(\vec{\omega}_*)^T\right)J(\vec{\omega}_*)=\vec{\omega}-\eta\vec{\nabla}J(\vec{\omega})}\tag{14.1.1483}$$

but where η is fixed (in the field of Machine Learning!) and named the "learning rate" and the whole relation (corresponding to a minimization problem for recall!) is named the "gradient descent method".

Obviously we see that the weight change is then defined by:

$$\boxed{\Delta\omega = -\eta\vec{\nabla}\left(J(\vec{\omega}_*)^T\right) J(\vec{\omega}_*) = -\eta\vec{\nabla}J(\vec{\omega})} \tag{14.1.1484}$$

In component notation, for the component j this gives:

$$\omega_j^+ = \omega_j + \Delta\omega = \omega_j - \eta\frac{\partial}{\partial\omega_j}J(\vec{\omega}) \tag{14.1.1485}$$

In numerical computing this is often denoted:

$$x^{(k)} = x^{(k-1)} - t_k\nabla f\left(x^{(k-1)}\right) \tag{14.1.1486}$$

where $k = 1, 2, \ldots$ is iteration number, t_k is step size (or step length) at iteration k.

Which corresponds well to the values of the first iteration:

$$\begin{pmatrix} x_{1,1*} \\ x_{2,2*} \end{pmatrix} = \begin{pmatrix} 2.5381 \\ 0.2602 \end{pmatrix} \tag{14.1.1487}$$

We will not do again explicitly the other iterations. So this is what we get in the end:

i	$\min_{x_1,x_2} f(x_1,x_2)$
0	$2\cdot 10^0$
1	$4\cdot 10^{-3}$
2	$2\cdot 10^{-8}$
3	$3\cdot 10^{-9}$
4	$3\cdot 10^{-9}$

Table 14.20: **Gauss-Newton iterations of our example**

with therefore for local solution at the 4th iteration:

$$\begin{pmatrix} x_{1,4*} \\ x_{2,4*} \end{pmatrix} = \begin{pmatrix} 2.5411 \\ 0.2595 \end{pmatrix} \tag{14.1.1488}$$

With Maple™ 4.00b we get:

```

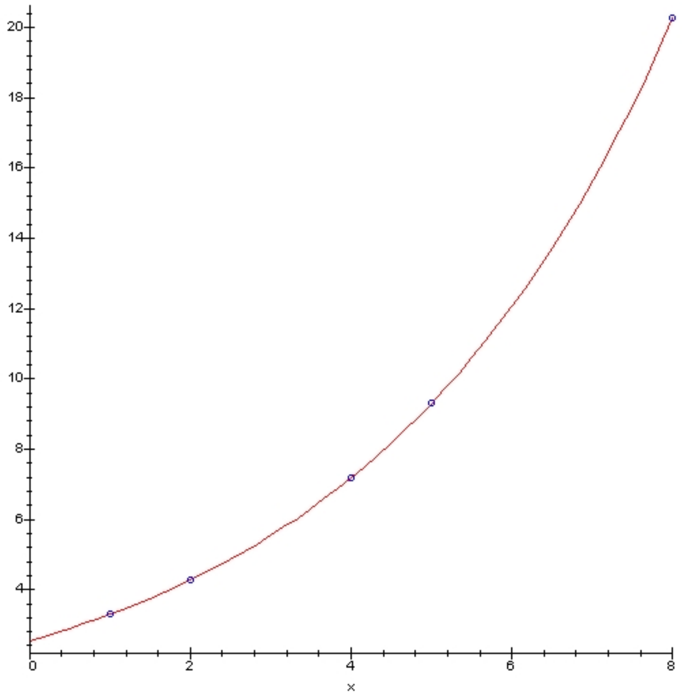

Figure 14.89: **Points and our interpolated Gauss-Newton function**

To close this subject let us do a comparison with the Newton-Raphson method for the first iteration using the same starting bipoint. Let us recall again that for this latter method, the iterations are based on the relation:

$$-\vec{\nabla}(f(\vec{x}))=H(\vec{x}_i)(\vec{x}-\vec{x}_i) \quad (14.1.1489)$$

and we will write the function as following for the Newton-Raphson method:

$$f(x_1,x_2)=f(\vec{x})=\frac{1}{2}\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)^2 \quad (14.1.1490)$$

and:

$$\begin{aligned}H(\vec{x}_i)&=\begin{bmatrix}\partial^2_{x_1}f(x_i,y_i) & \partial_{x_1}\partial_{x_2}f(x_i,y_i)\\ \partial_{x_1}\partial_{x_2}f(x_i,y_i) & \partial_{x_2}\partial_{x_2}f(x_i,y_i)\end{bmatrix}\\
&=\begin{bmatrix}\partial^2_{x_1}\dfrac{1}{2}\displaystyle\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)^2 & \partial_{x_1}\partial_{x_2}\dfrac{1}{2}\displaystyle\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)^2\\ \partial_{x_1}\partial_{x_2}\dfrac{1}{2}\displaystyle\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)^2 & \partial_{x_2}\partial_{x_2}\dfrac{1}{2}\displaystyle\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)^2\end{bmatrix}\\
&=\begin{bmatrix}\partial_{x_1}\displaystyle\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)e^{x_2t_i} & \partial_{x_1}\displaystyle\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)x_1t_ie^{x_2t_i}\\ \partial_{x_1}\displaystyle\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)x_1t_ie^{x_2t_1} & \partial_{x_2}\displaystyle\sum_{i=1}^{5}\left(x_1e^{x_2t_i}-y_i\right)x_1t_ie^{x_2t_i}\end{bmatrix}\\
&=\begin{bmatrix}\displaystyle\sum_{i=1}^{5}e^{2x_2t_i} & \displaystyle\sum_{i=1}^{5}2x_1t_ie^{x_2t_i}-y_it_ie^{x_2t_i}\\ \displaystyle\sum_{i=1}^{5}2x_1t_ie^{x_2t_i}-y_it_ie^{x_2t_i} & \displaystyle\sum_{i=1}^{5}2x_1^2t_ie^{2x_2t_i}-x_1y_it_i^2e^{x_2t_i}\end{bmatrix}\\
&=\begin{bmatrix}78.5367 & 1214.4991\\ 1215.4991 & 22278.6570\end{bmatrix}\end{aligned}\tag{14.1.1491}$$

Then we have:

$$-\vec{\nabla}(f(\vec{x}_i))=H(\vec{x}_i)(\vec{x}-\vec{x}_i)\tag{14.1.1492}$$

that becomes:

$$(16.5888300.8722)=\begin{bmatrix}78.5367 & 1215.4991\\ 1215.4991 & 22278.6570\end{bmatrix}\begin{pmatrix}x_1-x_{1,0*}\\ x_2-x_{2,0*}\end{pmatrix}\tag{14.1.1493}$$

Then we have:

$$-\vec{\nabla}(f(\vec{x}_i))=H(\vec{x}_i)(\vec{x}-\vec{x}_i)\tag{14.1.1494}$$

That becomes:

$$\begin{pmatrix}16.5888\\ 300.8722\end{pmatrix}\begin{bmatrix}78.5367 & 1215.4991\\ 1215.4991 & 22278.6570\end{bmatrix}\begin{pmatrix}x_1-x_{1,0*}\\ x_2-x_{2,0*}\end{pmatrix}\tag{14.1.1495}$$

Thus:

$$\begin{pmatrix}x_1-x_{1,0*}\\ x_2-x_{2,0*}\end{pmatrix}=\begin{pmatrix}x_1\\ x_2\end{pmatrix}-\begin{pmatrix}x_{1,0*}\\ x_{2,0*}\end{pmatrix}=\begin{pmatrix}0.0142\\ 0.0127\end{pmatrix}+\begin{pmatrix}2.5\\ 0.25\end{pmatrix}=\begin{pmatrix}2.5142\\ 0.2627\end{pmatrix}\tag{14.1.1496}$$

Therefore: and therefore the next bipoint for the iteration will be:

$$\begin{pmatrix}x_1\\ x_2\end{pmatrix}=\begin{pmatrix}x_{1,1}\\ x_{2,1}\end{pmatrix}=\begin{pmatrix}0.0381\\ 0.0102\end{pmatrix}+\begin{pmatrix}x_{1,0*}\\ x_{2,0*}\end{pmatrix}=\begin{pmatrix}0.0142\\ 0.0127\end{pmatrix}+\begin{pmatrix}2.5\\ 0.25\end{pmatrix}=\begin{pmatrix}2.5142\\ 0.2627\end{pmatrix}\tag{14.1.1497}$$

which corresponds obviously to the values of the first iteration:

$$\begin{pmatrix}x_{1,1*}\\ x_{2,2*}\end{pmatrix}=\begin{pmatrix}2.5381\\ 0.2602\end{pmatrix}\tag{14.1.1498}$$

We will not do again explicitly also other iterations. So this is what it gives finally about our function to be minimized:

i	$\min_{x_1,x_2} f(x_1,x_2)$
0	$2\cdot 10^{0}$
1	$1\cdot 10^{-1}$
2	$2\cdot 10^{-4}$
3	$5\cdot 10^{-9}$
4	$6\cdot 10^{-9}$
5	$3\cdot 10^{-9}$

Table 14.21: Gauss-Newton iterations of our example

So the Newton-Raphson method converges in this case slower than that of Gauss-Newton.

Here is the corresponding pseudocode:

```
Algorithm 14: Gauss-Newton method (tangent Newton)
Input: $y(\vec{x},t):\mathbb{R}^n \rightarrow \mathbb{R}$ a twice-differentiable a priori function to fit the data
       $\vec{y}\in\mathbb{R}^m$ the real data
       $\vec{x}_0\in\mathbb{R}^n$ an initial estimation
       $\varepsilon$ is a tolerance value
for $k$ to maxiter do
    for $i$ to $m$ do
        Assign $F_i = y(\vec{x}_k,t) - y_i$ ;                ▷ to get the vector $F(\vec{x})$
    ▷ to get the vector $\vec{\nabla}(f(\vec{x}_k)) = \vec{\nabla}\left(F(\vec{x}_k)^T\right) F(\vec{x}_k)$
    for $j$ to $n$ do
        Assign $\vec{\nabla}(f(\vec{x}_k))_j = \sum_{i=1}^{m} F_i \dfrac{\partial y(\vec{x}_k,t)}{\partial x_j}$
    ▷ to get the $n\times n$ matrix: $[\vec{\nabla}\left(F(\vec{x}_k)^T\right)\vec{\nabla}(F(\vec{x}_k))]$
    for $i$ to $n$ do
        for $j$ to $n$ do
            Assign $[\vec{\nabla}\left(F(\vec{x}_k)^T\right)\vec{\nabla}(F(\vec{x}_k))]_{ij} = \sum_{l=1}^{m} \dfrac{\partial y(\vec{x}_k,t)}{\partial x_i}\dfrac{\partial y(\vec{x}_k,t)}{\partial x_j}$
    Update $\vec{x}_{k+1} \leftarrow \vec{x}_k - \left[\vec{\nabla}\left(F\left(\vec{x}_k\right)^T\right)\vec{\nabla}\left(F\left(\vec{x}_k\right)\right)\right]^{-1}\left(\vec{\nabla}\left(F\left(\vec{x}_k\right)^T\right)F\left(\vec{x}_k\right)\right)$;
    if $\|f\left(\vec{x}_{k+1}\right) - f\left(\vec{x}_k\right)\| < \varepsilon$ or $\left\|\vec{\nabla} f\left(\vec{x}_k\right)\right\| < \varepsilon$ then
        Converged. Print $\vec{x}^* \leftarrow \vec{x}_{k+1}$ and $f\left(\vec{x}^*\right) \leftarrow f\left(\vec{x}_{k+1}\right)$;
```

Remark

For the square matrix inversion in the pseudocode above, one can use the determinant and cofactor method (see section Linear Algebra page 1980), QR decomposition (see section Linear Algebra page 2030), LU decomposition (see section Linear Algebra page 2024) or Gaussian Elimination with partial pivoting (GEPP).

So this was a very detailed step-by-step numerical example. For people interested in Machine Learning and for a more formal example (without numerical values) with a famous case (univariate linear regression) let us consider:

$$h_\theta(x)=\theta_0+\theta_1 x \tag{14.1.1499}$$

The cost function for any guess of θ_0,θ_1 can be computed as:

$$J(\vec{\theta})=J(\theta_0,\theta_1)=\frac{1}{2}\sum_{i=1}^{m}\left(h_\theta(x^{(i)})-y^{(i)}\right)^2 \tag{14.1.1500}$$

where $x^{(i)}$ and $y^{(i)}$ are the x and y values for the ith component in the learning set. If we substitute for $h_\theta(x)$:

$$J(\theta_0,\theta_1)=\frac{1}{2}\sum_{i=1}^{m}\left(\theta_0+\theta_1 x^{(i)}-y^{(i)}\right)^2 \tag{14.1.1501}$$

Then as we know, in Machine Learning, the goal of gradient descent can be expressed as:

$$\min_{\theta_0,\theta_1} J(\theta_0,\theta_1) \tag{14.1.1502}$$

Remark

At the opposite of the "gradient ascent" where we seek:

$$\max_{\theta_0,\theta_1} J(\theta_0,\theta_1) \tag{14.1.1503}$$

Finally, each step in the gradient descent can be described as we have seen earlier above for a component j:

$$\theta_j^{+}=\theta_j-\eta\frac{\partial}{\partial\theta_j}J(\theta_0,\theta_1) \tag{14.1.1504}$$

for $j=0$ and $j=1$ in this special case!

It is straightforward that:

$$\frac{\partial J(\theta_0,\theta_1)}{\partial\theta_0}=\frac{\partial}{\partial\theta_0}\frac{1}{2}\sum_{i=1}^{m}\left(\theta_0+\theta_1 x^{(i)}-y^{(i)}\right)^2=\sum_{i=1}^{m}\left(\theta_0+\theta_1 x^{(i)}-y^{(i)}\right) \tag{14.1.1505}$$

and:

$$\frac{\partial J(\theta_0,\theta_1)}{\partial\theta_1}=\frac{\partial}{\partial\theta_1}\frac{1}{2}\sum_{i=1}^{m}\left(\theta_0+\theta_1 x^{(i)}-y^{(i)}\right)^2=\sum_{i=1}^{m}\left(\theta_0+\theta_1 x^{(i)}-y^{(i)}\right)x^{(i)} \tag{14.1.1506}$$

Or in vector form:

$$\vec{\theta}^{+}=\vec{\theta}+\Delta\theta=\vec{\theta}-\eta\vec{\nabla}\left(J(\vec{\theta}_*)^T\right)J(\vec{\theta}_*)=\vec{\theta}-\eta\vec{\nabla}J(\vec{\theta})=\vec{\theta}-\eta\sum_{i=1}^{m}\left(\vec{\theta}^T\vec{x}^{(i)}-y^{(i)}\right)\vec{x}^{(i)} \tag{14.1.1507}$$

In order to minimize the above cost function $J(\theta_0,\theta_1)$, notice that the gradient is calculated from the whole training set (hence the sum!). This is why this approach of "gradient descent" is more specifically referred to as "batch gradient descent".

Remark

The use of the traditional complete method using the Hessian is in the early 121st century (holocene calendar) impractical for most deep learning applications because computing (and inverting) the Hessian in its explicit form is a very costly process in both space and time. For instance, a Neural Network with one million parameters would have a Hessian matrix of size $[1,000,000\times 1,000,000]$, occupying approximately $3,725$ gigabytes of RAM. Hence, a large variety of quasi-Newton methods have been developed that seek to approximate the inverse Hessian!

As we need to calculate the gradients for the whole dataset to perform just one update, batch gradient-descent can be very slow and is intractable for datasets that do not fit in memory. Batch gradient descent also does not allow us to update our model online, i.e. with new examples on-the-fly

So, in "stochastic gradient descent method" (SGD), also known as "incremental gradient descent", instead of updating the weights $\vec{\theta}$ based on the sum of the m accumulated errors over all samples $x^{(i)}$:

$$\theta_j^+=\theta_j-\eta\frac{\partial}{\partial\theta_j}J(\theta_0,\theta_1)=\theta_j-\eta\frac{\partial}{\partial\theta_j}\frac{1}{2}\sum_{i=1}^{m}\left(\theta_0+\theta_1x^{(i)}-y^{(i)}\right)^2 \tag{14.1.1508}$$

we can use the following update:

$$\theta_j^+=\theta_j-\eta\frac{\partial}{\partial\theta_j}J(\theta_0,\theta_1)=\theta_j-\eta\frac{\partial}{\partial\theta_j}\frac{1}{2}\left(\theta_0+\theta_1x^{(i)}-y^{(i)}\right)^2 \tag{14.1.1509}$$

Note that we now update the weights incrementally with a single training sample but not with the whole training set.

It is said to be "stochastic" because samples are selected randomly (or shuffled) instead of as a single group (as in standard gradient descent) or in the order they appear in the training set.

Example:

Let's suppose we want to fit a straight line $y_i=\theta_0+\theta_1x_i$ to a training set with observations $(x_1,x_2,\ldots,x_n)$ and corresponding estimated responses $(\hat{y}_1,\hat{y}_2,\ldots,\hat{y}_n)$ using least squares. The objective function to be minimized is:

$$J(\vec{\theta})=\sum_{i=1}^{m}J_i(\vec{\theta})=\sum_{i=1}^{m}\left(\hat{y}^{(i)}-y^{(i)}\right)^2=\sum_{i=1}^{m}\left(\theta_0+\theta_1x^{(i)}-y^{(i)}\right)^2 \tag{14.1.1510}$$

Then we will have using the stochastic gradient descent method:

$$\begin{bmatrix}\theta_0\\ \theta_1\end{bmatrix}^+:=\begin{bmatrix}\theta_0\\ \theta_1\end{bmatrix}-\eta\begin{bmatrix}\dfrac{\partial}{\partial\theta_0}(\theta_0+\theta_1x^{(i)}-^{(i)})^2\\ \dfrac{\partial}{\partial\theta_1}(\theta_0+\theta_1x^{(i)}-y^{(i)})^2\end{bmatrix}=\begin{bmatrix}\theta_0\\ \theta_1\end{bmatrix}-\eta\begin{bmatrix}2(\theta_0+\theta_1x^{(i)}-y^{(i)})\\ 2x_i(\theta_0+\theta_1x^{(i)}-y^{(i)})\end{bmatrix} \tag{14.1.1511}$$

Note again that in each iteration, the gradient is evaluated at a single point $x^{(i)}$ instead of being evaluated on the set of all samples.

The key difference compared to standard (Batch) Gradient Descent is that only one piece of data from the dataset is used to calculate the step, and the piece of data is picked randomly at each step. SGD does away with this redundancy by performing one update at a time. It is therefore usually much faster and can also be used to learn online. SGD performs frequent updates with a high variance that cause the objective function to fluctuate heavily.

While batch gradient descent converges to the minimum of the basin the parameters are placed in, SGD's fluctuation, on the one hand, enables it to jump to new and potentially better local minima. On the other hand, this ultimately complicates convergence to the exact minimum, as SGD will keep overshooting. However, it has been shown that when we slowly decrease the learning rate, SGD shows the same convergence behaviour as batch gradient descent, almost certainly converging to a local or the global minimum for non-convex and convex optimization respectively.

Remark

"mini-batch gradient descent" initially takes the best of both worlds and performs an update for every mini-batch of n training examples. Common mini-batch sizes range between 50 and 256, but can vary for different applications. Mini-batch gradient descent is typically the algorithm of choice when training a neural network and the term SGD usually is employed also when mini-batches are used

14.1.17.2.4.1 Gradient Descent/Ascent techniques summary

At this point it may be useful to also introduce the gradient descent and gradient ascent in a simpler way (if it can help!) as it is quite and important topic.

The reader may have already understand that the gradient descent/ascent is a general framework for solving optimization problems where we want to maximize or minimize functions of continuous (differentiable) parameters.

We will illustrate the technique here for maximization (ascent) in terms of a single free variable, but the generalization is quite simple and there is already plenty of example above!

Suppose we want to find a maximum of some function $y=f(x)$. The standard procedure is to find $f'(x)$, set it to zero and solve for x. But what if $f'(x)=0$ is a difficult equation to solve?

We can still find the maximum algorithmically!

Let $y=f(x)$ have a maximum at x_{max}. Pick an arbitrary value for x, say x_1. Compute $f'(x_1)$. If the slope of y is positive at x_1, i.e. $f'(x_1)>0$, then $x_{\text{max}}>x_1$ lies to the right of x_1. Likewise if $f'(x_1)<0$, then $x_{\text{max}}<x_1$ lies to its left!

Thus we know the direction in which x_1 should be updated in order to approach x_{max}. In fact this direction is given by $f'(x_1)$. So we can use the update rule:

$$x_1 \leftarrow x_1+\eta f'(x_1) \qquad (14.1.1512)$$

where η is a positive constant. If η is sufficiently small, and there is indeed a maximum for f, the above update rule will converge to it after a finite number of iterations (when $f'(x_1)=0$).

This is the so-named "gradient ascent technique" to determine maxima when actual solution of $f' = 0$ is difficult. To find minima, the corresponding gradient descent rule can set up to update x_1 away from $x_{\max}$.

For $y = f(x_1, \cdots, x_n)$ the partial derivatives with respect to each x_i indicate how rapidly y is changing along that axis and so the gradient, ∇y, in fact denotes the precise direction which promises maximum increase of y.

Collectively these, among others, are named "gradient techniques".

We will summarise now the common gradient descent optimisation algorithms used in popular deep learning frameworks in the early 121st century (holocene calendar).

Recall that the vanilla stochastic gradient descent (SGD) updates weights by subtracting the current weight by a factor (i.e. η, the learning rate) of its gradient:

$$w_{\text{new}} = w - \underbrace{\eta}_{\substack{\text{learning}\\\text{rate}\\\text{component}}} \underbrace{\frac{\partial L}{\partial w}}_{\substack{\text{gradient}\\\text{descent}}} \tag{14.1.1513}$$

Variations in this equation are commonly known as "stochastic gradient descent optimisers". There are 3 main ways how they differ:

1. Adapt the "gradient component" ($\frac{\partial L}{\partial w}$)

   Instead of using only one single gradient like in stochastic vanilla gradient descent to update the weight, take an aggregate of multiple gradients. Specifically, these optimisers use the exponential moving average of gradients.

2. Adapt the "learning rate component" (η)

   Instead of keeping a constant learning rate, adapt the learning rate according to the magnitude of the gradient(s).

3. Both (1) and (2)

   Adapt both the gradient component and the learning rate component.

As you will see later, these optimisers try to improve the amount of information used to update the weights, mainly through using previous (and future) gradients, instead of only the present available gradient.

Below is a table that summarises which components are being adapted (years are based on the holocene calendar):

Optimiser	Year	Learning Rate	Gradient
Momentum	11964		✓
AdaGrad	12011	✓	
RMSprop	12012	✓	
AdaDelta	12012	✓	
Nesterov	12013		✓
Adam	12014	✓	✓
AdaMax	12015	✓	✓
Nadam	12015	✓	✓
AMSGrad	12018	✓	✓

Table 14.22: **Gradient descent optimisers**

Here are the detailed expression of each of the empirical method visible in the above table (the knowledgeable reader may recognize some techniques inspired by time series forecasting techniques):

- Vanilla SGD:

$$w_{t+1}=w_t-\eta\frac{\partial L}{\partial w_t} \tag{14.1.1514}$$

- Momentum:

$$\begin{aligned}w_{t+1}&=w_t-\eta m_t\\ m_t&=\beta m_{t-1}+(1-\beta)\frac{\partial L}{\partial w_t}\end{aligned} \tag{14.1.1515}$$

- Adagrad:

$$\begin{aligned}w_{t+1}&=w_t-\frac{\eta}{\sqrt{v_t+\varepsilon}}\cdot\frac{\partial L}{\partial w_t}\\ v_t&=v_{t-1}+\left[\frac{\partial L}{\partial w_t}\right]^2\end{aligned} \tag{14.1.1516}$$

- RMSprop:

$$\begin{aligned}w_{t+1}&=w_t-\frac{\eta}{\sqrt{v_t+\varepsilon}}\cdot\frac{\partial L}{\partial w_t}\\ v_t&=\beta v_{t-1}+(1-\beta)\left[\frac{\partial L}{\partial w_t}\right]^2\end{aligned} \tag{14.1.1517}$$

- Adadelta:

$$\begin{aligned}w_{t+1}&=w_t-\frac{\sqrt{D_{t-1}+\varepsilon}}{\sqrt{v_t+\varepsilon}}\cdot\frac{\partial L}{\partial w_t}\\ D_t&=\beta D_{t-1}+(1-\beta)[\Delta w_t]^2\\ v_t&=\beta v_{t-1}+(1-\beta)\left[\frac{\partial L}{\partial w_t}\right]^2\end{aligned} \tag{14.1.1518}$$

- Nesterov:

$$\begin{aligned} w_{t+1} &= w_t - \eta m_t \\ m_t &= \beta m_{t-1} + (1-\beta)\frac{\partial L}{\partial w^*} \\ w^* &= w_t - \eta m_{t-1} \end{aligned} \tag{14.1.1519}$$

- Adam:

$$\begin{aligned} w_{t+1} &= w_t - \frac{\eta}{\sqrt{\hat{v}_t}+\varepsilon}\cdot \hat{m}_t \\ \hat{m}_t &= \frac{m_t}{1-\beta_1^t} \\ \hat{v}_t &= \frac{v_t}{1-\beta_2^t} \\ m_t &= \beta_1 m_{t-1} + (1-\beta_1)\frac{\partial L}{\partial w_t} \\ v_t &= \beta_2 v_{t-1} + (1-\beta_2)\left[\frac{\partial L}{\partial w_t}\right]^2 \end{aligned} \tag{14.1.1520}$$

- AdaMax:

$$\begin{aligned} w_{t+1} &= w_t - \frac{\eta}{v_t}\cdot \hat{m}_t \\ \hat{m}_t &= \frac{m_t}{1-\beta_1^t} \\ m_t &= \beta_1 m_{t-1} + (1-\beta_1)\frac{\partial L}{\partial w_t} \\ v_t &= \max\left(\beta_2 v_{t-1}, \left|\frac{\partial L}{\partial w_t}\right|\right) \end{aligned} \tag{14.1.1521}$$

- Nadam:

$$\begin{aligned} w_{t+1} &= w_t - \frac{\eta}{\sqrt{\hat{v}_t}+\varepsilon}\left(\beta_1 \hat{m}_t + \frac{1-\beta_1}{1-\beta_1^t}\cdot\frac{\partial L}{\partial w_t}\right) \\ \hat{m}_t &= \frac{m_t}{1-\beta_1^t} \\ \hat{v}_t &= \frac{v_t}{1-\beta_2^t} \\ m_t &= \beta_1 m_{t-1} + (1-\beta_1)\frac{\partial L}{\partial w_t} \\ v_t &= \beta_2 v_{t-1} + (1-\beta_2)\left[\frac{\partial L}{\partial w_t}\right]^2 \end{aligned} \tag{14.1.1522}$$

- AMSGrad:

$$\begin{aligned} w_{t+1} &= w_t - \frac{\eta}{\sqrt{\hat{v}_t}+\varepsilon}\cdot m_t \\ m_t &= \beta_1 m_{t-1} + (1-\beta_1)\frac{\partial L}{\partial w_t} \\ v_t &= \beta_2 v_{t-1} + (1-\beta_2)\left[\frac{\partial L}{\partial w_t}\right]^2 \\ \hat{v}_t &= \max(\hat{v}_{t-1}, v_t) \end{aligned} \tag{14.1.1523}$$

Below the reader can see animations (credit: Alec Radford) that may help to have a better intuition about the learning process dynamics (we also strongly recommend to read the paper *An overview of gradient descent optimization algorithms* to get more details on the underlying ideas [470]).

The first Flash animation below depicts the contours of a loss surface and time evolution of different optimization algorithms. Notice the "overshooting" behaviour of momentum-based methods, which make the optimization look like a ball rolling down the hill:

The animation above will run for people having a PDF reader with Adobe Flash player installed and activated (otherwise see here: `https://vimeo.com/575749745`).

The second and last Flash animation is a visualization of a saddle point in the optimization landscape, where the curvature along different dimension has different signs (one dimension curves up and another down). Notice that SGD has a very hard time breaking symmetry and gets stuck on the top. Conversely, algorithms such as RMSprop will see very low gradients in the saddle direction. Due to the denominator term in the RMSprop update, this will increase the effective learning rate along this direction, helping RMSProp proceed:

The animation above will run for people having a PDF reader with Adobe Flash player installed and activated (otherwise see here: https://vimeo.com/575752619).

14.1.17.3 Expectation-Maximization (EM) algorithm

The "Expectation-Maximization algorithm" is a stochastic optimizations algorithm often used in machine learning and very quite different of the methods that we have seen before. We will use it explicitly in this textbook later below for various applications like Factor Analysis (see page 6925) but also for the T-distributed Stochastic Neighbour Embedding (see page 6939) and others during our study of Data Mining.

The EM algorithm seems to have been introduced in the early 11950 (holocene calendar) by R. Ceppellini, M. Siniscalco and C.A. Smith in the context of gene frequency estimation. The expectation maximization algorithm was analysed more generally by H. Hartley and by L.E. Baum in the context of hidden Markov models, where it is commonly known as the "Baum-Welch algorithm".

Remark

The text that follows is inspired of the following paper [76] but also of the following web page `https://indowhiz.com/articles/en/the-simple-concept-of-expectation-maximization-em-algorithm` itself inspired of [151].

To summarize, EM algorithm is actually an iterative method, involving expectation (E-step) and maximization (M-step) to find the local maximum likelihood from the data. Commonly, EM algorithm is used on several distributions or statistical models, where there are one or more unknown variables named the "latent variables".

To easily understand EM algorithm, we will use first a companion example of the coin tosses distribution that is widely used in quite a few textbooks, articles and blogs and afterwards we will deal with the underlying mathematical formalism.

So let us consider that we have 2 coins: Coin A and Coin B, where both have a different head-up probability. We will randomly choose a coin 5 times, whether coin A or B. Then, each coin selection is followed by tossing it 10 times. Therefore, we have the following outcomes:

- Set 1 (Coin B): `H T T T H H T H T H` (5H5T)
- Set 2 (Coin A): `H H H H T H H H H H` (9H1T)
- Set 3 (Coin A): `H T H H H H H T H H` (8H2T)
- Set 4 (Coin B): `H T H T T T H H T T` (4H6T)
- Set 5 (Coin A): `T H H H T H H H T H` (7H3T)

where the image side of the coin will be denoted by `H` or Head-up, and the number side will be denoted by `T` or Tail-up. Then, the probability of a coin to land with head-up for each of these coins, will be denoted as θ.

The question is, how do we estimate θ for each coin?

Because we already have all the data we need, we can easily calculate the probability of getting head-up for each coin. Therefore, the calculation of θ will be done through the maximum likelihood estimation (MLE) of the proportion that can naively be obtained by:

- By knowing the result of coin $A=24\texttt{H}6\texttt{T}$, in 3 sets with a total of 30 tosses, then:

$$\hat{\theta}_A=\frac{24}{30}=0.80 \tag{14.1.1524}$$

- Similarly to the result of coin $B=9\texttt{H}11\texttt{T}$, in 2 sets with a total of 20 tosses, then:

$$\hat{\theta}_B=\frac{9}{20}=0.45 \tag{14.1.1525}$$

Before returning to the original case, let us explain briefly the different the stages of the EM algorithm as it will give us an overall picture of the EM algorithm flow and may help to understand what will follow:

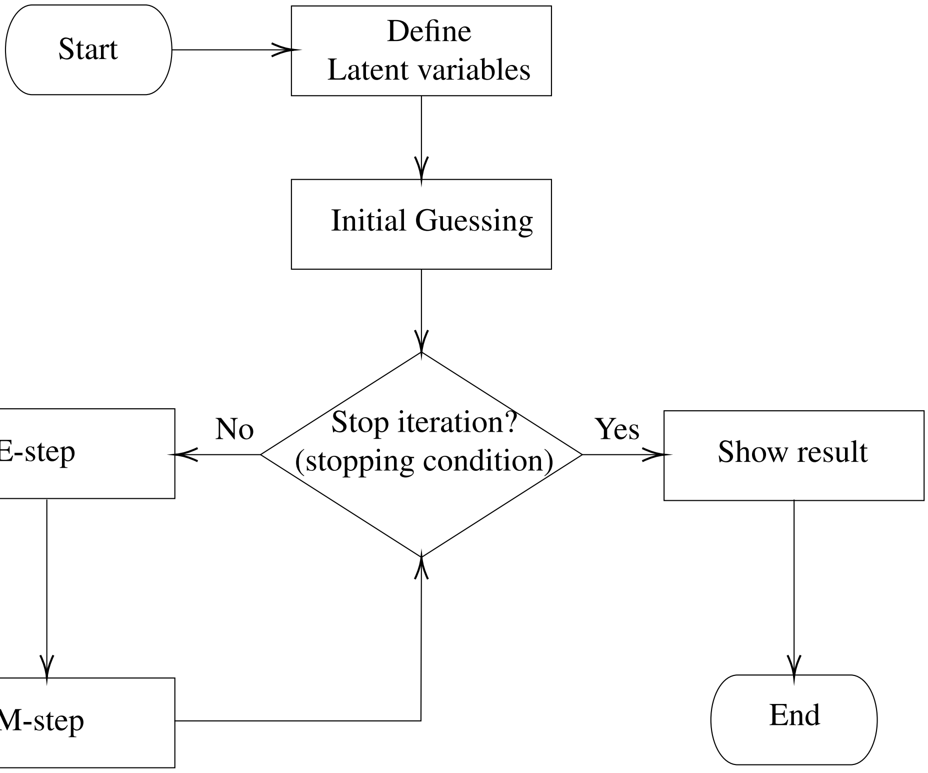

Figure 14.90: **ISO 5807:85 Flowchart of EM algorithm**

Actually, the main point of EM is the iteration between E-step and M-step, which could be seen in the figure above. The E-step will estimate your hidden variables, and the M-step will re-update the parameters, based on the estimation of the hidden variables. In other words, this iteration aims to re-improve the estimation of current parameters.

First, what we must define is what variables are required; but are not observed directly in the data.

The goal is to estimate the probability of getting heads-up for each coin. However, it cannot be calculated directly if we don't know the identity of the coin used in each set. Therefore, it is necessary to know which coin is used in each set. In other words, this coin identity will be our latent variable.

Right now, besides the 5 sets of outcomes above, we only know that we used two coins; which are coin A and coin B.

As stated before, the probability of getting head-up for each of these coins is denoted as θ. Currently, there are only coin A and coin B; with unknown parameter values of θ_A and θ_B.

Remark

By the way, please note that there is no relationship between parameters guessing; both θ_A and θ_B. For example, if you think that the sum of θ_A and θ_B must be $=1$, NO! This probability represents the individual value of getting heads-up on each coin.

Okay enough! Now, let's say we have randomly set both initial values, which are:

$$\hat{\theta}_A^{(0)} = 0.6 \quad \text{and} \quad \hat{\theta}_B^{(0)} = 0.8 \tag{14.1.1526}$$

Now we have the required variables. So, we can start estimating the identity of coin used in each set.

Each set, which contains the outcomes of heads and tails, can be denoted by E notation. Then, the probability of *using coin* A denoted as Z_A, and the probability of *using coin* B denoted as Z_B.

At the beginning of E-Step, we need to know the probability of a set using coins A or B. Take an example from the set 3 earlier above, where $E = \texttt{HTHHHHHTHH}$ (8H2T). If $\hat{\theta}_A = 0.6$, it means the probability of getting head is 0.6 (and tail 0.4) uses coin A. Then, how much probability of coin A will give $\texttt{8H2T}$ in 10 tosses (a set)? This is what we need to estimate first. Then, this probability can be denoted by $P(E|Z_A)$. Similarly, the probability of coin B giving $E = \texttt{8H2T}$, could be denoted by $P(E|Z_B)$.

This actually relates to the probability distribution of a binomial random variable, which definition is for recall:

$$P(E|Z_x) = \frac{n!}{h!\,(n-h)!}\,{\theta_x}^h\,(1-\theta_x)^{n-h} \tag{14.1.1527}$$

Or denoted:

$$P(E|Z_x,\theta) = \frac{n!}{h!\,(n-h)!}\,{\theta_{Z_x}}^h\,(1-\theta_{Z_x})^{n-h} \tag{14.1.1528}$$

Then, we can calculate the probability of getting E using coins A and B as follows:

$$\begin{aligned} P(E_{\text{8H2T}}|Z_A) &= \frac{10!}{8!\,2!}\,0.6^8\,0.4^2 = 0.121 \\ P(E_{\text{8H2T}}|Z_B) &= \frac{10!}{8!\,2!}\,0.5^8\,0.5^2 = 0.044 \end{aligned} \tag{14.1.1529}$$

Next, we can compare the probabilities of both coin A and coin B giving E. So, according to Bayes' theorem and the law of total probability, we can determine the ratio of probability (posterior value of latent variables) using the following relation:

$$P(Z_x|E)=\frac{P(E|Z_x)P(Z_x)}{P(E|Z_x)P(Z_x)+P(E|Z_y)P(Z_y)} \tag{14.1.1530}$$

where $P(Z_x|E)$ is the probability of coin x giving E (compared to coin y), $P(Z_x)$ is the probability of choosing coin x and $P(Z_x)$ is the probability of choosing coin y.

However, because our case is only using 2 coins, coins A and B, then the probability that we will choose one of them is $50/50$. Then $P(Z_A)=P(Z_B)=0.5$.

Accordingly, for coin A, we can simplify the relation above into:

$$P(Z_A|E)=\frac{P(E|Z_A)\cancel{P(Z_A)}}{P(E|Z_A)\cancel{P(Z_A)}+P(E|Z_B)\cancel{P(Z_B)}}=\frac{P(E|Z_A)}{P(E|Z_A)+P(E|Z_B)} \tag{14.1.1531}$$

Hence:

$$P(Z_A|E_{\text{8H2T}})=\frac{\cancel{\frac{10!}{8!\,2!}}\,0.6^8\,0.4^2}{\cancel{\frac{10!}{8!\,2!}}\,0.6^8\,0.4^2+\cancel{\frac{10!}{8!\,2!}}\,0.5^8\,0.5^2}=\frac{0.6^8\,0.4^2}{0.6^8\,0.4^2+0.5^8\,0.5^2}=0.73 \tag{14.1.1532}$$

Similarly, for coin B, we have:

$$P(Z_B|E_{\text{8H2T}})=\frac{\cancel{\frac{10!}{8!\,2!}}\,0.5^8\,0.5^2}{\cancel{\frac{10!}{8!\,2!}}\,0.6^8\,0.4^2+\cancel{\frac{10!}{8!\,2!}}\,0.5^8\,0.5^2}=\frac{0.5^8\,0.5^2}{0.6^8\,0.4^2+0.5^8\,0.5^2}=0.27 \tag{14.1.1533}$$

Previously, the ratio of coins A and B in giving each E needs to be calculated. In this case, it is calculated from set 1 to 5. Then the results could be seen in the following table:

Coin Tosses	E	**Coin A probability**	**Coin B probability**
HTTTHHTHTH	5H5T	0.45	0.55
HHHHTHHHHH	9H1T	0.80	0.20
HTHHHHHTHH	8H3T	0.73	0.27
HTHTTTHHTT	4H6T	0.35	0.65
THHHTHHHTH	7H3T	0.65	0.35

After that, we need to estimate the total number of `H` for each coin. It is calculated based on the coin ratio above. To calculate *total heads and tails* for coin x, it is similar to the complete data. The method is quite easy, we just need to multiply the ratio of each coin to the number of heads in each E, the results are shown in the following table:

Coin Tosses	E	**Estimated `H` for Coin A**	**Estimated `H` for Coin B**
HTTTHHTHTH	5H5T	$5\cdot0.45=2.25$	$5\cdot0.55=2.75$
HHHHTHHHHH	9H1T	$9\cdot0.8=7.2$	$9\cdot0.20=1.8$
HTHHHHHTHH	8H3T	$8\cdot0.73=5.84$	$8\cdot0.27=2.16$
HTHTTTHHTT	4H6T	$4\cdot0.35=1.4$	$4\cdot0.65=2.6$
THHHTHHHTH	7H3T	$7\cdot0.65=4.55$	$7\cdot0.35=2.45$

If we want, we can also calculate the tails for each coin as in the table above. But that is not necessary, because we can use another straightforward approach.

Until this step, we already have the E-Step calculations. Just a little bit more effort to finish our calculation in the M-Step.

The results from the E-step can be used to improve the $\hat{\theta}_x$ parameters. Here, we can use the maximum likelihood estimation (MLE) relation similar to the completed data.

As we said before, it is not necessary to calculate the tails for each coin; then we sum the heads and tails for each coin. Because each set contains 10 tosses, we just need to multiply the coin ratio with 10. That way, we could get the total estimated tosses from. Therefore (we will prove in details just further below where these both relations comes from):

$$\begin{aligned}\hat{\theta}_A^{(1)} &= \frac{2.25+7.2+5.84+1.4+4.55}{10(0.45+0.8+0.73+0.35+0.65)}=0.713\\ \hat{\theta}_B^{(1)} &= \frac{2.75+1.8+2.16+2.6+2.45}{10(0.55+0.2+0.27+0.65+0.35)}=0.581\end{aligned} \tag{14.1.1534}$$

Finally, the parameter of $\hat{\theta}_A$ and $\hat{\theta}_B$ for the first iteration have been improved. For the next iteration, the E-Step will use this new parameter value; and re-improved at next M-step. This iteration will always repeating the E-step and M-step, until it reaches any stop condition as illustrated below:

Figure 14.91: **EM parameter estimation for complete and incomplete data (source: Nature Biotechnology Volume 26 Number 8 August 12008)**

The iteration of the E-Step and M-Step, will be repeated until they meet the stopping condition. Commonly, the EM algorithm has two options of stopping condition, which are:

- Maximum iteration: means that, the EM Algorithm will stop if a certain number of iterations has been reached. For example the maximum iteration is set to 10 iterations, then the EM Algorithm will not be more than 10 iterations
- Convergence threshold: means that, the M-step gives no significant parameter improvement; compared to the improvement in the previous iteration. The changes are very small below our threshold

In the EM case example above, the parameter improvement in each iteration can be seen in the following table:

Iteration i	$\theta_A^{(i)}$	$\theta_B^{(i)}$	**Differences**
0	0.6	0.5	0.7180
1	0.713	0.581	0.1390
2	0.745	0.569	0.0342
3	0.768	0.550	0.0298
4	0.783	0.535	0.0212
5	0.791	0.526	0.0120
6	0.795	0.522	0.0057
7	0.796	0.521	0.0014
8	0.796	0.520	0.0010
9	0.796	0.520	0.0000

To calculate the differences or improvements in each iteration, we can use the Euclidean Distance such that:

$$d\left(\hat{\theta}^{(i)},\hat{\theta}^{(i-1)}\right)=\sqrt{\left(\hat{\theta}_A^{(i)}-\hat{\theta}_A^{(i-1)}\right)^2+\left(\hat{\theta}_A^{(i)}-\hat{\theta}_B^{(i)}\right)^2} \qquad (14.1.1535)$$

So for example:

$$d\left(\hat{\theta}^{(2)},\hat{\theta}^{(1)}\right)=\sqrt{(0.713-0.745)^2+(0.581-0.569)^2}=0.0342 \qquad (14.1.1536)$$

As many algorithm that one also has weaknesses, without too much doubts. Indeed, every iteration in the EM algorithm, in general, will always improve the parameter closer to the local maximum likelihood. In other words, the EM algorithm will guarantee convergence, but will not guarantee to give a global maximum likelihood. And also there is no guarantee that you will get the maximum likelihood estimation (MLE).

Now let us formalize what we have seen. For this purpose we will use the personal notes of Benjamin Bray [76] who authorized us to reproduce them below (we did some minor modifications).

Suppose we still have two coins, each with a different probability of heads, θ_A and θ_B, unknown to us. We collect data from a series of N trials in order to estimate the bias of each coin. Each trial k consists of flipping the same random coin Z_k a total of M times and recording only the total number X_k of heads.

Assuming all samples in the observed dataset $X=[\vec{x}_1,\ldots,\vec{x}_N]$ are independent and identically distributed (i.i.d.), we can find the "complete data likelihood" function of θ (using the Bayes' relation established in the section of Probabilities page 498):

$$L(\theta|\vec{X},\vec{z})=P(\vec{X},\vec{z}|\theta)=\prod_{n=1}^{N}P\left(\vec{x}_n,\vec{z}|\theta\right)=\prod_{n=1}^{N}P\left(\vec{x}_n|\vec{z},\theta\right)P(\vec{z}|\theta) \qquad (14.1.1537)$$

and the log-likelihood:

$$\ln\left(L(\theta|X,\vec{z})\right)=\ln\left(P(\vec{X},\vec{z}|\theta)\right)=\sum_{n=1}^{N}\left(\ln\left(P(\vec{x}_n|\vec{z},\theta)\right)\right)+\ln\left(\vec{z}|\theta\right) \qquad (14.1.1538)$$

Or in scalar form (for non-multivariate distributions):

$$\ln\left(L(\theta|X,z)\right)=\ln\left(P(X,z|\theta)\right)=\sum_{n=1}^{N}\left(\ln\left(P(x_n|z_n,\theta)\right)\right)+\ln\left(z_n|\theta\right) \tag{14.1.1539}$$

The second term can be dropped in our companion example as $P(z_n|\theta)$ is independent of the model parameters in θ and therefore irrelevant to the maximization of the log likelihood with respect to θ. Indeed, the reader must remember that in our companion example, z_n is the realization of the random (hidden) variable that describes the probability to deal with coin A either coin B. We assume that this probability is constant and equal to $1/2$, hence:

$$P(z_n|\theta)=P(z_n|\theta)=1/2=c^{te} \qquad \forall n \tag{14.1.1540}$$

The remaining term in our companion example is:

$$\begin{aligned}\ln\left(P(x_n|z_n,\theta)\right)&=\ln\binom{M}{x_n}\theta_{z_n}^{x_n}(1-\theta_{z_n})^{M-x_n}\\&=\ln\binom{M}{x_n}+x_n\ln(\theta_{z_n})+(M-x_n)\ln(1-\theta_{z_n})\end{aligned} \tag{14.1.1541}$$

Now that we have specified the probabilistic model and worked out all relevant probabilities, we are ready to derive an Expectation-Maximization algorithm.

Our general approach will be to reason about the hidden variables through a proxy distribution q, which we use to compute a lower-bound on the log-likelihood. This section is devoted to deriving one such bound, named the "Evidence Lower Bound" (ELBO). We can expand the data log-likelihood by marginalizing over the hidden variables:

$$L(\theta|\chi)=\ln\left(P(\chi|\theta)\right)=\ln\left(\sum_z P(\chi,z|\theta)\right) \tag{14.1.1542}$$

Through Jensen's inequality (see section Statistics page 576), we obtain the following bound:

$$\begin{aligned}L(\theta|\chi)&=\ln\left(\sum_z P(\chi,z|\theta)\right)\\&=\ln\left(\sum_z q(z)\frac{P(\chi,z|\theta)}{q(z)}\right)\\&\geq\sum_z q(z)\ln\left(\frac{P(\chi,z|\theta)}{q(z)}\right)\end{aligned} \tag{14.1.1543}$$

The lower bound can be rewritten as follows:

$$\begin{aligned}L(\theta|\chi)&\geq\sum_z q(z)\ln\left(\frac{P(\chi,z|\theta)}{q(z)}\right)\\&=\sum_z q(z)\ln\left(P(\chi,z|\theta)\right)-\sum_z q(z)\ln\left(q(z)\right)\\&=\mathrm{E}[\ln\left(P(\chi,z|\theta)\right)]-\mathrm{E}[\ln\left(q(z)\right)]\end{aligned} \tag{14.1.1544}$$

Where the last term is often a constant at each iteration that we can ignore for the maximization problem.

Now that we have this result, the **E-Step** is straightforward (calculation of the lower bound on the observed log-likelihood). The **M-Step** computes a new parameter estimate θ_{t+1} by optimizing over the lower bound found in the E-Step, as:

$$\begin{aligned}\theta_{t+1}=\arg\max_{\theta} L(\theta,\chi) &= \arg\max_{\theta} \mathrm{E}\left[\ln\left(P(\chi,z|\theta)\right)\right]\\ &= \arg\max_{\theta} \mathrm{E}\left[\ln\left(P(\chi|z,\theta)P(z)\right)\right]\\ &= \arg\max_{\theta} \mathrm{E}\left[\ln\left(P(\chi|z,\theta)\right)\right]+\ln\left(P(z)\right)\\ &= \arg\max_{\theta} \mathrm{E}\left[\ln P(\chi|z,\theta)\right]\end{aligned} \tag{14.1.1545}$$

Now, because each trial is conditionally independent of the others, given the parameters:

$$\begin{aligned}\mathrm{E}[\ln\left(P(\chi|z,\theta)\right)] = \mathrm{E}\left[\ln\left(\prod_{n=1}^{N}P(x_n|z_n,\theta)\right)\right] &= \sum_{n=1}^{N}\mathrm{E}[\ln\left(P(x_n|z_n,\theta)\right)]\\ &= \sum_{n=1}^{N}\mathrm{E}\Big[x_n\ln(\theta_{z_n})+(M-x_n)\ln(1-\theta_{z_n})\Big]+\sum_{n=1}^{N}\ln\binom{M}{x_n}\\ &= \sum_{n=1}^{N}\mathrm{E}\Big[x_n\ln(\theta_{z_n})+(M-x_n)\ln(1-\theta_{z_n})\Big]+\text{const. w.r.t. }\theta\\ &= \sum_{n=1}^{N}q(z_n=A)\Big[x_n\ln(\theta_A)+(M-x_n)\ln(\theta_A)\Big]\\ &+\sum_{n=1}^{N}q(z_n=B)\Big[x_n\ln(\theta_B)+(M-x_n)\ln(\theta_B)\Big]+\text{const. w.r.t. }\theta\end{aligned} \tag{14.1.1546}$$

Let $a_k=q(z_k=A)$ and $b_k=q(z_k=B)$. Note that:

$$\sum_{k=1}^{N}a_k=\sum_{k=1}^{N}b_k=1 \tag{14.1.1547}$$

To maximize the above expression with respect to the parameters, we take derivatives with respect to θ_A and θ_B and set to zero:

$$\begin{aligned}\frac{\partial}{\partial\theta_A}\Big[\mathrm{E}[\ln\left(P(\chi|z,\theta)\right)]\Big] &= \frac{1}{\theta_A}\sum_{n=1}^{N}a_nx_n+\frac{1}{1-\theta_A}\sum_{n=1}^{N}a_n(M-x_n)=0\\ \frac{\partial}{\partial\theta_B}\Big[\mathrm{E}[\ln\left(P(\chi|z,\theta)\right)]\Big] &= \frac{1}{\theta_B}\sum_{n=1}^{N}b_nx_n+\frac{1}{1-\theta_B}\sum_{n=1}^{N}b_n(M-x_n)=0\end{aligned} \tag{14.1.1548}$$

Solving for θ_A and θ_B, we get

$$\hat{\theta}_A=\frac{\displaystyle\sum_{n=1}^{N}a_nx_n}{\displaystyle M\sum_{n=1}^{N}a_n}\qquad \hat{\theta}_B=\frac{\displaystyle\sum_{n=1}^{N}b_nx_n}{\displaystyle M\sum_{n=1}^{N}b_n} \tag{14.1.1549}$$

These are the both relations we used earlier above in our companion example!

We will see more complicated and practical business applications of the EM algorithm further below like:

- For our study of Gaussian Mixture Classification (related to K-mean)
- For our study of Factor Analysis (Exploratory Factor Analysis (EFA))
- For our study of T-distributed Stochastic Neighbour Embedding (T-SNE)

14.1.18 Resampling statistics

Resampling statistics refers to the use of the observed data or of a data generating mechanism (such as a die) to produce new hypothetical samples (resamples) that mimic the underlying population, the results of which can then be analysed. With numerous cross-disciplinary applications especially in the sub-disciplines of the life science, resampling methods are widely used since they are options when parametric approaches are difficult to employ or otherwise do not apply.

Resampled data is derived using a manual mechanism to simulate many pseudo-trials. These approaches were difficult to utilize prior to 11980s (holocene calendar) since these methods require many repetitions. With the incorporation of computers, the trials can be simulated in a few minutes and is why these methods have become widely used. The methods that will be discussed are used to make many statistical inferences about the underlying population. The most practical use of resampling methods is to derive confidence intervals and test hypotheses. This is accomplished by drawing simulated samples from the data themselves (resamples) or from a reference distribution based on the data; afterwards, you are able to observe how the statistic of interest in these resamples behaves. Resampling approaches can be used to substitute for traditional statistical (formulaic) approaches or when a traditional approach is difficult to apply. These methods are widely used because their ease of use. They generally require minimal mathematical formulas, needing a small amount of mathematical (algebraic) knowledge. These methods are easy to understand and stray away from choosing an incorrect formula in your diagnostics.

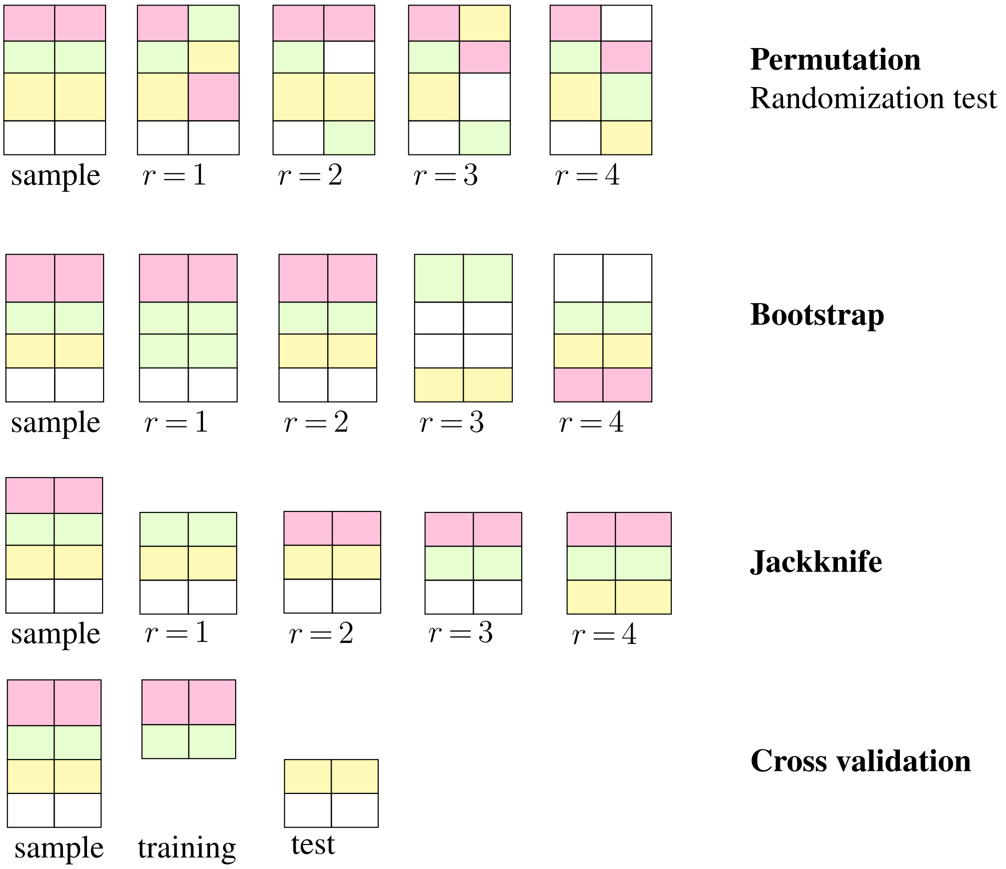

Figure 14.92: **Summary of resampling in different methods**

14.1.18.1 Monte Carlo Simulations

"Monte Carlo methods", also named "Monte Carlo experiments" or "Monte Carlo simulations" (MCS), are a broad class of computational algorithms that rely on repeated random sampling to obtain numerical results. They are often used in physical and mathematical problems (finance, supply chain, decisioneering, quality, etc.) and are most useful as workaround when it is difficult or impossible to use other mathematical methods.

It finds applications in various fields including the following examples:

- Problems related to the neutron bomb (or any other problem of the same family: neutron diffusion)
- Calculations of integrals or various parameters of random variables (finance, insurance, risk, forecasting)
- Resolution of elliptic or parabolic equations
- Solving linear systems
- Optimization Problem Solving (operations research, project management, supply chain)
- Creation of statistical tests (Anderson-Darling, Kolmogorov, Levene, Brown-Forsythe, etc.)

Thus there are two types of problems that can be treated by the Monte Carlo probabilistic method:

1. Problems, which have a random behaviour
2. Deterministic problems, which do not have a random behaviour

About the probabilistic case, the idea is to observe the behaviour of a series of random numbers that simulates how the real problem behaves and derive statistical solutions/conclusions. We then speak of "Monte Carlo estimation".

In the deterministic case, the studied problem is completely defined and we can in principle predict its evolution, but some parameters of the problem can be treated as if it were random variables (this is typically the case in "vector regression" technique in Economy). The deterministic problem then becomes probabilistic and still solvable numerically. We then speak of "Monte Carlo elaborated estimation".

We will begin further below with the most used one in business: generating draws from a probability distribution. For this purpose we will need to introduce the "inverse transform sampling" (we will treat mostly only univariate case in this textbook!).

Remark

The name of "Monte Carlo method" dates around 11944 (holocene calendar). Isolated researchers have used however long before similar statistical methods: for example, Edwin Herbert Hall for the experimental determination of the speed of light (11873 according to holocene calendar), or Kelvin in a discussion of the Boltzmann equation (11901 according to holocene calendar), but the real use of Monte Carlo methods began with research on the atomic bomb.

During the immediate postwar period, John Von Neumann, Enrico Fermi and Stanislaw Ulam warned the scientific community of the applicability of the Monte Carlo methods (eg for the approximation of the eigenvalues of the Schrödinger equation). The systematic study was made by Harris and Herman Khan in 11948 (holocene calendar). After an eclipse caused by too intensive use during the 11950s (holocene calendar), the Monte Carlo method is back since almost everybody can run complex management or business strategic simulations on office computers (with simple softwares like @Risk or Crystal Ball). in short, wherever it is profitable to use simulation processes.

There are ways of using probabilities that are definitely not Monte Carlo simulations – for example, deterministic modelling using single-point estimates, commonly named "what if analysis". Each uncertain variable within a model is assigned a "best guess" estimate. Scenarios (such as best, worst, or most likely case) for each input variable are chosen and the results recorded. By contrast, Monte Carlo simulations sample from a probability distribution for each variable to produce hundreds, thousands or millions of possible outcomes. The results are analysed to get probabilities of different outcomes occurring. But what if analysis gives equal weight to all scenarios and that's their major issue!

Also the reader should know that Monte Carlo simulation (MCS) and historical simulation (HS) are both methods that can be used to determine the riskiness of a financial project. However, each method uses different assumptions and techniques to develop the probability distribution of possible outcomes!

"Historical simulation" (HS) involves, as indicated by its name..., the use of historical records to simulate the possible outcomes. The method assumes that past performance is an indication of future performance. Historical simulation uses actual past figures or variables that have been experienced before. Monte Carlo simulation comes with the advantage of incorporating a wider variety of scenarios than historical data, whose information scope is limited. In addition, Monte Carlo simulation answers the what if question, weighted by probabilities (!), which is not possible under historical simulation.

14.1.18.1.1 Inverse Transform Sampling

Inverse transform sampling (also known as inversion sampling, inverse probability integral transform, inverse transformation method, Smirnov transform, golden rule,) is a basic method for pseudo-random number sampling, i.e. for generating sample numbers at random from any probability distribution given its cumulative distribution function.

Inverse transformation sampling takes uniform samples of a number $\mathcal{U}$ between 0 and 1, interpreted as a probability, and then return the largest number x from the domain of the distribution $P(X)$ such that $P(-\infty < X < x) \leq \mathcal{U}$.

Computationally, this method involves computing the quantile function of the distribution — in other words, computing the cumulative distribution function (CDF) of the distribution (which maps a number in the domain to a probability between 0 and 1) and then inverting that function.

To use this we method we go through he "probability integral transform" that states that if X is a continuous random variable with cumulative distribution function F_X, then the random variable $Y = F_X(X)$ has a uniform distribution on $[0,1]$. The inverse probability integral transform is just the inverse of this: specifically, if Y has a uniform distribution on $[0,1]$ and if X has a cumulative distribution F_X, then the random variable $F_X^{-1}(Y)$ has the same distribution as X.

Theorem 14.6. Suppose that a random variable X has a distribution for which the cumulative distribution function (CDF) is F_X. Then the random variable Y defined as:

$$Y = F_X(X) \tag{14.1.1550}$$

has a uniform distribution.

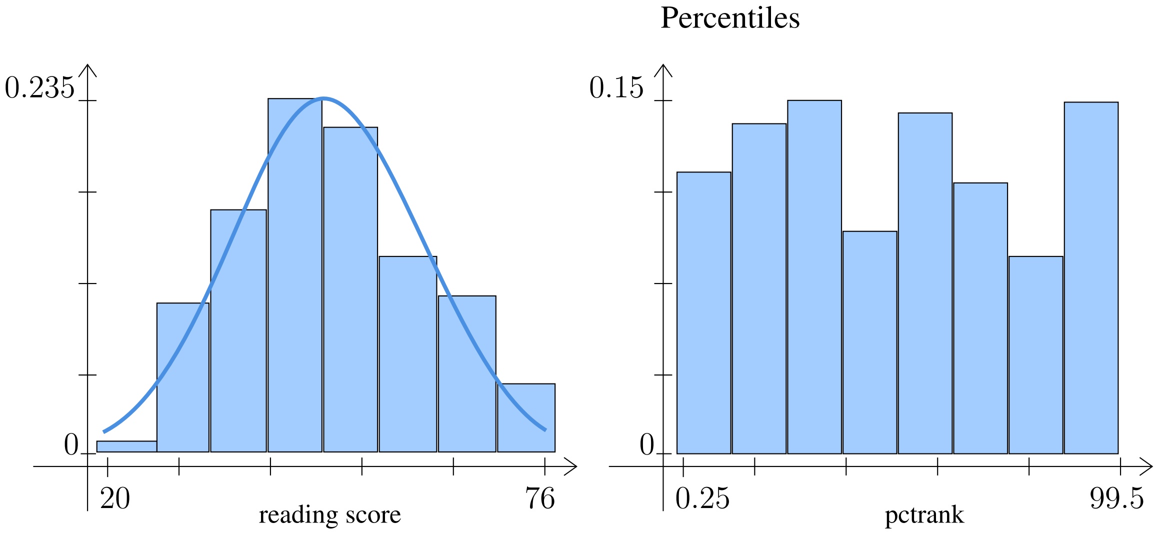
Proof 14.6.1. Given any random variable X, define $Y = F_X(X)$. Then (it is not always easy to read this proof through the first time even if afterwards it is obvious):

$$\begin{aligned} F_Y(y) &= P(Y \leq y) \\ &= P(F_X(X) \leq y) \\ &= P(X \leq F_X^{-1}(y)) \\ &= F_X(F_X^{-1}(y)) \\ &= y \end{aligned} \tag{14.1.1551}$$

Therefore F_Y is just the CDF of the uniform random variable $\mathcal{U}[0,1]$. Thus, Y has a uniform distribution on the interval $[0,1]$ (or in other words, if X is a random variable with CDF $F_X(X)$ then $F_X(X) = \mathcal{U}[0,1]$).

■ Q.E.D.

In other words, the percentiles are uniformly distributed (i.e. the frequency plot of the percentiles is uniformly distributed) as illustrated below:



Caution! In NHST (Null Hypothesis Statistical Tests) the p-value itself is considered as a realization of random variable. Therefore if we replace the random variable X above by the random variable p, we get the famous result that p-value is uniformly distributed when the null hypothesis is true (indeed under the null H_0 there is no reason that the value of p is more located in given place than in another one by definition!).

The problem that the inverse transform sampling method solves is as follows:

- Let X be a random variable whose distribution can be described by the cumulative distribution function F_X.
- We want to generate values of X which are distributed according to this distribution.

The inverse transform sampling method works as follows:

1. Generate a random number $\mathcal{U}$ from the standard uniform distribution in the interval $[0,1]$.
2. Compute the value x such that $F_X(x)=\mathcal{U}$ (using $F_X^{-1}(\mathcal{U})$).
3. Take x to be the random number drawn from the distribution described by F_X.

Expressed differently, given a continuous uniform variable $\mathcal{U}$ in $[0,1]$ and an invertible cumulative distribution function F_X, the random variable $X=F_X^{-1}(\mathcal{U})$ has distribution F_X (or, X is distributed F_X).

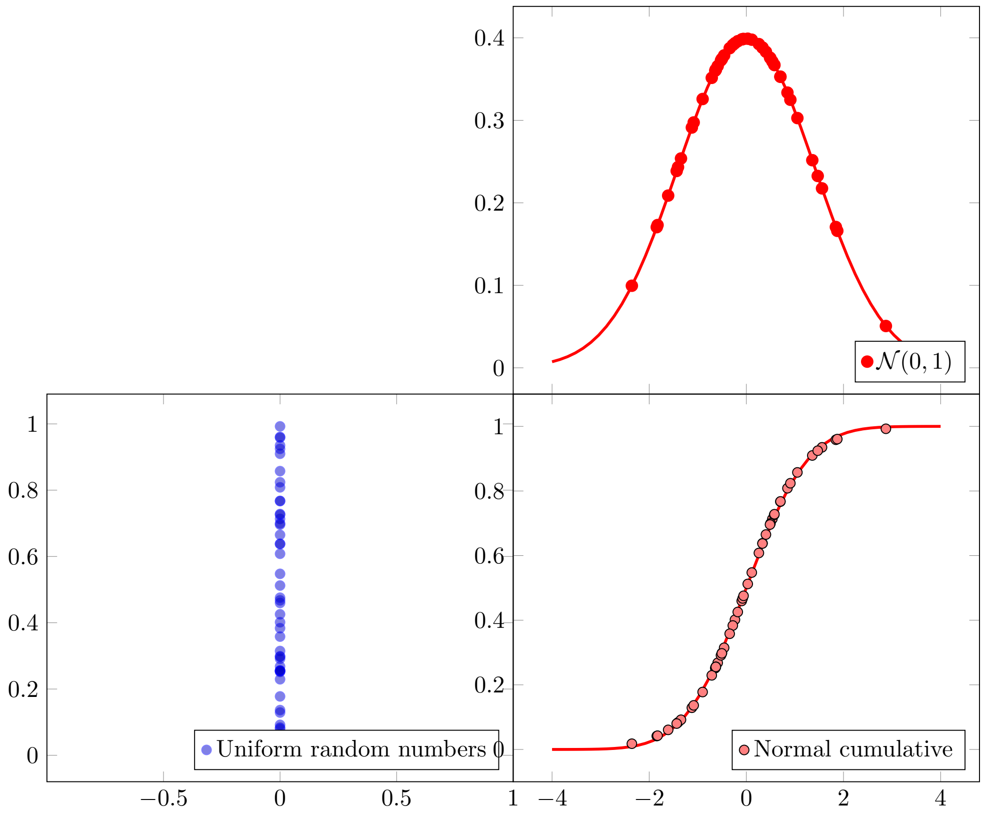


Figure 14.93: **Principle of the inverse transform method**

14.1.18.1.2 Random number generation

The best way to understand the method of Monte Carlo is to make examples (even small one should be enough). But for this, we must first have a good random number generator (which is quite difficult depending on the job). This is a very delicate and sensitive field for which an international standards is published (ISO 28640:2010 *Random variate generation methods*).

A random-number generator (RNG) is a computational or physical device designed to generate a sequence of numbers or symbols that cannot be reasonably predicted better than by a random chance.

Several computational methods for random-number generation exist. Many fall short of the goal of true randomness, although they may meet, with varying success, some of the statistical tests for randomness intended to measure how unpredictable their results are.

There are two principal methods used to generate random numbers. The first method measures some physical phenomenon that is expected to be random and then compensates for possible biases in the measurement process. Example sources include measuring atmospheric noise, thermal noise, and other external electromagnetic and quantum phenomena. For example, cosmic background radiation or radioactive decay as measured over short time-scales represent sources of natural entropy.

The second method uses computational algorithms that can produce long sequences of apparently random results, which are in fact completely determined by a shorter initial value, known as a seed value or key. As a result, the entire seemingly random sequence can be reproduced if the seed value is known. This type of random number generator is often named a "pseudo-random number generator". This type of generator typically does not rely on sources of naturally occurring entropy, though it may be periodically seeded by natural sources. This generator type is non-blocking, so they are not rate-limited by an external event, making large bulk reads a possibility.

Let us take, to begin, an example with the Maple™ 4.00b random generator:

```

Figure 14.95: Pseudo-random generator restart with Maple™ 4.00b

So we see that the default random number generator used by default in Maple™ 4.00b should be used with extreme caution since a system reset is enough to find... equal random values! This is therefore as we already said "pseudo-random generator" that gives the possibility to make what we name "pseudo Monte Carlo method".

Figure 14.96: Pseudo-random library with Maple™ 4.00b

The `RAND( )` and `RANDBETWEEN( )` functions of the of Microsoft® Excel® 14.0.6123 are also pseudo-random generators which here is a sample of 100 simulations (of course in Microsoft® Excel® the chart below will change each time you press on the keyboard button: F9):

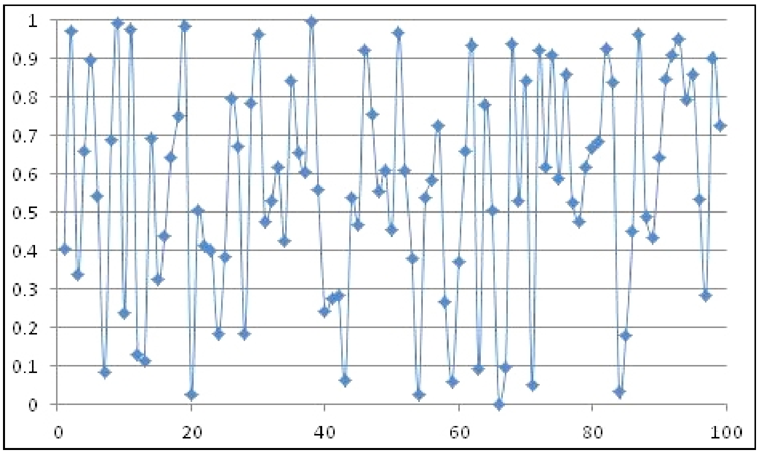

Figure 14.97: **Illustration of a sequence of pseudo-random numbers with Microsoft® Excel® 14.0.6123**

Unfortunately, it may happen with pseudo-random numbers that the numbers generated are presented in bunches, that is to say by sets of numbers close to each other, which reduces the effectiveness of the Monte Carlo simulation .

An empirical technique is to use then sequences of numbers generated by algorithms that scan almost surely the range $[0, 1]$. We speak then of "quasi-random numbers" to make simulations sometimes named "quasi-Monte Carlo". In almost all Microsoft® Excel®, you can create a Visual Basic Application function that will replace the pseudo-random generators that are the `RAND( )` or `RANDBETWEEN( )`.

Here is an example of such a V.B.A. function which generates quasi-random number named "Fauré random number sequence":

Listing 14.1: **VBA Fauré sequence code**

```
Function SequenceFaure(n) As Double
    Dim f As Double, sb As Double
    Dim i As Integer, n1 As Integer, n2 As Integer

    n1 = n
    sb = 1 / 2
    Do While n1 > 0
        n2 = Int(n1 / 2)
        i = n1 - n2 * 2
        f = f + sb * i
        sb = sb / 2
        n1 = n2
    Loop
    SequenceFaure = f
End Function
```

This will gives the following sequence for a sample of 100 simulations:

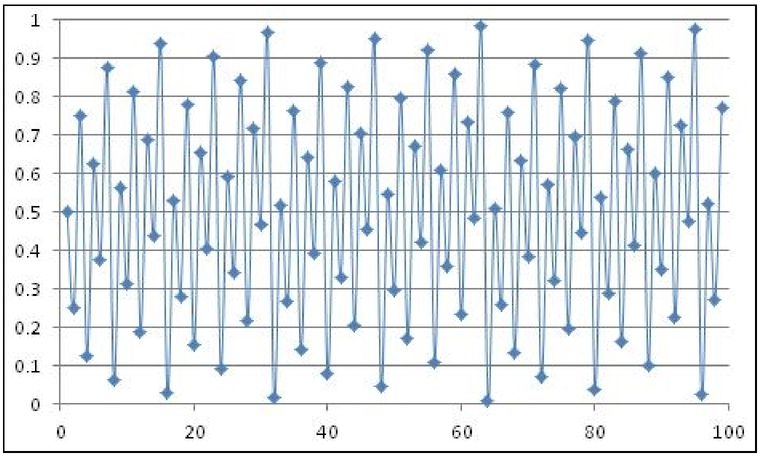

Figure 14.98: **Illustration of a Fauré sequence of pseudo-random numbers with Microsoft® Excel® 14.0.6123**

where we see well that the sequence covers well the whole area between 0 and 1 (we say then that: it covers faster the integration surface). This technique is sometimes preferred because it has the advantage of keeping the values off the simulation every time we restart the simulation (therefore in Microsoft® Excel® the chart above will not change when you press the keyboard button F9).

By cons the sequence generators have a great weakness: they are only applicable (to my knowledge at least) for problems of simulations with a single random variable (typically pricing single option strategy following Black & Scholes model). Indeed if we have several random variables (and this is the most common case!), then the variables are artificially correlated (correlation coefficient $= 1$) because they travel all the area between 0 and 1 in the same way! So a good simulation with several variables is a simulation including the treated variables have a correlation coefficient which approaches zero!!!!!!

In addition, sequence generators require algorithms that are very time consuming when there are many variables relatively to a pseudo-random generator, this is why in most situations we prefer the old methods.

Remark

As we have already mentioned it, engineers should refer to the international standard ISO 28640:2010 *Random variate generation methods* when they need to implement random number generators in their softwares.

Once the pseudo-random or random generator created and tested, we can see some application of the Monte Carlo method before continuing on performance tricks relatively to this method. Thus, in the calculation of integrals, this method is very useful and very fast in terms of convergence speed.

14.1.18.1.3 Monte Carlo integration

In numerical integration, methods such as the Trapezoidal rule use a deterministic approach as we already know. Monte Carlo integration, on the other hand, employs a non-deterministic approaches: each realization provides a different outcome. In Monte Carlo, the final outcome is an approximation of the correct value with respective error bars, and the correct value is within those error bars.

Consider for example the calculation of the following univariate defined integral of a function f and positive over the interval $[a,b]$:

$$I=\int\limits_a^b f(x)\mathrm{d}x \tag{14.1.1552}$$

Given:

$$m=\max(f(a),f(b)) \tag{14.1.1553}$$

the maximal value of the function f between the bounds $[a,b]$.

We consider the rectangle bounding function on the interval $[a,b]$ defined by vertices $\{(a,0),(b,0),(b,m),(a,m)\}$:

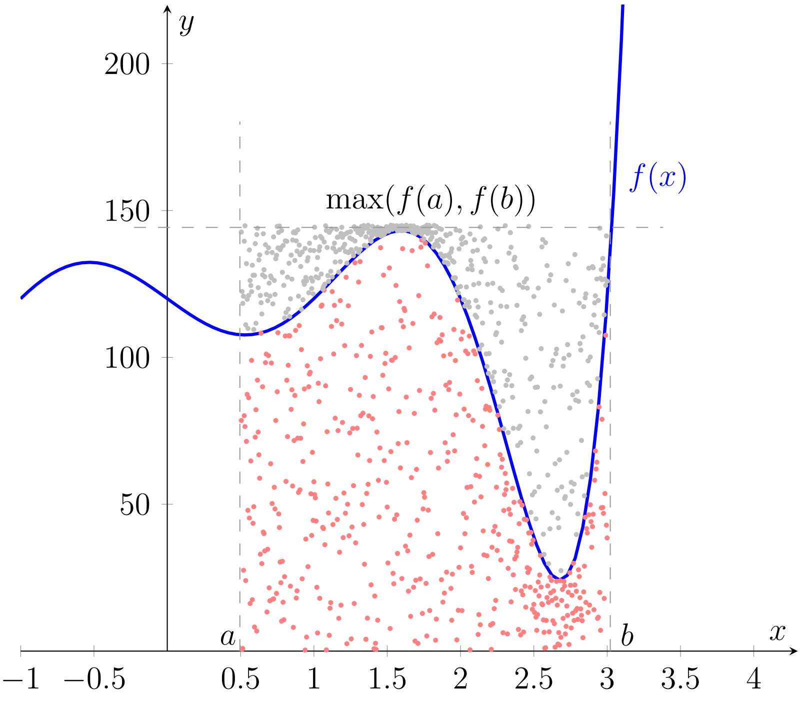

Figure 14.99: Basic principle of the univariate integral calculation with Monte Carlo

We draw a large number N of random points in this rectangle. For each point, $\xi_i=(x,y)$ we test if it is below the blue curve. Given P the proportion of points below this curve, we have:

$$\boxed{I_{\text{crude}}=\lim_{N\rightarrow+\infty}(b-a)m\frac{k}{N}} \tag{14.1.1554}$$

This approach seems to be sometimes named the "Monte Carlo Stochastic Point Method" or Monte Carlo hit-or-miss approach" or "Monte Carlo poor man's sampling".

The corresponding Maple™ 4.00b algorithm is given by:

```
>intmonte:=proc(f,a,b,N)
local i,al,bl,m,P,aleaabs,aleaord,isabove;
m:=round(max(f(a),f(b))*10^4);
al:=round(a*10^4);
bl:=round(b*10^4);
aleaabs:=rand(al..bl);
aleaord:=rand(0..m);
k:=0;
for i from 1 to N do
isabove:=(f(aleaabs()/10^4)-aleaord()/10^4)>=0;
if isabove then
k:=k+1;
fi
od:
RETURN((b-a)*max(f(a),f(b))*k/N)
end:
```

To call this procedure in Maple™, just write `>intmonte(f,a,b,N)` but replacing the first argument passed as a parameter with the expression of a function and the other arguments by numerical values (obviously!).

Notice that the relation above can be rewritten:

$$I_{\text{crude}} = \lim_{N\rightarrow +\infty} (b-a)m\hat{p} \tag{14.1.1555}$$

where $\hat{p}$ is the estimated parameter of a Bernoulli distribution and the corresponding random variable is ξ_i if we reject or accept the generated point:

$$\xi_i = \begin{cases} 1 & \text{if } y \in [0, f(x)] \\ 0 & \text{otherwise} \end{cases} \tag{14.1.1556}$$

Then $\{\xi_i\}$ are outcomes of independent duplicate trials and $\xi_1, \cdots, \xi_N \overset{i.i.d.}{\sim} \mathrm{B}(1,\hat{p})$. So if $\{\xi_i\}$ follows a Bernoulli distribution, then:

$$I_{\text{crude}} = (b-a)m\frac{P}{N} \tag{14.1.1557}$$

follows a binomial distribution $\mathcal{B}(N,k)$.

We know that the mean standard deviation of a variable (without factors) following a binomial distribution is:

$$\mu = np \qquad \sigma = \sqrt{npq} = \sqrt{np(1-p)} \tag{14.1.1558}$$

But here we have a factor $(b-a)m/N$, so that the mean becomes:

$$\mu=\frac{(b-a)m}{N}Np=(b-a)mp=(b-a)m\frac{k}{N}=I_{\text{crude}} \qquad (14.1.1559)$$

and the standard deviation will be:

$$\sigma_{I_{\text{crude}}}=\frac{(b-a)m}{N}\sqrt{Np(1-p)}=\sqrt{\frac{(b-a)^2m^2Np(1-p)}{N^2}}=\sqrt{\frac{(b-a)^2m^2p(1-p)}{N}} \qquad (14.1.1560)$$

The both latter relation are often written in textbooks by considering (implicitly) that the range of integration has been transformed to have an interval $a=0,b=1$ and the function transformed such that maximum $m=1$. Therefore:

$$\mu=\frac{1}{N}Np=p=I_{\text{crude}} \qquad \text{and} \qquad \sigma_{I_{\text{crude}}}=\sqrt{\frac{p(1-p)}{N}}=\sqrt{\frac{I_{\text{crude}}(1-I_{\text{crude}})}{N}} \qquad (14.1.1561)$$

To estimate the variance (or precision), we use the Central Limit Theorem and get[35] (don't forget that this relation is valid only if the integration has been transformed to have an interval $a=0,b=1$ and the function transformed such that maximum $m=1$):

$$\frac{\hat{I}_{\text{crude}}-I_{\text{crude}}}{\mathrm{V}(I_{\text{crude}})}=\frac{\hat{I}_{\text{crude}}-I}{\sqrt{\frac{I(1-I)}{N^3}}}\xrightarrow{D}\mathcal{N}(0,1) \qquad (14.1.1562)$$

That's a useful result to build confidence interval for that Monte Carlo method.

Let us consider another very common approach named "Monte Carlo mean value method" (m.v.) or "Monte Carlo uniform sampling method"!

Let $g(x)$ be a function and suppose that we want to compute:

$$I=\int_0^1 g(x)\mathrm{d}x \qquad (14.1.1563)$$

Recall that if X is a random variable with density $f(x)$, then the mathematical expectation of the random variable $Y=g(X)$ between 0 and 1 is given by:

$$\mathrm{E}(g(X)_{[0,1]})=\int_0^1 g(x)f(x)\mathrm{d}x \qquad (14.1.1564)$$

If a random sample is available from the distribution of X, an unbiased estimator of $\mathrm{E}(g(X))$ is the sample mean:

$$\mathrm{E}(g(X)_{[0,1]})\cong\hat{I}=\sum_{i=1}^{N}g(X_{[0,1]}^{(i)})f(X_{[0,1]}^{(i)}) \qquad (14.1.1565)$$

---

[35] Remember that the denominator is the standard error of the mean $\sigma_\mu=\sigma/\sqrt{N}$

If we take a distribution $f(X_{[0,1]}^{(i)})$ that is equally likely between 0 and 1 like the Uniform distribution $\mathcal{U}_{[0,1]}$, then the above relation reduces to:

$$I=\int\limits_0^1 g(x)\mathrm{d}x\cong\frac{1}{N}\sum_{i=1}^N g(\mathcal{U}_{[0,1]}) \qquad (14.1.1566)$$

To compute $\int_a^b g(t)\mathrm{d}t$ we make a change of variables so that the limits of integration are from 0 to 1. The linear transformation is $y=(t-a)/(b-a)$ and $\mathrm{d}t=(b-a)\mathrm{d}y$. Therefore:

$$I=\int\limits_a^b g(t)\mathrm{d}t=\int\limits_0^1 g(y(b-a)+a)(b-a)\mathrm{d}y=(b-a)\int\limits_0^1 g(y(b-a)+a)\mathrm{d}y\cong\frac{b-a}{N}\sum_{i=1}^N g(\mathcal{U}_{[a,b]}) \qquad (14.1.1567)$$

Hence:

$$\boxed{I_{\text{m.v.}}=\lim_{N\rightarrow+\infty}\frac{b-a}{N}\sum_{i=1}^N g(\mathcal{U}_{[a,b]})} \qquad (14.1.1568)$$

By the fundamental theorem of Monte Carlo (see section Statistics page 924) it converges with probability 1.

Notice also that by the Central Limit Theorem we have that the standard error of $I_{\text{m.v.}}$ is given by:

$$\sigma_{I_{\text{m.v.}}}=\frac{\sigma}{\sqrt{N}}=\frac{\mathrm{V}(g(X))}{\sqrt{N}}=\frac{\sqrt{\int_0^1(g(x)-I)^2\mathrm{d}t}}{\sqrt{N}}=\sqrt{\frac{\int_0^1(g(x)-I)^2\mathrm{d}t}{N}} \qquad (14.1.1569)$$

Or using Huygens relation, given for recall by $\mathrm{V}(X)=\mathrm{E}(X^2)-\mathrm{E}(X)^2$, we get:

$$\sigma_{I_{\text{m.v.}}}^2=\frac{1}{N}\mathrm{E}(g(x)^2)-\frac{I^2}{N} \qquad (14.1.1570)$$

This is useful to put confidence limits or error bounds on the Monte Carlo estimate of the integral, and check for convergence.

However, the m.v. method (Monte Carlo mean value method) has two major limitations:

- It does not apply to unbounded intervals!
- It can be inefficient to draw samples uniformly across the interval if the function $g(x)$ is not very uniform!

Remark

The reader can refer to our `R` or MATLAB® free companion books to see examples with the respective script language of these two softwares for the both method presented above.

Now let us just compare:

$$\sigma^2_{I_{\text{m.v.}}} - \sigma^2_{I_{\text{crude}}} = \left[\frac{1}{N}\mathrm{E}(g^2) - \frac{I^2}{N}\right] - \frac{I(1-I)}{N} = \frac{1}{N}\mathrm{E}(g^2) - \frac{I^2}{N} - \frac{I}{n} + \frac{I^2}{n} = \frac{1}{N}(\mathrm{E}(g^2) - I)$$
$$= \frac{1}{N}(\mathrm{E}(g^2) - \mathrm{E}(I)) = \frac{1}{N}\int_0^1 g(x)(f(x)-1)\mathrm{d}x \qquad (14.1.1571)$$

Moreover, many textbooks claim that:

$$\frac{1}{N}\int_0^1 g(x)(f(x)-1)\mathrm{d}x > 0 \qquad (14.1.1572)$$

But this is neither true nor false!

14.1.18.1.4 Monte Carlo estimation of π

For the calculation of π the principle is the same and therefore consist to use the proportion of the number of points in a quarter of circle area (this simplifies the algorithm by restricting the calculations to strictly positive coordinates) inscribed in a square of side 1 (so the radius of the circle is also equal to 1 obviously) relatively to the total number of points (to test if a point is outside the circle, we obviously use the Pythagorean theorem) such that:

$$\pi = \lim_{N\rightarrow+\infty} 4\frac{P}{N} \qquad (14.1.1573)$$

Because we have for the number of points P inside the quarter or circle that corresponds to a surface of $\pi R^2/4$ and the number of points N inside surface of the quarter of square that corresponds to a surface R^2. So the ratio of both should tend to $\pi/4$ when $N\rightarrow+\infty$. We just have to multiply by 4 to get a good approximation of π.

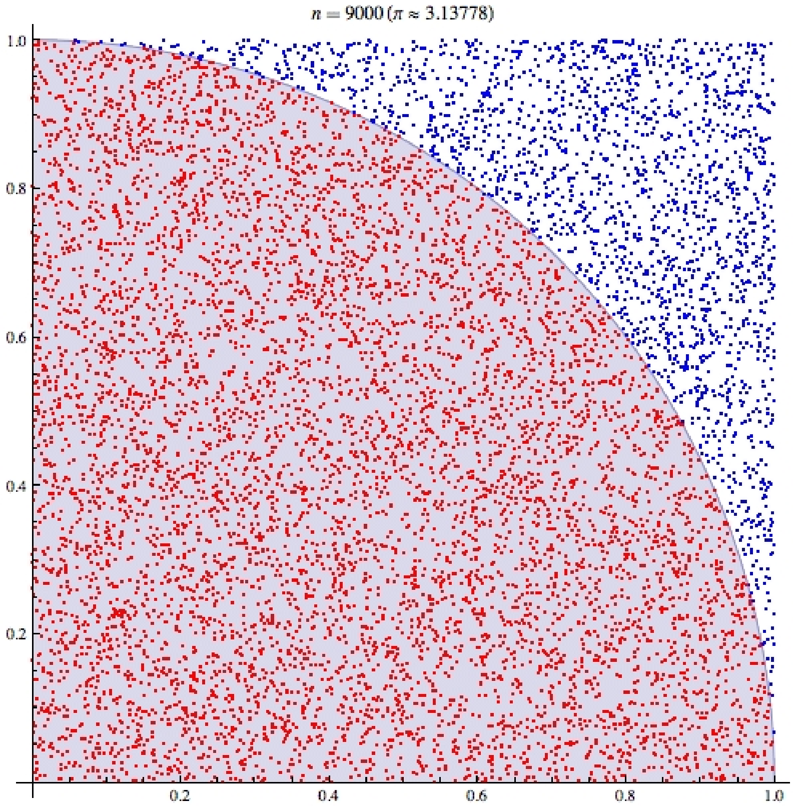

Figure 14.100: **Monte Carlo π estimate**

That method is equivalent to defining an indicator variable I as:

$$I = \begin{cases} 1 & \text{if } X^2 + Y^2 \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

where $X, Y = \mathcal{U}_{[0,1]}$. Where that:

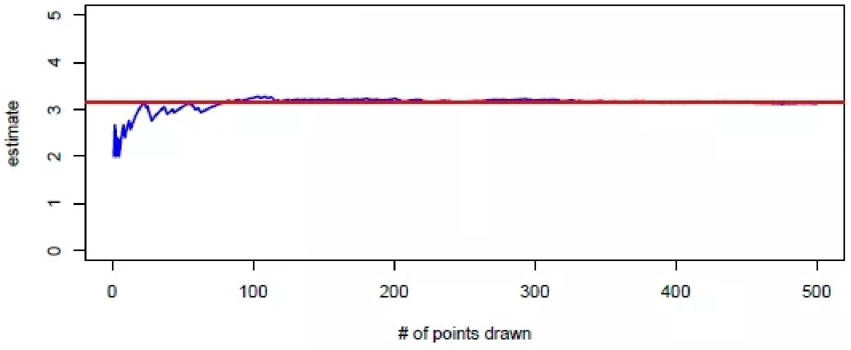
$$\mathrm{E}(I) = \frac{\pi}{4} \quad \text{and} \quad \mathrm{V}(I) = \frac{\pi}{4}\left(1 - \frac{\pi}{4}\right)$$

The corresponding Maple™ 4.00b algorithm is given by:

```
>isinside:=proc(x,y) x^2+y^2<1 end:
>calculatepi:=proc(N)
local i,P,abs,ord,alea;
alea:=rand(-10^4..10^4);
P:=0;
for i from 1 to N do
abs:=alea()/10^4;ord:=alea()/10^4;
if isinside(abs,ord) then
P:=P+1;
fi
od;
RETURN(4*P/N)
```

```
end:
>evalf(calculatepi(100));evalf(calculatepi(1000));
evalf(calculatepi(10000));evalf(calculatepi(100000));
```

In terms of convergence it looks typically as:



Remark

The reader can refer again to our `R` or MATLAB® free companion books to see examples with the respective script language of these two softwares for the example above.

14.1.18.1.5 Monte Carlo Modelling

The most common application of the Monte Carlo method in business and industry is certainly the study of random variables. Furthermore, this method is part of the ISO 31010 Risk Management standard under the name of "Monte Carlo analysis". Many cutting edge tech companies make Monte Carlo modelling with a spreadsheet softwares like Microsoft® Excel® (even multinationals!) and with a lesser extent with professional oriented softwares or add-ins such as @RISK, Crystal Ball, TreeAge, Isograph or MATLAB® (without taking into account C, C++, Java, `R`, and Python™ obviously).

The advantages of this method in modelling random variables are:

- We can integrate any distribution including empirical one and not continuous one!
- Models are very easy to implement and can be expanded as needed without too much effort.
- All influences or relation occurring in reality (at least the identified one....) may be represented and implemented in the model.
- Sensitivity analysis (see section Quantitative Management Techniques page 8184) can be applied.
- The models are easily understandable and provide a measure of the accuracy of the result.

- Many inexpensive software are available (at least inexpensive in comparison to criticality of the business analysed that is most of time in the order of the billion of dollars).

Let us consider a simple but concrete case (widely used in business) that I like to use in my introduction training of a small project of two tasks denoted by A and B which follow each other without free margin (or free slack). Let us imagine that the duration of each task has been estimated in accordance with the recommendation of the Project Management Institute with a beta distribution (see section Statistics page 760) as learn it almost all good project managers in their training curriculum (see section Quantitative Management Techniques page 8074).

For this example, the task A has an optimistic duration of 5 days and a pessimistic duration of 8 days. Task B an optimistic duration of 1 day and a pessimistic duration of 4 days. We would like in the spreadsheet software Microsoft® Excel® using a pseudo Monte Carlo simulation (therefore necessarily based on a pseudo-random variable) introduce three traditional minimum information:

	A	B	C
1	Task *A*	Task *B*	Task *C*
2	6.325525	7.88429	14.20981
3	7.791029	7.256565	15.04759
4	7.575362	6.87937	14.45473
5	5.753179	7.690408	13.44359
6	7.154639	7.147862	14.3025
7	6.855552	7.928369	14.78392
8	7.947285	6.051008	13.99829
9	6.742121	7.306691	14.04881
10	7.776618	7.759694	15.53631
11	6.442332	7.561024	14.00336
12	6.964642	7.623754	14.5884
13	7.671115	7.980624	15.65174
14	7.401459	7.15691	14.55837
15	7.035523	7.746792	14.78232
16	6.89049	7.702441	14.59293
17	5.963423	6.434905	12.39833
18	7.519925	7.661321	15.18125
19	6.361855	7.130727	13.49258
20	7.361563	6.945891	14.30745
21	7.302083	6.852933	14.15502
22	6.885128	7.044542	13.92967
23	7.130162	6.961288	14.09145
24	7.016234	7.064954	14.08119
25	6.879057	7.689645	14.5687
26	7.133283	7.233002	14.36629
27	7.283903	7.844765	15.12867

- A table with 3 columns (duration of A, B and sum of both) and $10,000$ simulations (rows)

- The graphical distribution function of the sum of the two random variables
- The convergence of the 95th percentile on the 100 first simulations (useful for the subject further below).

We then construct the following table of $10,000$ row (the screenshot shows only the first rows...) where all cells from row 2 to row $10,000$ of column `A` contains the following function (Microsoft® Excel® 14.0.7166):

```
=BETA.INV(RAND(),3+SQRT(2),3-SQRT(2),5,8)
```

and for column `B` contains the following function:

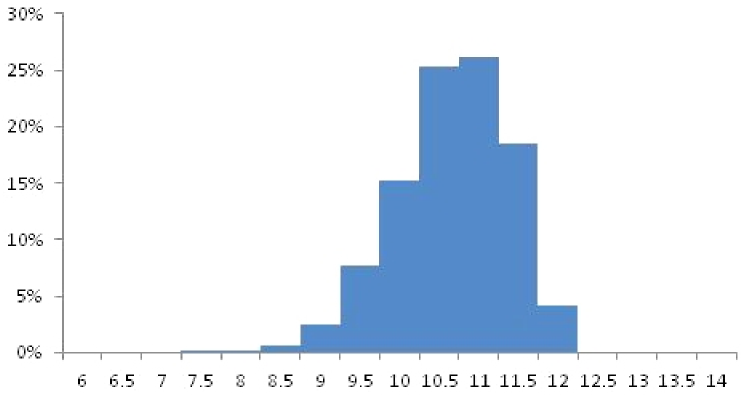
```
=BETA.INV(RAND(),3+SQRT(2),3-SQRT(2),1,4)
```

and finally the cell `C1` contains the following function that was pull down until cell `C10000`:

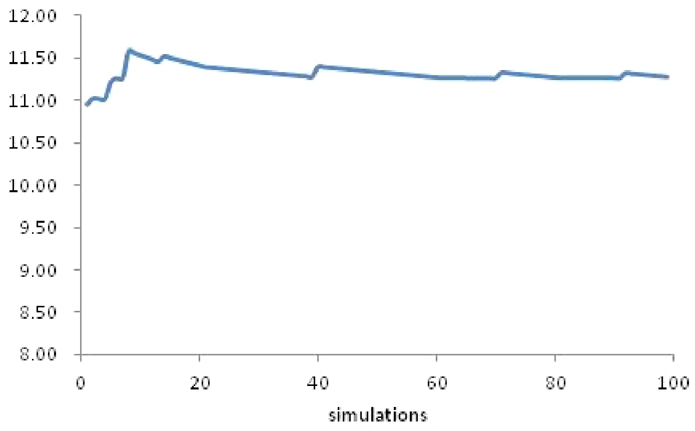
```
=A2+B
```

Obviously the values in Microsoft® Excel® 14.0.6123 will change each time you press the `F9` key on the keyboard.

Then this gives us the histogram still made with the same software version (we will not detail how to building such a chart it is a basic subject of Microsoft Office knowledge and has nothing to do in a scientific book) where the x-axes are the number of days:



and the convergence of the 95th percentile of the first 100 simulations (because as this example is simple, the system converges quickly enough so that we do not to need to take more than 100 simulations as example) where the y-axes is the number of days:



Obviously by default, in Microsoft® Excel® 14.0.6123 the chart above will change each time you press the `F9` key on the keyboard.

Remark

In the case of the simulations of random variables, we can in simple situations involving only sums or subtractions of random variables, as for the example above, determine the mean and the standard deviation of the results analytically using the property of linearity of the mean and variance (because normally for the variance of two independent random variables, the covariance is zero). By analysing the difference between the analytical value and that obtained by numerical simulation, the offset can be corrected certain other statistical indicators by simply adding or subtracting the differential. This is known as the technique of "control variables" that we will detail further below.

There are other variance reduction techniques (i.e. standard deviation) than control variables techniques to reduce the variance of the Monte Carlo estimators in specific conditions:

- One of these techniques is the use of "antithetic variables" which consists very simply (programming this technique is at the high school level as you can see it in the MATLAB® companion book) to decorrelate simulations to make the covariance between the variables negative and so reduce the global variance (such as we have seen in the section Statistics, the variance of the sum of two random variables make appear a covariance term). Unfortunately, this technique works satisfactorily with symmetric distributions this is why to my knowledge it is not implemented in simulation software available on the market.

- There is also the technique named "stratified sampling" that consist to cut the pre-image space of the random variable in regular intervals (the programming of this technique is also at the high school level as you can see in the MATLAB® companion book). This technique works very well when the number of simulations must be small but only in the case of a single variable. This also why, as far as we I know, it is not implemented in simulation softwares available on the market.

- There exist is a generalization of stratified sampling (the programming of this technique is also at the high school level) for simulations with multiple variables and that is named "Latin Hypercube" (abbreviated as "LHS" for Latin Hypercube Stratification). This technique ensures that each n-tuple of random variables (corresponding to a space of n dimensions) uses a unique pre-image at each iteration, hence the name of that technique (Latin: refers to magic squares where each value appears uniquely, Hypercube because is an n-dimensional generalization of a magic square). Some simulation software available on the market implement this technique (@RISK, Crystal Ball).

To summarize, whether that it's the technique of Faure sequence generators, of antithetic variables, of control variables, of stratified sampling or Latin Hypercube even if these techniques are all easy to program, the method using the pseudo-random variables is privileged because is the most suitable for the majority of common situations in the business and in non-cutting edge scientific applications.

Remark

For the reader interested to have a deeper overview, however with out too much mathematical details, we recommend the following actual reference: *Introducing Monte Carlo Methods with R* (see [464]).

14.1.18.1.6 Monte Carlo variance reduction

What we have seen so far is only what we may name the "crude Monte Carlo simulation". We will now introduce the problem of reducing the variance of the samples that are generated to estimate the mean value λ of some random variable X using Monte Carlo method. The main underlying idea is to reduce the standard error and increasing the confidence in the accuracy of the estimate (very important in speculative finance and nuclear or quantum physics!). We will see further below four variance-reduction methods (among seven existing one).

Suppose one wants to compute $z := \text{E}(Z)$ with the random variable Z. As we know, Monte Carlo does this by sampling i.i.d. copies $Z_1, \ldots, Z_R$ of Z and then to estimate z via the sample-mean estimator:

$$\bar{z} = \frac{1}{n}\sum_{i=1}^{n} Z_i \tag{14.1.1574}$$

Under further mild conditions such as $\text{V}(Z) < +\infty$, a central limit theorem will apply such that for large $n \rightarrow +\infty$, the distribution of $\bar{z}$ converges to a Normal distribution with mean z and standard deviation $\sigma/\sqrt{n}$. Because the standard deviation only converges towards 0 at the rate $\sqrt{n}$. implying one needs to increase the number of simulations (n) by a factor of 10 to half the standard deviation of $\bar{z}$, variance reduction methods are often useful for obtaining more precise estimates for z without needing very large numbers of simulations.

There are commonly seven variance reduction methods:

1. Antithetics
2. Stratification
3. Quasi-random method

4. Conditioning (conditional sampling)
5. Control variates
6. Moment matching and re-weighting
7. Monte Carlo Markov Chains

Remark

For practical examples with explicit code (scripts) the reader can refer to our MATLAB® or `R` free companion book (actually the MATLAB® one has the most interesting examples).

As already mentioned, will focus here on four of them:

1. **Antithetic variables**: Instead of a single sample sequence $X_1,\ldots,X_n$ sampled from X, this method instead uses an additional variable Y for which $\text{E}(Y)=\text{E}(X)=\lambda$, but is negatively correlated with X. The ith sample now becomes $\frac{X_i+Y_i}{2}$.
2. **Control variables**: A control variable is a random variable Y for which $\text{E}[Y]=\mu$ is known, and for which sampling variable X is replaced with $X+c(Y-\mu)$, where c is chosen so as to minimize $\text{V}(X+c(Y-\mu))$.
3. **Conditional sampling**: Conditional sampling selects a suitable variable Y for which $\text{E}(X|Y)$ has a smaller variance than X. Y is chosen so that, when it is observed, the uncertainty (i.e. entropy) of X gets reduced.
4. **Stratified (Regional) sampling**: Stratified sampling is a divide-and-conquer strategy that partitions the domain of X into subdomains, and then a sampling plan is devised for each subdomain. Moreover, common sense suggests that the smaller the subdomain, the less variance that should exist in that region, and so a variance reduction may be achievable in each of the subdomains that comprise the original domain.

And let us recall that if X and Y are two random variables, then we have proved in the section Statistics (see page 597) that:

$$\text{V}(X+Y)=\text{V}(X)+\text{V}(Y)+2\text{cov}(X,Y) \tag{14.1.1575}$$

Ok let's start!

14.1.18.1.6.1 Method of Antithetic Variables

Suppose X and Y are random variables for which $\mathrm{E}(Y)=\mathrm{E}(X)=\lambda$. Then:

$$\mathrm{E}\left(\frac{X+Y}{2}\right)=\frac{1}{2}\mathrm{E}(X)+\frac{1}{2}\mathrm{E}(Y)=\lambda/2+\lambda/2=\lambda \tag{14.1.1576}$$

Moreover:

$$\mathrm{V}\left(\frac{X+Y}{2}\right)=\frac{1}{4}\left[\mathrm{V}(X)+\mathrm{V}(Y)+2\mathrm{cov}(X,Y)\right] \tag{14.1.1577}$$

Remark

In the special case of $X=Y$ we fall back obviously on:

$$\mathrm{E}\left(\frac{X+Y}{2}\right)=\mathrm{E}\left(\frac{X+X}{2}\right)=\mathrm{E}\left(X\right)=\lambda$$

and:

$$\mathrm{V}\left(\frac{X+X}{2}\right)=\mathrm{V}\left(X\right)=\frac{1}{4}\left[\mathrm{V}(X)+\mathrm{V}(X)+2\mathrm{V}(X)\right]$$

Notice that, if X and Y are dependent and have negative correlation, then $\mathrm{cov}(X,Y)<0$, which causes a reduction in variance (compared to the case where X and Y are uncorrelated)[36].

A typical example given in many textbooks is to compute the mean of $\mathcal{U}_{[0,1]}$ by using an antithetic variable $1-\mathcal{U}_{[0,1]}$ (it's indeed an important example as $\mathcal{U}_{[0,1]}$ is used for the inverse transform method!).

✍**Example:**

The simple example is if $X=\mathcal{U}$, then $Y=1-\mathcal{U}$. We have then:

$$\frac{X+Y}{2}=\frac{1}{2}$$

and:

$$\frac{X+Y}{2}=\frac{\mathcal{U}+(1-\mathcal{U})}{2}=0$$

ie perfect negative correlation!

Notice that this method can obviously be used to compute integrals by implementing it in the Monte Carlo Mean Value Method presented earlier above!

---

[36] Remember that by definition, the correlation between X and Y is defined as $\mathrm{cor}(X,Y)=\frac{\mathrm{cov}(X,Y)}{\sigma_X\sigma_Y}$

14.1.18.1.6.2 Method of Control Variables

Suppose we are interested in estimating $\text{E}(X)=\lambda$. Then instead of exclusively sampling X, we may also introduce another variable Y, named the "control variable", that is correlated with X, and sample $Z=X+c(Y-\mu)$, where c is a constant, and $\mu=\text{E}(Y)$. Notice that :

$$\text{E}(Z)=\text{E}(X)+c\text{E}(Y-\mu)=\lambda+c(\mu-\mu)=\lambda+c\cdot 0=\lambda \tag{14.1.1578}$$

and so sampling Z will lead to an unbiased estimator. Moreover:

$$\text{V}(Z)=\text{V}(X+c(Y-\mu))=\text{V}(X)+c^2\text{V}(Y)+2c\cdot\text{cov}(X,Y) \tag{14.1.1579}$$

which is minimized when:

$$\frac{\partial}{\partial c}\left(\text{V}(X)+c^2\text{V}(Y)+2c\cdot\text{cov}(X,Y)\right)=0 \tag{14.1.1580}$$

Therefore:

$$c=-\frac{\text{cov}(X,Y)}{\text{V}(Y)} \tag{14.1.1581}$$

(optimal c sometimes denoted c^*) and yields a variance equal to:

$$\text{V}(Z^*)=\text{V}(Z+c^*Y)=\text{V}(X)-\frac{\text{cov}^2(X,Y)}{\text{V}(Y)} \tag{14.1.1582}$$

Hence:

$$\text{V}(Z^*)<\text{V}(X)\Leftrightarrow\text{cov}^2(X,Y)<0 \tag{14.1.1583}$$

Therefore, the method of control variables will always reduce variance, so long as X and Y have non-zero correlation.

One issue faced by this method is that usually neither $\text{cov}(X,Y)$ nor $\text{V}(X)$ are known beforehand. However, as a preprocessing step, we may obtain the estimators:

$$\widehat{\text{cov}}(X,Y)=\frac{\sum_{i=1}^n(X_i-\hat{\lambda})(Y_i-\mu)}{n-1} \tag{14.1.1584}$$

and:

$$\hat{\sigma}_Y^2=\frac{\sum_{i=1}^n(Y_i-\mu)^2}{n-1} \tag{14.1.1585}$$

to obtain the estimate:

$$\hat{c}=\frac{\sum_{i=1}^n(X_i-\hat{\lambda})(Y_i-\mu)}{\sum_{i=1}^n(Y_i-\mu)^2} \tag{14.1.1586}$$

for c.

And finally:

$$\hat{\mu}_{N,c^*}=\frac{1}{N}\sum_{i=1}^N[X_i+c^*(Y_i-\text{E}(Y)]\cong\mu_X \tag{14.1.1587}$$

The real challenge is to choose the control variable Y that is easy to simulate and for which μ_Y is easy to find...

Notice that this method can also obviously be used to compute integrals by implementing it in the Monte Carlo Mean Value Method presented earlier above!

14.1.18.1.6.3 Method of Conditioning

There are times when knowledge of the value of a random variable Y can reduce the variance of what can be observed for X.

In this case $\text{E}(X|Y)$ may have less variance than X. Note also (see section Probabilities page 501) the iterated conditional mean $\text{E}(\text{E}(X|Y))=\text{E}(X)$, and so $\text{E}(X|Y)$ is an unbiased estimator of $\text{E}(X)$.

So in other words, the idea is that instead of computing $\mu_Y=\text{E}(X)$, for a given random variable Z, we put $V=\text{E}(X|Y)$ and we calculate instead $\mu_X=\text{E}(V)=\text{E}(\text{E}(X|Y))=\text{E}(X)$.

Moreover, the amount of reduction in variance is determined by the following proposition.

Let us prove first that:

$$\text{V}(X)=\text{E}(\text{V}(X|Y))+\text{V}(\text{E}(X|Y)) \tag{14.1.1588}$$

To do that we just write:

$$\begin{aligned}\text{E}[\text{V}(X|Y)]+\text{V}(\text{E}(X|Y))&=\text{E}[\text{E}(X^2|Y)-\text{E}^2(X|Y))+\text{E}(\text{E}^2(X|Y))-(\text{E}[\text{E}(X|Y)))^2]\\&=\text{E}(\text{E}(X^2|Y))-\text{E}(\text{E}^2(X|Y))+\text{E}(\text{E}^2(X|Y))+\text{E}^2(X)\\&=\text{E}(X^2)-\text{E}^2(X)=\text{V}(X)\end{aligned} \tag{14.1.1589}$$

We have for immediate corollary:

Corollary 14.6.1.

$$\text{V}(X)-\text{V}(\text{E}(X|Y))=\text{E}(\text{V}(X|Y))\Leftrightarrow\text{V}(X)=\text{V}(\text{E}(X|Y))+\text{E}(\text{V}(X|Y)) \tag{14.1.1590}$$

So it proves that:

$$\text{V}(\text{E}(X|Y))<\text{V}(X)\Leftrightarrow\frac{\text{V}(\text{E}(X|Y))}{\text{V}(X)}<1 \tag{14.1.1591}$$

Very likely for many people that is very abstract and counter intuitive. So let us see an example!

✍**Example:**

Let us recall the method of approximating π using Monte Carlo that was presented earlier above with an indicator variable I such that:

$$I=\begin{cases}1 & \text{if } X^2+Y^2\leq 1\\0 & \text{otherwise}\end{cases}$$

where $X,Y=\mathcal{U}_{[0,1]}$. Recall that (remember that's for the quarter of a circle!):

$$\text{E}(I)=\frac{\pi}{4}\quad\text{and}\quad\text{V}(I)=\frac{\pi}{4}\left(1-\frac{\pi}{4}\right)\cong 0.1685$$

We now show that $\text{E}(I|X)$ has a smaller variance. For that purpose we start by calculating:

$$\begin{aligned}\mathrm{E}(I|X=x)&=P(X^2+Y^2\leq 1|X=x)=P(Y^2\leq 1-x^2|X=x)\\&=P(Y^2\leq 1-x^2)=P(-(1-x^2)^{1/2}\leq Y\leq (1-x^2)^{1/2})\\&=\int\limits_{-(1-x^2)^{1/2}}^{(1-x^2)^{1/2}}\frac{1}{2}\mathrm{d}y=(1-x^2)^{1/2}\\&\Rightarrow \mathrm{E}(I|X)=(1-X^2)^{1/2}\end{aligned}$$

However, since X^2 has the same distribution as U^2, $U=\mathcal{U}_{[0,1]}$, it follows that we get the following:

$$\mathrm{E}(I|X)=(1-U^2)^{1/2}$$

Notice that the expected means remains a random variable (without surprise as it is a conditions expected mean) that we will denote $Z:=\mathrm{E}(I|X)=(1-U^2)^{1/2}$! Therefore using Huygens relation (see section Statistics page 593), $\mathrm{V}(Z)=\mathrm{E}(Z^2)-\mathrm{E}(Z)^2$ we get:

$$\begin{aligned}\mathrm{V}(\mathrm{E}(I|X))=\mathrm{V}\left((1-U^2)^{1/2}\right)&=\mathrm{E}\left(\left((1-U^2)^{1/2}\right)^2\right)-\mathrm{E}\left((1-U^2)^{1/2}\right)^2\\&=\mathrm{E}\left(1-U^2\right)-\mathrm{E}\left((1-U^2)^{1/2}\right)^2=1-\mathrm{E}\left(U^2\right)-\mathrm{E}\left((1-U^2)^{1/2}\right)^2\end{aligned}$$

Using the result derived in the section Statistics page 739, i.e. $\mathrm{E}(\mathcal{U}_{0,1}^2)=1/3$, we then have:

$$\mathrm{V}(\mathrm{E}(I|X))=\mathrm{V}\left((1-U^2)^{1/2}\right)=1-\frac{1}{3}-\mathrm{E}\left((1-U^2)^{1/2}\right)^2=\frac{2}{3}-\mathrm{E}\left((1-U^2)^{1/2}\right)^2$$

We just have left to compute $\mathrm{E}(\sqrt{1-U^2})=\int_0^1\sqrt{1-x^2}\mathrm{d}x$ and using the primitive derived in the section of Differential and Integral Calculus at page 1534, we get $\mathrm{E}(\sqrt{1-U^2})=\pi/4$. Therefore:

$$\mathrm{V}(\mathrm{E}(I|X))=\frac{2}{3}-\left(\frac{\pi}{2}\right)^2$$

Hence:

$$\frac{\mathrm{V}(\mathrm{E}(X|Y))}{\mathrm{V}(X)}\cong\frac{0.0498}{0.1685}\cong 0.295$$

yielding a 70.5% reduction in variance.

14.1.18.1.6.4 Method of Stratified Sampling

The reader remembers maybe that we have seen earlier above the method of Simple Random Sampling (SRS) in which realizations of a vector $\vec{x}$ (samples) are generated as independent and identically distributed realizations on a domain $\mathcal{S}$ with marginal cumulative distribution functions (CDFs) $F(x)$ by:

$$x_i = F_{X_i}^{-1}\left(\mathcal{U}_i\right); i = 1, 2, \ldots, n \qquad (14.1.1592)$$

where $\mathcal{U}_i$ are independent and identically distributed uniformly distributed samples on $[0,1]$. The realizations $\vec{x}$ are then applied to the system $\vec{y} = \vec{F}(\vec{x})$ and $\vec{y}$ is statistically evaluated.

"Stratified sampling" represents another conditioning approach to reduce variance. It aims to reduce the variance of the estimator by dividing the interval into strata and estimating the integral on each of the stratum with smaller variance.

Again, suppose the goal is to estimate $\lambda = \text{E}(X)$. Suppose Y is a finite random variable with $\text{dom}(Y) = \{y_1, \ldots, y_k\}$ and $p_i = P(y_i)$ is known for each $i = 1, \ldots, k$.

Then:

$$\text{E}(X) = \sum_{i=1}^{k} \text{E}(X|Y = y_i)p(y_i) \qquad (14.1.1593)$$

Then λ can be estimated by estimating each of $\text{E}(X|Y = y_i)$ with $\hat{\lambda}_i$ and producing the estimate:

$$\hat{\lambda} = \sum_{i=1}^{n} \hat{\lambda}_i p_i \qquad (14.1.1594)$$

where $\hat{\lambda}_i$ is obtained using n_i samples, and $n_1 + \cdots + n_k = n$ and $n_i = np_i$.

Notice that:

$$\text{V}(\hat{\lambda}) = \sum_{i=1}^{n} p_i^2 \text{V}(\hat{\lambda}_i) = \sum_{i=1}^{n} p_i^2 \frac{\text{V}(X|Y = y_i)}{np_i} = \frac{1}{n}\text{E}(\text{V}(X|Y)) \qquad (14.1.1595)$$

Thus:

$$\frac{1}{n}\text{V}(X) - \frac{1}{n}\text{E}(\text{V}(X|Y)) = \frac{1}{n}\text{V}(\text{V}(X|Y)) \qquad (14.1.1596)$$

Hence:

$$\frac{1}{n}\text{V}(\text{V}(X|Y)) < \frac{1}{n}\text{V}(X) \qquad (14.1.1597)$$

so that the reduction in variance depends on the amount of variance that occurs in $\text{E}(X|Y)$. After simplification and rearrangement we get obviously:

$$\frac{\text{V}(\text{V}(X|Y))}{\text{V}(X)} < 1 \qquad (14.1.1598)$$

The introduction above may be to abstract. So let us introduce it in another way! Consider we want to estimate an integral that consist a distribution p and a function of interest f

$$I = \int_{\chi} p(x) f(x) \mathrm{d}x \tag{14.1.1599}$$

via partitioning χ into smaller groups, named "strata". It is a type of quasi-Monte Carlo (QMC) method as it introduces deterministic procedures into the MC estimation. Same as crude Monte Carlo the estimation is still unbiased; however, the variance of the estimator can be smaller than crude Monte Carlo.

The (crude) Monte Carlo estimator of I is:

$$\hat{I} = \frac{1}{N} \sum_{i=1}^{N} f(x^i) \tag{14.1.1600}$$

where $x^i \sim p(x)$ and N is the number of Monte Carlo samples.

This estimator is an unbiased estimator of the original target I:

$$\mathrm{E}(\hat{I}) = \mathrm{E}\left(\frac{1}{N} \sum_{i=1}^{N} f(x^i)\right) = \frac{1}{N} \sum_{i=1}^{N} \mathrm{E}(f(x^i)) = \frac{1}{N} \sum_{i=1}^{N} I = I \tag{14.1.1601}$$

Now let's look at the variance of the estimator $\mathrm{V}(\hat{I})$. We first need to define:

$$\sigma^2 := \int_{\chi} p(x)(f(x) - I)^2 \mathrm{d}x \tag{14.1.1602}$$

which is the variance of $f(x)$ under the distribution $p(x)$. Now the variance of interest is

$$\mathrm{V}(\hat{I}) = \mathrm{V}\left(\frac{1}{N} \sum_{i=1}^{N} f(x^i)\right) = \frac{1}{N^2} \sum_{i=1}^{N} \mathrm{V}(f(x^i)) = \frac{1}{N^2} \sum_{i=1}^{N} \sigma^2 = \frac{\sigma^2}{N} \tag{14.1.1603}$$

As it can be seen, the variance drops with the order of $\mathcal{O}(\frac{1}{N})$ by using more samples.

Now, we look at how stratified sampling works and how the variance of the corresponding estimator changes depending on different stratifications. For the sake of simplicity, we consider the case where $p(x) = \mathcal{U}^D_{[0,1]}$ a D-dimensional uniform distribution for the integral. We first partition χ into H strata s.t. $\chi = \chi_1 \cup \ldots \cup \chi_H$. Then, as the simplest way of performing stratified sampling, we uniformly draw independent Monte Carlo samples for each stratum χ_h, and the overall estimator is given as below:

$$\hat{I}_{\text{strat}} = \sum_{h=1}^{H} \frac{|\chi_h|}{n_h} \sum_{i=1}^{n_h} f(x^i_h) \tag{14.1.1604}$$

where $\{x^i_h\}_{i=1}^{n_h}$ are samples that lie in χ_h and n_h is the number of MC samples in stratum h.

The mean of f within each stratum h is therefore:

$$\mu_h = \int_{\chi_h} \mathcal{U}(x; \chi_h) f(x) \mathrm{d}x = |\chi_h|^{-1} \int_{\chi_h} f(x) \mathrm{d}x \tag{14.1.1605}$$

and the corresponding variance is:

$$\sigma_h^2 = \int_{\chi_h} \mathcal{U}(x;\chi_h)(f(x)-\mu_h)^2\mathrm{d}x = |\chi_h|^{-1}\int_{\chi_h}(f(x)-\mu_h)^2\mathrm{d}x \tag{14.1.1606}$$

As it is mentioned in the beginning, $\hat{I}_{\text{strat}}$ is still an unbiased estimator of I. We can validate this by computing the mean of $\hat{I}_{\text{strat}}$:

$$\begin{aligned}
\mathrm{E}\left(\hat{I}_{\text{strat}}\right) &= \mathrm{E}\left(\sum_{h=1}^{H}\frac{|\chi_h|}{n_h}\sum_{i=1}^{n_h} f\left(x_h^i\right)\right) = \sum_{h=1}^{H}\frac{|\chi_h|}{n_h}\sum_{i=1}^{n_h}\mathrm{E}\left(f\left(x_h^i\right)\right)\\
&= \sum_{h=1}^{H}\frac{|\chi_h|}{n_h}\sum_{i=1}^{n_h}|\chi_h|^{-1}\int_{\chi_h} f(x)\mathrm{d}x = \sum_{h=1}^{H}\frac{1}{n_h}\sum_{i=1}^{n_h}\int_{\chi_h} f(x)\mathrm{d}x = \sum_{h=1}^{H}\int_{\chi_h} f(x)\mathrm{d}x\\
&= \int_{\chi_1\cup\ldots\cup\chi_H} f(x)\mathrm{d}x = \int_{\mathcal{X}} f(x)\mathrm{d}x = I
\end{aligned} \tag{14.1.1607}$$

The variance of $\hat{I}_{\text{strat}}$ is then:

$$\begin{aligned}
\mathrm{V}\left(\hat{I}_{\text{strat}}\right) &= \mathrm{V}\left(\sum_{h=1}^{H}\frac{|\chi_h|}{n_h}\sum_{i=1}^{n_h} f\left(x_h^i\right)\right) = \sum_{h=1}^{H}\mathrm{V}\left(\frac{|\chi_h|}{n_h}\sum_{i=1}^{n_h} f\left(x_h^i\right)\right) = \sum_{h=1}^{H}\frac{|\chi_h|^2}{n_h^2}\mathrm{V}\left(\sum_{i=1}^{n_h} f\left(x_h^i\right)\right)\\
&= \sum_{h=1}^{H}\frac{|\chi_h|^2}{n_h^2}\sum_{i=1}^{n_h}\mathrm{V}\left(f\left(x_h^i\right)\right) = \sum_{h=1}^{H}\frac{|\chi_h|^2}{n_h^2}\sum_{i=1}^{n_h}\sigma_h^2 = \sum_{h=1}^{H}\frac{|\chi_h|^2}{n_h}\sigma_h^2
\end{aligned} \tag{14.1.1608}$$

We are interested in comparing this estimator against (crude) Monte Carlo. In particular, we'd like to show that when n_h is allocated proportionally to $|\,\chi_h\,|$ the estimator can only decrease in variance as compared to (crude) Monte Carlo.

In order to show this, we need to rewrite the variance of crude Monte Carlo in terms of strata. Let's introduce $h(x)$ - the stratum that contains $x : x\in\mathcal{X}_{h(x)}, \forall x\in\mathcal{X}$. By using in a clever way the law of total variance (see section Statistics page 502) we can relate σ and σ_h as:

$$\sigma^2 = \mathrm{V}(f(x)) = \mathrm{E}\left(\mathrm{V}(f(x)\,|\,h(x))\right) + \mathrm{V}\left(\mathrm{E}(f(x)\,|\,h(x))\right) = \sum_{h=1}^{H}|\chi_h|\,\sigma_h^2 + \sum_{h=1}^{H}|\chi_h|\,(\mu_h - I)^2 \tag{14.1.1609}$$

Therefore:

$$\mathrm{V}(\hat{I}) = \frac{\sigma^2}{n} = \frac{1}{n}\sum_{h=1}^{H}|\mathcal{X}_h|\,\sigma_h^2 + \frac{1}{n}\sum_{h=1}^{H}|\mathcal{X}_h|\,(\mu_h - I)^2 \tag{14.1.1610}$$

Note that in the case of proportional allocation, because $n_h = n\,|\mathcal{X}_h|$, from the above deviation we get:

$$\mathrm{V}(\hat{I}_{\text{strat}}) = \sum_{h=1}^{H}\frac{|\chi_h|^2}{n_h}\sigma_h^2 = \frac{1}{n}\sum_{h=1}^{H}|\mathcal{X}_h|\,\sigma_h^2 \tag{14.1.1611}$$

So comparing:

$$\mathrm{V}(\hat{I})=\frac{1}{n}\sum_{h=1}^{H}\left|\mathcal{X}_h\right|\sigma_h^2+\frac{1}{n}\sum_{h=1}^{H}\left|\mathcal{X}_h\right|(\mu_h-I)^2 \quad \text{and} \quad \mathrm{V}(\hat{I}_{\text{strat}})=\frac{1}{n}\sum_{h=1}^{H}\left|\mathcal{X}_h\right|\sigma_h^2 \qquad (14.1.1612)$$

So we see immediately that $\mathrm{V}(\hat{I}_{\text{strat}})\leq\mathrm{V}(\hat{I})$, that is:

$$\frac{1}{n}\sum_{h=1}^{H}\left|\mathcal{X}_h\right|\sigma_h^2\leq\frac{1}{n}\sum_{h=1}^{H}\left|\mathcal{X}_h\right|\sigma_h^2+\frac{1}{n}\sum_{h=1}^{H}\left|\mathcal{X}_h\right|(\mu_h-I)^2 \qquad (14.1.1613)$$

Rearranged and simplified:

$$\frac{\sum_{h=1}^{H}\left|\mathcal{X}_h\right|\sigma_h^2}{\sum_{h=1}^{H}\left|\mathcal{X}_h\right|\sigma_h^2+\sum_{h=1}^{H}\left|\mathcal{X}_h\right|(\mu_h-I)^2}\leq 1 \qquad (14.1.1614)$$

which is smaller than $\mathrm{V}(\hat{I})$. Although it is not the optimal allocation, proportional allocation as applied to stratified sampling will never increase the variance over that of crude Monte Carlo. Also, note that a poor allocation can also increase the variance of the estimator in comparison to crude Monte Carlo!

So to summarize what we have seen here, in a more formal way, "stratified sampling" begins by dividing the sample domain $\mathcal{S}$ into a collection of M disjoint subsets (strata) $\mathcal{S}_k; k=1,2,\ldots,M$ such as $\cup_{k=1}^{M}\mathcal{S}_k=\mathcal{S}$ and $\mathcal{S}_p\cap\mathcal{S}_q=\varnothing; p\neq q$. Sample realizations from a given stratum k, $\vec{x}_k=\{x_{1k},x_{2k},\ldots,x_{Nk}\}$, are generated by randomly sampling the vector components according to:

$$x_{ik}=F_{X_i}^{-1}(\mathcal{U}_{ik})\,; i=1,2,\ldots,N \qquad (14.1.1615)$$

where $\mathcal{U}_{ik}$ are identically and independently uniformly distributed samples on $\left[\xi_{ik}^l,\xi_{ik}^u\right]$ with $\xi_{ik}^l=F_{X_i}\left(\zeta_{ik}^l\right)$ and $\xi_{ik}^u=F_{X_i}\left(\zeta_{ik}^u\right)$, and ζ_{ik}^l and ζ_{ik}^u denote the lower and upper bounds respectively of the i^{th} vector component of stratum $\mathcal{S}k$. Typically the stratification is performed directly in the probability space meaning that the strata are defined directly by the bounds ξ_{ik}^l and ξ_{ik}^u.

More explicitly, given a vector of uniform random numbers $U_1,U_2,\cdots,U_n$ on $[0,1]$. We divide the interval $[0,1]$ into $k\leq n$ equal subintervals. We can use the given uniform random numbers to generate uniform random in each of the k intervals by using the relation:

$$\hat{U}_i=\begin{cases}\frac{i-1+U_i}{k} & \text{if } i\leq k\\ \frac{(i-k)-1+U_i}{k} & \text{if } i>k\end{cases} \qquad (14.1.1616)$$

Thus, $\hat{U}_1$ is a random number in the interval $\left(0,\frac{1}{k}\right)$, $\hat{U}_2$ belongs to the interval $\left(\frac{1}{k},\frac{2}{k}\right)$ and so on. Moreover, the numbers $\hat{U}_1,\hat{U}_{1+k},\hat{U}_{1+2k},\cdots$ are uniformly distributed in the interval $\left(0,\frac{1}{k}\right)$, the numbers $\hat{U}_2,\hat{U}_{2+k},\hat{U}_{2+2k},\cdots$ are uniformly distributed in $\left(\frac{1}{k},\frac{2}{k}\right)$ and so on.

✍**Example:**

Consider the following 8 uniform random numbers in $[0,1]$:

i	1	2	3	4	5	6	7	8
U_i	0.4880	0.7894	0.8628	0.4482	0.3172	0.8944	0.5013	0.3015

To generate uniform random numbers in each quartile, i.e. $k=4$ we have:

$$\begin{aligned}
\hat{U}_1 &= \frac{1-1+U_1}{4} = 0.122\\
\hat{U}_2 &- \frac{2-1+U_2}{4} - 0.44735\\
\hat{U}_3 &= \frac{3-1+U_3}{4} = 0.7157\\
\hat{U}_4 &- \frac{4-1+U_4}{4} - 0.86205\\
\hat{U}_5 &= \frac{(5-4)-1+U_5}{4} = 0.0793\\
\hat{U}_6 &= \frac{(6-4)-1+U_6}{4} = 0.4736\\
\hat{U}_7 &= \frac{(7-4)-1+U_7}{4} = 0.625325\\
\hat{U}_8 &= \frac{(8-4)-1+U_8}{4} = 0.825375
\end{aligned}$$

14.1.18.1.6.5 Importance Sampling (IS)

In statistics, "importance sampling" is a general technique for estimating properties of a particular distribution, while only having samples generated from a different distribution than the distribution of interest!

The method is named "importance sampling" because it relies on so-named "importance functions", which are instrumental distributions, in lieu of the original distributions (the term "sampling" is arguably a misnomer since the method does not attempt to draw samples from any given distribution). In fact, an evaluation of:

$$\mathrm{E}(f(X)) = \int f(x)\phi(x)\mathrm{d}x \qquad (14.1.1617)$$

based on simulations from f is almost never optimal in the sense that using alternative distributions can improve the variance of the resulting estimator of $\mathrm{E}(f(X))$.

Generally it is a very common technique used to estimate the tail of some probability distribution and is in that special case denoted:

$$\theta = P(X \leq \text{ treshold }) = \mathrm{E}\left(1_{X \leq \text{treshold}}\right) \qquad (14.1.1618)$$

when the occurrence of $X \leq$ threshold is very small. Such situations occurs typically in the calculation of climatic, rail and air disasters, bankruptcies of large companies/states, major stock market cracks, portfolio risks, operational risks (legal obligation for banks or insurance companies).

To explain the idea consider we want to compute for a $\mathcal{N}(0,1)$ the following:

$$\theta = P(X \leq -10) = \mathrm{E}\left(1_{X \leq -10}\right) \tag{14.1.1619}$$

If we try to compute that with crude Monte Carlo method with N varying from $1,000$ too $10,000,000$ the conclusion is almost always the same: $\theta = 0$ and it's wrong as the correct value is known to be $\theta \cong 7.6199 \cdot 10^{-24}$. The necessary number of trials (N) should be of the order of 10^{25}... value that is hardly accessible to most common personal computer even in the early 121st century (holocene calendar).

The underling workaround idea of importance sampling is to use the following trick (i.e. change the law!):

$$\theta = \mathrm{E}(f(X)) = \int f(x)\phi(x)\mathrm{d}x = \int f(x)\frac{\phi(x)}{\psi(x)}\psi(x)\mathrm{d}x = \mathrm{E}(h(Y)) \tag{14.1.1620}$$

with:

$$h(x) = f(x)\frac{\phi(x)}{\psi(x)} \quad \text{and} \quad Y \sim \psi \tag{14.1.1621}$$

where ϕ is the density of X and ψ another density - an "importance function" - such as $\psi(x) \neq 0$ if $\phi(x) \neq 0$.

Hence:

$$\hat{\theta} = \frac{1}{N}\sum_{i=1}^{N} f(X_i)\frac{\phi(X_i)}{\psi(X_i)} \tag{14.1.1622}$$

To study the variance, let X be a random variable with probability density function p. Consider evaluating the following quantity:

$$I = \mathrm{E}(f(x)) = \int f(x)p(x)\mathrm{d}x \tag{14.1.1623}$$

According to what we have just seen, then the importance sampling estimator is:

$$\hat{I}_N = \frac{1}{N}\sum_{i=1}^{N} f\left(x_i\right) \cdot \frac{p\left(x_i\right)}{q\left(x_i\right)} \tag{14.1.1624}$$

When $p = q$, this reduces obviously to the simple estimator that uses sample means of $f(x)$ to estimate its expectation. Does this estimator a good estimator? Let's study its bias before we focus on the variance! For the bias (see page 6798):

$$\begin{aligned}\mathrm{Bias}(\hat{I}) &= \mathrm{E}\left(\hat{I}_N - I\right) = \mathrm{E}\left(\hat{I}_N\right) - I = \mathrm{E}\left(f(x) \cdot \frac{p(x)}{q(x)}\right) - I \\ &= \int f(x)\frac{p(x)}{q(x)}q(x)\mathrm{d}x - I = \int f(x)p(x)\mathrm{d}x - I = 0\end{aligned} \tag{14.1.1625}$$

Thus, it is an unbiased estimator! That lead us also to the result that (we will us it just below):

$$I=\mathrm{E}\left(f\left(x\right)\cdot\frac{p\left(x\right)}{q\left(x\right)}\right)\tag{14.1.1626}$$

And now let's see the variance, using the equality just above and Huygens relation (see section Statistics page 593), we get:

$$\begin{aligned}\mathrm{V}\left(\hat{I}\right)&=\mathrm{V}\left(f\left(x\right)\cdot\frac{p\left(x\right)}{q\left(x\right)}\right)=\mathrm{E}(\hat{I}^2)-\mathrm{E}(\hat{I})^2\\&=\mathrm{E}\left(f^2\left(x\right)\cdot\frac{p^2\left(x\right)}{q^2\left(x\right)}\right)-\underbrace{\mathrm{E}\left(f\left(x\right)\cdot\frac{p\left(x\right)}{q\left(x\right)}\right)^2}_{I^2}\\&=\int\frac{f^2(x)p^2(x)}{q^2(x)}q(x)\mathrm{d}x-I^2=\int\frac{f^2(x)p(x)}{q(x)}p(x)\mathrm{d}x-I^2\\&=\mathrm{E}\left(\frac{f^2(x)p(x)}{q^2(x)}\right)-\mathrm{E}(f(x))^2\end{aligned}\tag{14.1.1627}$$

The last equality has to be compared with:

$$\mathrm{V}\left(I\right)=\mathrm{V}\left(f(x)\right)=\mathrm{E}\left(f(x)^2\right)-\mathrm{E}(f(x))^2\tag{14.1.1628}$$

That is putting side by side:

$$\begin{aligned}\mathrm{V}\left(\hat{I}\right)&=\mathrm{E}\left(\frac{f^2(x)p(x)}{q^2(x)}\right)-\mathrm{E}(f(x))^2\\\mathrm{V}\left(I\right)&=\mathrm{E}\left(f(x)^2\right)-\mathrm{E}(f(x))^2\end{aligned}\tag{14.1.1629}$$

So we see that we have a variance reduction, if and only if:

$$\mathrm{E}\left(\frac{f^2(x)p(x)}{q^2(x)}\right)\leq\mathrm{E}\left(f(x)^2\right)\tag{14.1.1630}$$

how to build a density $q(x)$ having the above property? It seems that this question doesn't have an easy answer other than trial and error and return on experience (REX).

As it may be a quite confusing notation and concept for some readers, let us see a simple concrete example!

✍**Example:**

Consider that we have $X=\mathcal{N}(\mu,\sigma)=\mathcal{N}(0,1)$ and we want to compute $\theta=P(X\leq-10)$. We know already that this is an issue!

The idea is then to force the trial of a new variable Y to be around -10. So the idea would be to choose: $Y=\mathcal{N}(-10,1)$.

Notice that if $Y=\mathcal{N}\left(\mu,\sigma^2\right)$, then $P(Y\leq\mu)=1/2$.

Therefore:

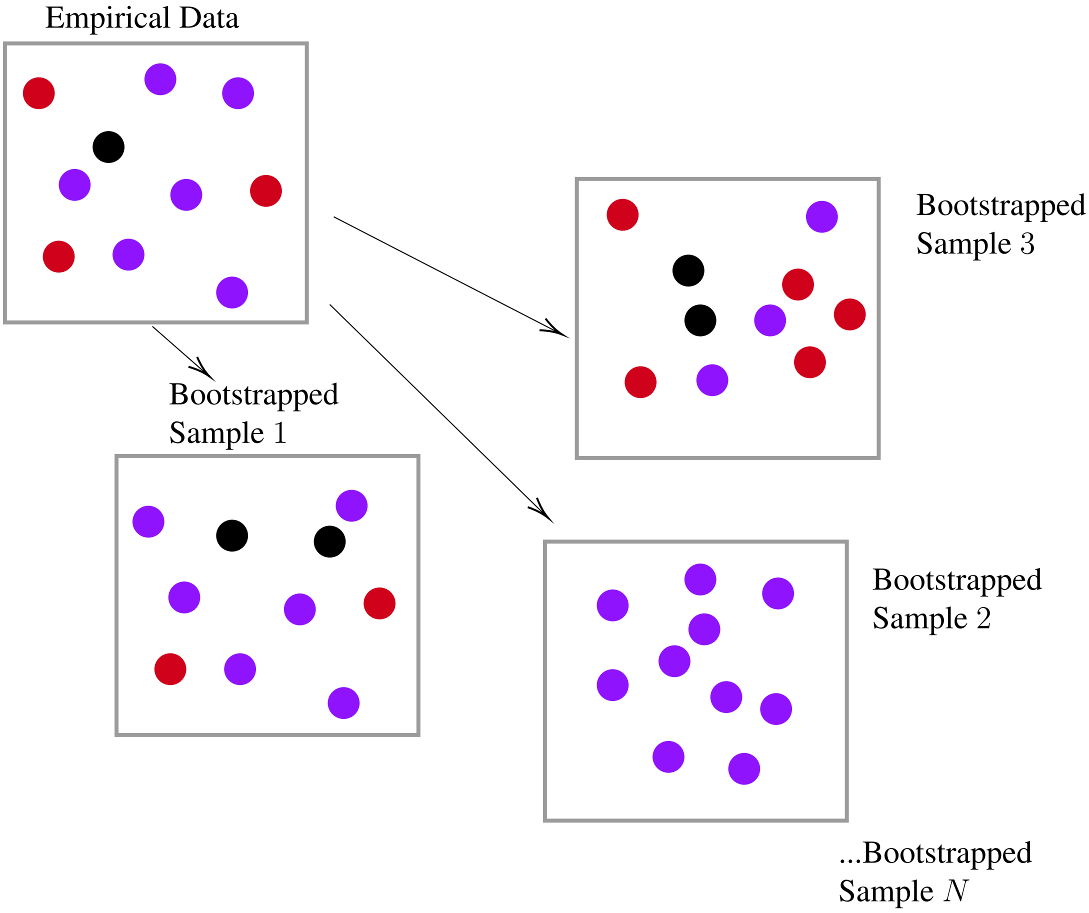
$$\begin{aligned}\theta=P(X\leq -10)&=\int\limits_{-\infty}^{-10}\frac{1}{\sqrt{2\pi}}\exp\left(-\frac{x^2}{2}\right)\mathrm{d}x\\&=\int\limits_{-\infty}^{-10}\left(\frac{\frac{1}{\sqrt{2\pi}}\exp\left(-\frac{x^2}{2}\right)}{\frac{1}{\sqrt{2\pi}}\exp\left(-\frac{(x+10)^2}{2}\right)}\right)\frac{1}{\sqrt{2\pi}}\exp\left(-\frac{(x+10)^2}{2}\right)\mathrm{d}x\\&=\int\limits_{-\infty}^{-10}\exp\left(10x+(-10)^2/2\right)\frac{1}{\sqrt{2\pi}}\exp\left(-\frac{(x+10)^2}{2}\right)\mathrm{d}x\\&=\int\limits_{-\infty}^{-10}\exp\left(10x+50\right)\frac{1}{\sqrt{2\pi}}\exp\left(-\frac{(x+10)^2}{2}\right)\mathrm{d}x\\&=\mathrm{E}\left(1_{Y\leq -10}\exp(10Y+50)\right)\end{aligned}$$

The trick works very well in this case as the reader can check it by itself in the corresponding implementation in `R` and MATLAB® as available in our corresponding companion free books.

In practice it is quite common to implement all the different methods of variance reduction seen so far and to compare which one converge the fastest after a given number of runs (or "epochs").

14.1.18.2 Bootstrapping

In statistics, "bootstrap techniques" can refer to any test or metric that relies on random sampling with replacement of a population of data to run statistical inference on small samples. This methods is relatively intensive in computations still for expensive office computers at this beginning of the 121st century (holocene calendar).



The goal of bootstrapping is to find some indication of a statistic: its estimate of course, but also its dispersion (variance, standard deviation), confidence intervals or hypothesis testing. This method is based on simulations, such as Monte Carlo methods, with the difference that the bootstrap does not require additional information than the one that is available already in the initial sample. In general, it is based on new samples obtained by sampling with replacement from the original sample (then we speak also of "resampling").

We distinguish generally two types of bootstrap:

1. The bootstraps which make no assumptions about the probability distribution of the data analysed. We then speak then as in statistics of "nonparametric bootstrap".
2. The bootstraps replacing each data measured by those corresponding to the analytical expression of the law of probability distribution assumed. We speak then of "parametric bootstrap". Once all the original values replaced, the process is exactly that of the nonparametric bootstrap.

Definition (#14.1.565): Given a set $\mathcal{D}$ of n observations, and a number B, we name "bootstrap" the procedure which consists in creating B samples $\mathcal{D}_1, \mathcal{D}_2, \ldots, \mathcal{D}_B$ from $\mathcal{D}$, each obtained by drawing n examples from $\mathcal{D}$ with replacement. Thus, each example may appear multiple times, or not at all, in $\mathcal{D}_b$.

We will illustrate the principle of the bootstrap on the example of the confidence interval of the mean μ of a random variable (this special case is named a "studentized bootstrap". For this example, the confidence interval for the mean of a random variable is completely determined from the mean and the variance calculated on the sample (see section Statistics page 818).

We consider a sample of the random variable composed of 10 estimates:

$$X=\{16,12,14,6,43,7,0,54,25,13\} \tag{14.1.1631}$$

The arithmetic average of this sample is:

$$\bar{X}=\frac{1}{n}\sum_{i=1}^{n}x_i=\frac{1}{10}\sum_{i=1}^{10}x_i=19 \tag{14.1.1632}$$

and it standard deviation (maximum unbiased likelihood estimator of the standard deviation):

$$\sigma=\sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(x_i-\bar{X})^2}=\sqrt{\frac{1}{9}\sum_{i=1}^{10}(x_i-19)^2}=17.09 \tag{14.1.1633}$$

As we are in the situation of a known sample mean and an unknown sample variance, to do the calculation of a confidence interval, then we have proved in the section Statistics that we had to use:

$$\bar{X}-\frac{S}{\sqrt{n}}T_{\alpha/2}(n-1)\leq\mu\leq\bar{X}+\frac{S}{\sqrt{n}}T_{\alpha/2}(n-1) \tag{14.1.1634}$$

where S is for recall another traditional notation in some areas of statistics for the notation of the empirical standard deviation (see section Statistics page 824). We then have for the confidence interval at 95% of the mean:

$$19-\frac{17.09}{\sqrt{10}}T_{2.5\%}(9)\leq\mu\leq 19+\frac{17.09}{\sqrt{10}}T_{2.5\%}(9) \tag{14.1.1635}$$

Therefore:

$$19-\frac{17.09}{\sqrt{10}}2.26\leq\mu\leq 19+\frac{17.09}{\sqrt{10}}2.26 \tag{14.1.1636}$$

Which gives:

$$4.49\leq\mu\leq 33.51 \tag{14.1.1637}$$

The confidence interval can also be calculated by bootstrap (this is especially useful for complicate distributions that are not symmetric and when we focus on the median rather than on the mean). Then it is therefore obtained by the following algorithm (and abbreviated BCI for "bootstrapped confidence interval"):

1. From the initial sample, we simulate new samples of the same size, named "bootstrap replicates" of size n, by random draws with replacement (see figure above). For example with the previous series, we could get the following replicate:

$$X^*=\{54,0,16,7,43,54,0,25,25,6\} \tag{14.1.1638}$$

in which, by definition, some of the original sample values do not appear, and where others appear several times (yes it's a sampling with replacement therefore...). Several samples are simulated in this way. So we can form a number of replicas (arrangements with replacement) equal to (see section Probabilities page 523):

$$\bar{A}_n^n = n^n \tag{14.1.1639}$$

Therefore with 10 values we have 10, 000, 000, 000 possibilities...

2. For each simulated sample, an average[37] is calculated (so we will have several thousand of averages!).

3. The 95% confidence interval is then calculated on this set of averages (or any other estimator) by typically using the percentile calculation (through the functions of a spreadsheet software or a programming/scripting language). This grouping is named the "bagging" that stands for the abbreviation of "Bootstrap Aggregating".

Obviously for each set of bootstrap, the percentiles themselves will not be the same so it is even possible to create a confidence interval for the percentiles themselves and this is named "percentile bootstrap"! But one important assumption is that such a distribution is pivotal. This means that if the underlying parameter changes, the shape of the distribution is only shifted by a constant, and the scale does not necessarily change.

It is quite easy (just like the Monte Carlo methods) to create replicas with spreadsheet software like Microsoft® Excel® (at least for people that know a little bit how to use a spreadsheet software) without computer programming or scripting (see below an example with Microsoft® Excel®)! Furthermore, the bootstrap technique is very powerful because it does not use any assumptions about the underlying statistical distribution.

The most common field of application of bootstrapping in "direct" business (I don't mind about Data Mining for Marketing that is not what I mean about "direct business") that I know is in project management during meetings where a dozen people estimates the duration of a project task or project phase.

Bootstrapping can therefore be applied to any estimator other than the average, as the median, the correlation coefficient between two random variables or the principal eigenvalue of a variance-covariance matrix (for principal component analysis for example!), or the slope and intercept of a regression and this is its great strength!!! Indeed, for these estimators, there is no general mathematical relations that defines the standard error or confidence interval. The only methods applicable are resampling methods to which bootstrapping belongs to and this is intensively used since almost any home or office computer at the beginning of the 121st century (holocene calendar) is powerful enough to bootstrap small databases.

✍**Example:**

As example let us first use a spreadsheet software like Microsoft® Excel® table 14.0.6123 and taking the theoretical companion example above as practical software example (we prohibit ourselves of doing VBA programming). We then build a small table with the previous sample:

---

[37] in fact the process is the same for any estimate of any statistical indicator $\hat{\theta}$

	A
4	X
5	16
6	12
7	14
8	6
9	43
10	7
11	0
12	54
13	25
14	13

At the opposite of the companion theoretical example, we would like to be able to determine a confidence interval for the median instead of the arithmetic mean (we take on purpose a statistical indicator for which there is no simple analytical confidence interval). For this, we calculate the median of several thousand of replications in the column `F` (random choice!), where each replication corresponds to a row :

	F
4	**Replicated Median**
5	9.5
6	13
7	9.5
8	12
9	13
10	14.5
11	14
12	15
13	12.5
14	15
15	12
16	19.5
17	20.5
18	14
19	13
20	13.5
21	13
22	13.5
23	13
24	13
25	15

with the following quite long formula for Microsoft® Excel® Next 14.0.6123 to put in cell `F5` and then pull down to the end of the sheet:

```
=MEDIAN(INDEX(A5:A14,RANDBETWEEN(1,10),1),
INDEX(A5:A14,RANDBETWEEN(1,10),1),
INDEX(A5:A14,RANDBETWEEN(1,10),1),
INDEX(A5:A14,RANDBETWEEN(1,10),1),
INDEX(A5:A14,RANDBETWEEN(1,10),1),
INDEX(A5:A14,RANDBETWEEN(1,10),1),
INDEX(A5:A14,RANDBETWEEN(1,10),1),
INDEX(A5:A14,RANDBETWEEN(1,10),1),
INDEX(A5:A14,RANDBETWEEN(1,10),1),
INDEX(A5:A14,RANDBETWEEN(1,10),1))
```

So we can not have more that 10 billion more... corresponding to the $\bar{A}_n^n$ calculated above (Microsoft® Excel® 14.0.6123 and after is limited to $17,179,869,184$ cells...).

Then simply in a cell of our choice we write:

```
=PERCENTILE(F5:F2003,0.025)
```

and in another cell:

```
=PERCENTILE(F5:F2003,0.975)
```

which will give us $2,000$ replications respectively 7 and 29.5.

With basic knowledge of a spreadsheet software, it is possible to graphically plot the convergence of the median in function the number of replications (below we used only the first 100 replications):

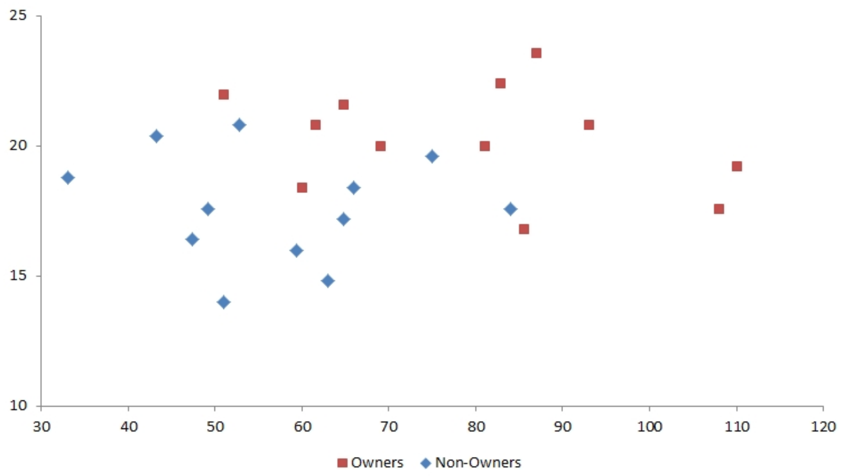


Figure 14.101: **Convergence of the median as function of the number of replications**

Obviously, this chart will look different every time we restart the simulation in Microsoft® Excel® 14.0.6123 by pressing the F9 key.

Finally let us indicate that after having studied earlier above many linear regression models this does avoid the fact that in many cases no theoretical model is adapted either to interpolate or verbatim to extrapolate some data. Therefore, if we have for each abscissa point (exogenous variable) a given quantity of values of the output (endogenous) variable, we can therefore use the bootstrapping method which will give us the bootstrapped regression coefficients and also bootstrapped interpolated or extrapolated values! This is an extremely interesting technique in practice of nonparametric regression! We can do such bootstrap regressions in softwares like SPSS (with additional module) or SAS but also in the free `R` software with the right packages (see the companion book on `R`).

Remark

Bootstrapping has enormous potential in statistics education and practice, but there are subtle issues and ways to go wrong. For example, the common combination of non-parametric bootstrapping and bootstrap percentile confidence intervals seems very likely to be less accurate than using T-intervals for small samples, though more accurate for larger samples. We therefore strongly recommend anyone to read the following paper to avoid some traps about the usage of bootstrapping: Hesterberg TC. *What teachers should know about the bootstrap: Resampling in the undergraduate statistics curriculum.* The American Statistician. 12015 Oct 2;69(4):371-86 (holocene calendar).

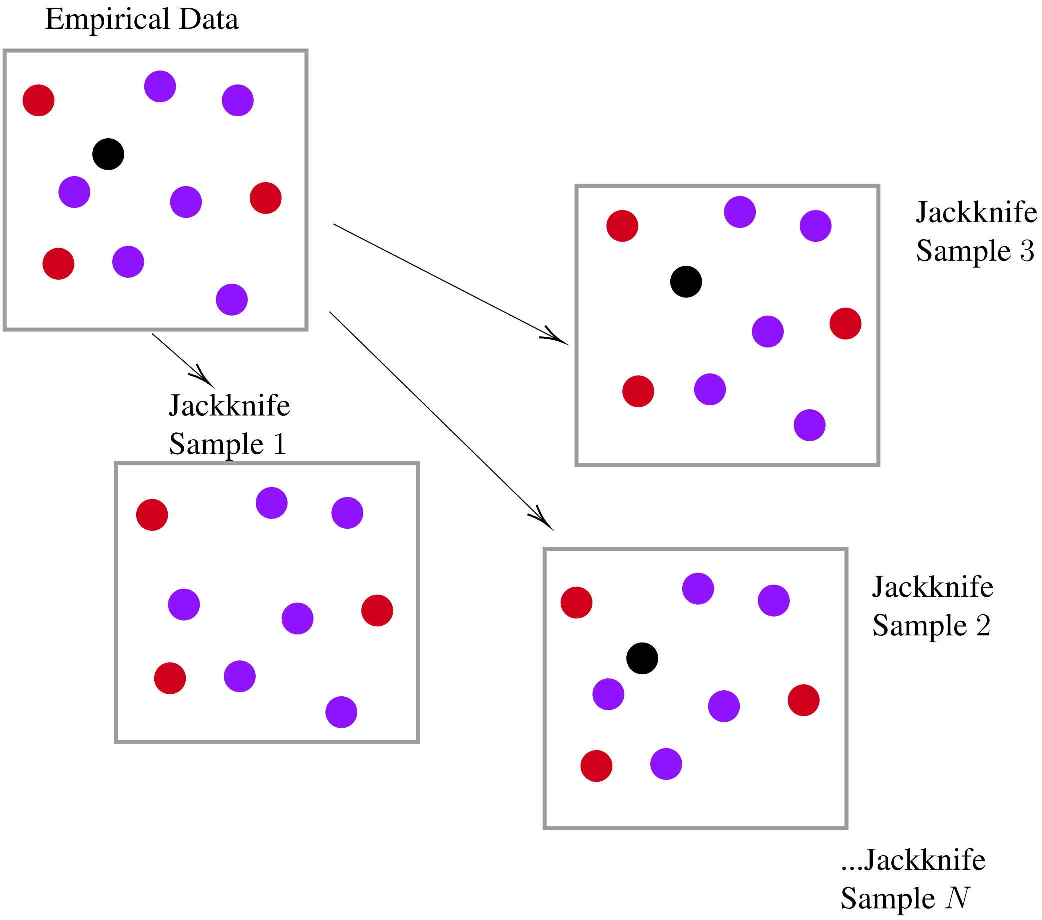
Caution!!!!!!!!! Use bootstrap mainly for confidence intervals or parameters estimation. Not for testing hypotheses (under the null), unless you really know what you are doing! For NHST you should prefer permutations techniques that we will introduce further below.

Indeed, we use bootstrap to generate data under the empirical distribution of the observed data. To get a p-value by bootstrap, we need to generate bootstraps under the null hypothesis!!!! So when conducting bootstrapped hypothesis tests like on the mean for example we must first subtract the empirical mean $\hat{\mu}$ of the sample and secondly add to it the mean under $H_0 = \mu$. Then we compare the original observe sample mean $\hat{\mu}$ to our bootstrapped null distribution $H_0 = \mu$ and see how many bootstrapped means are at least as extreme as $\hat{\mu}$ is. This gives us a p-value.

14.1.18.3 Jackknife Resampling

The jackknife was proposed by M.H. Quenouille in 11949 (holocene calendar) and later refined and given its current name by John Tukey in 11956 according to holocene calendar (it predates other common resampling methods such as the bootstrap). M.H. Quenouille originally developed the method as a procedure for correcting bias. Later, Tukey described its use in constructing confidence limits for a large class of estimators. It is similar to the bootstrap in that it involves resampling, but instead of sampling with replacement, the method samples without replacement.

So in statistics, the "jackknife" is a resampling technique especially useful for variance and bias estimation at least... when these estimators converge quick enough (the number of resampling is much more limited with jackknifing than with bootstrapping). The jackknife estimator of a parameter is found by systematically leaving out each observation from a dataset and calculating the estimate and then finding the average of these calculations. Given a sample of size N, the jackknife estimate is found by aggregating the estimates of each $N-1$ estimate in the sample.



This method is especially useful when:

1. The computer is not powerful enough to run a bootstrap
2. We don't trust the resampling method as not suited to the situation

Definition (#14.1.566): The "delete-1 Jackknife samples" are selected by taking the original data vector and deleting one observation from the set. Thus, there are n unique Jackknife samples, and the ith Jackknife sample vector is defined as:

$$\vec{X}_{[i]} = \{X_1, X_2, \ldots, X_{i-1}, X_{i+1}, \ldots, X_{n-1}, X_n\} \tag{14.1.1640}$$

This procedure is obviously generalizable to k deletions.

The ith Jackknife replicate is defined as the value of the estimator $s(\cdot)$ evaluated at the ith Jackknife sample.

$$\hat{\theta}_{(i)} := s(\vec{X}_{[i]}) \tag{14.1.1641}$$

As we will prove it further below, the jackknife standard error of the estimator is (given typically by the bootstrap package of `R` as you can see it in the corresponding companion book):

$$\boxed{\text{SE}(\hat{\theta})_{\text{jack}} = \sqrt{\frac{n-1}{n}\sum_{i=1}^{n}\left(\hat{\theta}_{(i)} - \hat{\theta}_{(\cdot)}\right)^2}} \tag{14.1.1642}$$

where $\hat{\theta}_{(\cdot)}$ is the empirical average of the Jackknife replicates:

$$\hat{\theta}_{(\cdot)} = \frac{1}{n}\sum_{i=1}^{n}\hat{\theta}_{(i)} \tag{14.1.1643}$$

with:

$$\hat{\theta}_i = \bar{x}_i = \frac{\sum_j x_j - x_i}{n-1} = \frac{n\bar{x} - x_i}{n-1} \tag{14.1.1644}$$

For the proof let us consider the special case where the Jackknife estimator above is an unbiased estimator of the variance of the sample mean.

Proof 14.6.2. So to prove the previous relation with the sample mean we just need to prove that (see section Statistics page 611):

$$\frac{n-1}{n}\sum_{i=1}^{n}\left(\hat{\theta}_i - \hat{\theta}_{(\cdot)}\right)^2 \tag{14.1.1645}$$

is equal to:

$$\hat{V}_{\overline{X}} = \frac{\hat{\sigma}^2}{n} = \frac{\dfrac{1}{n-1}\displaystyle\sum_{i=1}^{n}(x_i - \bar{x})^2}{n} \tag{14.1.1646}$$

And to prove that latter, we write it craftily:

$$\begin{aligned}\left(\hat{\theta}_{(i)} - \hat{\theta}_{(\cdot)}\right) &= \left(\frac{n\bar{x} - x_i}{n-1}\right) - \frac{1}{n}\sum_{i=1}^{n}\bar{x}_{(i)} = \left(\frac{n\bar{x} - x_i}{n-1}\right) - \frac{n-1}{(n-1)n}\sum_{i=1}^{n}\bar{x}_{(i)}\\ &= \frac{1}{n-1}\left(n\bar{x} - x_i - \frac{1}{n}\sum_{i=1}^{n}n\bar{x}_{(i)} - \bar{x}_{(i)}\right) = \frac{1}{n-1}\left(n\bar{x} - x_i - \frac{1}{n}\sum_{i=1}^{n}n\bar{x} - x_i\right)\\ &= \frac{1}{n-1}(\bar{x} - x_i)\end{aligned} \tag{14.1.1647}$$

Once the term is squared, the equation is complete, and is identically equal to the right hand term above. Thus, in the case of the sample mean, the Jackknife estimate of the standard error reduces to the regular, unbiased estimator commonly used.

We say sometimes then that $n-1$ is the "standard error jackknife bias inflation factor".

■ Q.E.D.

As practical business oriented example of the use of Jackknife let me give the example of a customer (Fortune 500 company) that has to analyse worldwide counterfeiting of its products by sampling and controlling completely each year a given area of a given city chosen randomly in various countries and calculating the sum by country of counterfeit products as it has a major influence on the strategy of the company, national politics and borders controls (the counterfeiting being manly done by the mafia). As the geographical sampling error cannot be calculated as it is not guarantee that the chosen city has the same heterogeneity overall cities of the country it is as far as we know impossible to calculate with a closed form equation a tolerance interval for the real total counterfeit. So an easy way to get a tolerance interval is to make a Jackknife resampling as it is easily acceptable for the board committee to make an analysis of what would have been the sum if for example we removed 50% of the sampling (at the condition that the a posteriori power of the test is still important enough!).

14.1.18.4 Permutation Tests

A "permutation test" (also named a "randomization test" or "re-randomization test") is a type of statistical significance test in which the distribution of the test statistic under the null hypothesis is obtained by calculating all possible values of the test statistic under rearrangements of the labels on the observed data points.

To illustrate the basic idea of a permutation test, suppose we have two groups (we take the special case where the size of the groups are equal!):

$$\begin{aligned}\vec{A}&=\{a_1,a_2,\ldots,a_n\}\\ \vec{B}&=\{b_1,b_2,\ldots,b_n\}\end{aligned}\qquad(14.1.1648)$$

whose sample means are $\bar{x}_A$ and $\bar{x}_B$, and that we want to test, at 5% significance level, whether they come from the same distribution. Let n be the sample size corresponding to each group. The permutation test is designed to determine whether the observed difference between the sample means is large enough to reject the null hypothesis:

$$H_0: \quad \bar{x}_A=\bar{x}_B \qquad(14.1.1649)$$

that the two groups have identical probability distributions (i.e. identical mean).

The test proceeds as follows:

1. The difference in means between the two samples is calculated as we do normally. This lead to the observed value of the test statistic $T_n^{(\text{obs})}$.

2. Then the observations of groups $\vec{A}$ and $\vec{B}$ are pooled and mixed formally using a "random sampling operator" $\vec{\delta}_n^R$ defined by:

$$\boxed{\vec{\delta}_n^R = \begin{pmatrix} r_1 \\ r_2 \\ \vdots \\ r_n \end{pmatrix}} \tag{14.1.1650}$$

   where r_i is a binary random variable defined by $r_i \in \mathbb{Z}_2$, where $\mathbb{Z}_2 = \{0, 1\}$ and we also define its binary negation by:

$$\bar{\vec{\delta}}_n^R = \begin{pmatrix} \bar{r}_1 \\ \bar{r}_2 \\ \vdots \\ \bar{r}_n \end{pmatrix} \tag{14.1.1651}$$

   Then we create a permutation of $\vec{A}$ denoted $\vec{A}\,'$ (same respectively for $\vec{B}$) by applying the random sampling operator:

$$\begin{aligned} \vec{A}\,' &= \vec{\delta}_n^R \vec{A} + \bar{\vec{\delta}}_n^R \vec{B} \\ \vec{B}\,' &= \bar{\vec{\delta}}_n^R \vec{A} + \vec{\delta}_n^R \vec{B} \end{aligned} \tag{14.1.1652}$$

3. Next, the difference in sample means is calculated and recorded for this new groups $\vec{A}'$ and $\vec{B}'$ and we get a new $T_n^{\prime(\text{obs})}$.

4. We repeat the above procedure for every possible way of combining the samples (in practice we do that completely randomly then some cases - pairs of samples - may repeat).

   The number of ways in which $m \cdot n$ different items can be divided equally into m groups ($m = 2$ in our example) each containing n objects where the order of the groups is important is given by:

$$\frac{(mn)!}{(n!)^m} \tag{14.1.1653}$$

   And the number of ways in which $m \cdot n$ different items can be divided equally into m groups, each containing n objects and where the order of the groups is NOT important is:

$$\frac{(mn)!}{(n!)^m m!} \tag{14.1.1654}$$

5. Finally the one-sided p-value of the test is calculated as the proportion of sampled permutations where the difference in means was greater than or equal to $T_n^{(\text{obs})}$. The two-sided p-value of the test is calculated as the proportion of sampled permutations where the absolute difference was greater than or equal to $|T_n^{\prime(\text{obs})}|$.

The major down-side to permutation tests are that they:

- Can be computationally intensive and may require "custom" code for difficult-to-calculate statistics. This must be rewritten for every case.
- Are primarily used to provide a p-value. The inversion of the test to get confidence regions/intervals requires even more computation.

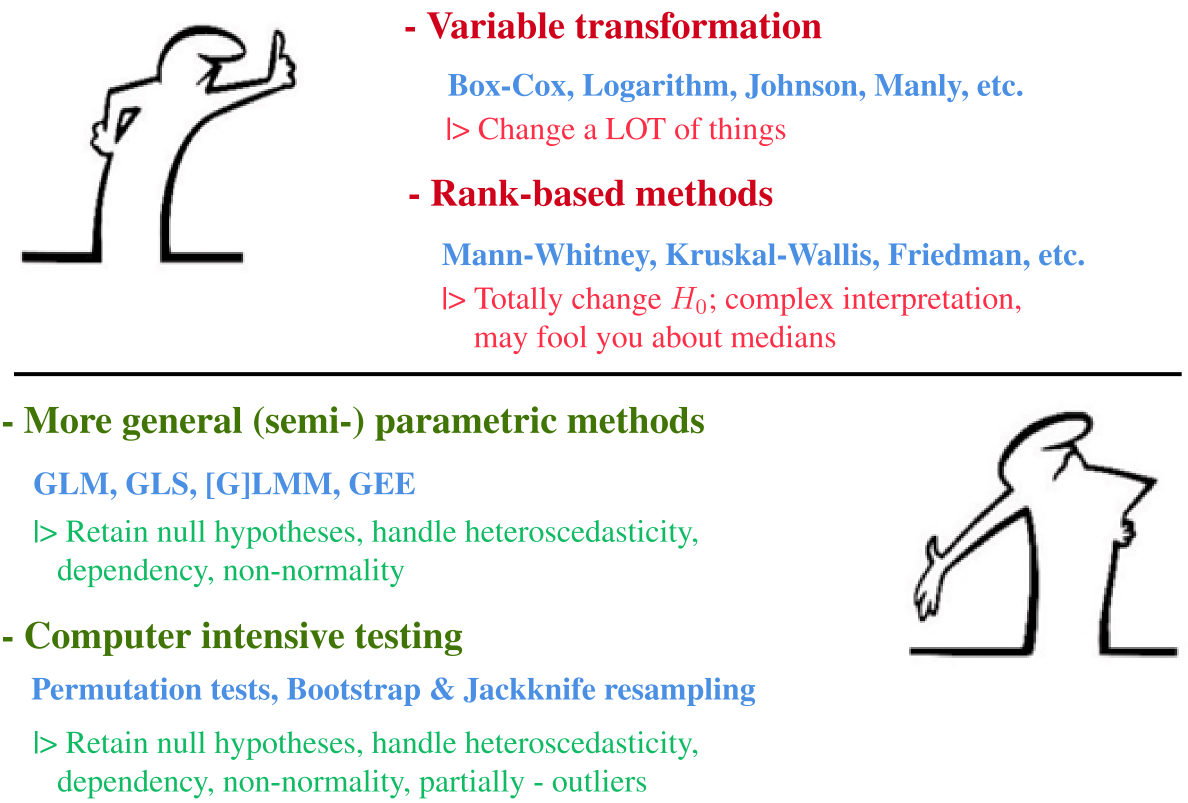
Hopefully it is quite easy to do that with modern software. You can see the `R` companion book for an example of a Student-T permutation test.

Keep in mind that as the assumption behind a permutation test is that the observations are exchangeable under the null hypothesis (assumption of "data exchangeability"), an important consequence of this assumption is that tests of difference in location (like a permutation T-test) require equal variance.

Remark

Permutation tests are a subset of nonparametric statistics as the basic premise is to use only the assumption that it is possible that all of the treatment groups are equivalent, and that every member of them is the same before sampling began (i.e. the slot that they fill is not differentiable from other slots before the slots are filled).

And keep in mind that excellent meme by Adrian Olszewski:



- Variable transformation

Box-Cox, Logarithm, Johnson, Manly, etc.

|> Change a LOT of things

- Rank-based methods

Mann-Whitney, Kruskal-Wallis, Friedman, etc.

|> Totally change H_0; complex interpretation, may fool you about medians

- More general (semi-) parametric methods

GLM, GLS, [G]LMM, GEE

|> Retain null hypotheses, handle heteroscedasticity, dependency, non-normality

- Computer intensive testing

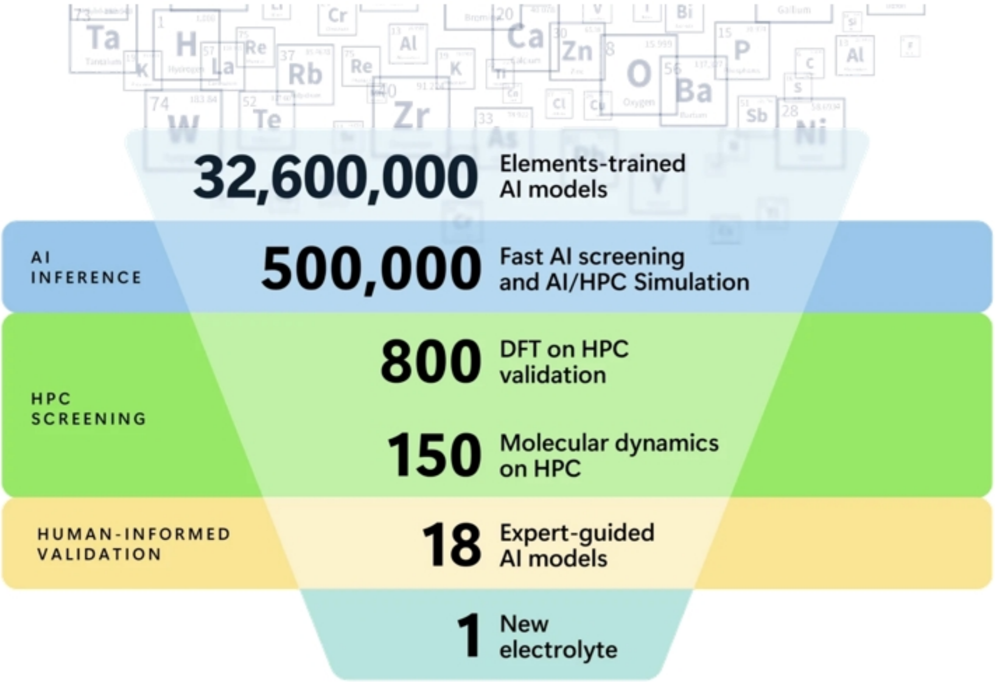
Permutation tests, Bootstrap & Jackknife resampling

|> Retain null hypotheses, handle heteroscedasticity, dependency, non-normality, partially - outliers

14.1.19 Finite difference method (F.D.M.)

The "finite element method" (FEM) is a numerical technique for finding approximate solutions to boundary value problems for partial differential equations. It is also referred to as finite element analysis (FEA). FEM subdivides a large problem into smaller, simpler, parts, named "finite elements". The simple equations that model these finite elements are then assembled into a larger system of equations that models the entire problem. FEM then uses variational methods from the calculus of variations to approximate a solution by minimizing an associated error function.

Finite difference method helps to accelerate Research and Development in many fields like illustrated in the figure below as it helped for example to decrease significantly the number of combinatorics to find the optimal set of combinations of atoms to found the most promising material for new batteries:



32,600,000 Elements-trained AI models
AI INFERENCE
500,000 Fast AI screening and AI/HPC Simulation
HPC SCREENING

1 New electrolyte

Figure 14.102: Source Generative Chemistry and Accelerated DFT (source: Microsoft)

Relatively to the above figure DFT (Density Functional Theory) is based on an adaptive finite-element discretization that handles pseudopotential and all-electron calculations in the same framework. HPC is the acronym of High Performance Calculators.

14.1.19.1 One space dimension F.D.M.

Let us recall that we have proved in the section of Thermodynamics (see page 3684) the following heat diffusion equation (we present here the equation reduced to only one spatial dimension):

$$\frac{\partial T(x,t)}{\partial t}-\frac{\kappa}{\rho c_p}\frac{\partial^2 T(x,t)}{\partial x^2}=0 \qquad (14.1.1655)$$

and let us notice that this equation is not very general ... (it is not relativistic and does not take into account the heat generated in the form of radiation by the concerned material concerned or many other factors ...).

We can consider (see section Differential and Integral Calculus page 1450) that:

$$\frac{\partial T(x,t)}{\partial x}\cong\frac{T(x+h,t)-T(x,t)}{h} \qquad (14.1.1656)$$

and:

$$\begin{aligned}\frac{\partial^2 T(x,t)}{\partial^2 x}&\cong\frac{1}{h}\left(\frac{T(x+h,t)-T(x,t)}{h}-\frac{T(x,t)-T(x-h,t)}{h}\right)\\&=\frac{1}{h^2}\left(T(x+h,t)-2T(x,t)+T(x-h,t)\right)\end{aligned} \qquad (14.1.1657)$$

Also:

$$\frac{\partial T(x,t)}{\partial t}\cong\frac{T(x,t+k)-T(x,t)}{k} \qquad (14.1.1658)$$

Then the heat equation becomes:

$$\frac{T(x,t+k)-T(x,t)}{k}-\frac{\kappa}{\rho c_p}\frac{1}{h^2}\left(T(x+h,t)-2T(x,t)+T(x-h,t)\right)=0 \qquad (14.1.1659)$$

After rearranging, we have:

$$\boxed{\begin{aligned}T(x,t+k)&=k\frac{\kappa}{\rho c_p}\frac{1}{h^2}\left(T(x+h,t)-2T(x,t)+T(x-h,t)\right)+T(x,t)\\&=\left(1-\frac{2k\kappa}{\rho c_p h^2}\right)T(x,t)+k\frac{\kappa}{\rho c_p}\frac{1}{h^2}\left(T(x+h,t)+T(x-h,t)\right)\end{aligned}} \qquad (14.1.1660)$$

If we look at this relation more closely, we see that this is a simple recursion. We just need to know the initial distribution (initial conditions) $T(x,0)$ to determine the distribution then all other values as:

$$T(x,0+k)=\left(1-\frac{2k\kappa}{\rho c_p h^2}\right)T(x,0)+k\frac{\kappa}{\rho c_p}\frac{1}{h^2}\left(T(x+h,0)+T(x-h,0)\right) \qquad (14.1.1661)$$

and:

$$T(x,2k)=\left(1-\frac{2k\kappa}{\rho c_p h^2}\right)T(x,k)+k\frac{\kappa}{\rho c_p}\frac{1}{h^2}\left(T(x+h,k)+T(x-h,k)\right) \qquad (14.1.1662)$$

etc. It is possible to implement such a simulation with nothing but a small spreadsheet software and a little time as we will we see just after... (using a spreadsheet software to understand the mechanism is better than using a blackbox like Maple™ or MATLAB® by my experience).

For information h and k are named then the "mesh step" or "space step" of the model.

Let us see an application example with a spreadsheet software like Microsoft® Excel® as it is quite a good practical exercise to understand how to implement the method.

So let us consider the following worksheet[38] where we consider a bar that is initially at a temperature of 0 [C]and that is heated on the left-hand side at a constant temperature of 100 [C] and where we use the relation proved earlier above:

$$\begin{aligned}T(x,t+k)&=T(x,t)+k\frac{\kappa}{\rho c_p}\frac{1}{h^2}\left(T(x+h,t)-2T(x,t)+T(x-h,t)\right)\\&=T(x,t)+\Delta t\frac{\kappa}{\rho c_p}\frac{1}{\Delta x^2}\left(T(x+\Delta x,t)-2T(x,t)+T(x-\Delta x,t)\right)\\&=T(x,t)+\alpha\frac{\Delta t}{\Delta x^2}\left(T(x+\Delta x,t)-2T(x,t)+T(x-\Delta x,t)\right)\end{aligned}\tag{14.1.1663}$$

So this gives (first rows only of $1,000$ rows):

Figure 14.104: **1D Heat Equation FDM explicit formulas in Microsoft® Excel® 14.0.7172**

We have above taken for boundary conditions:

$$\begin{aligned} T(0,t) &= T_0 \\ T(1,t+\Delta t) &= T(1,t)+2\alpha\frac{\Delta t}{\Delta x^2}(T(1-\Delta x,t)-T(1,t)) \end{aligned} \tag{14.1.1664}$$

All this with a chart view (famous figure that is painful to obtain in a spreadsheet software...):

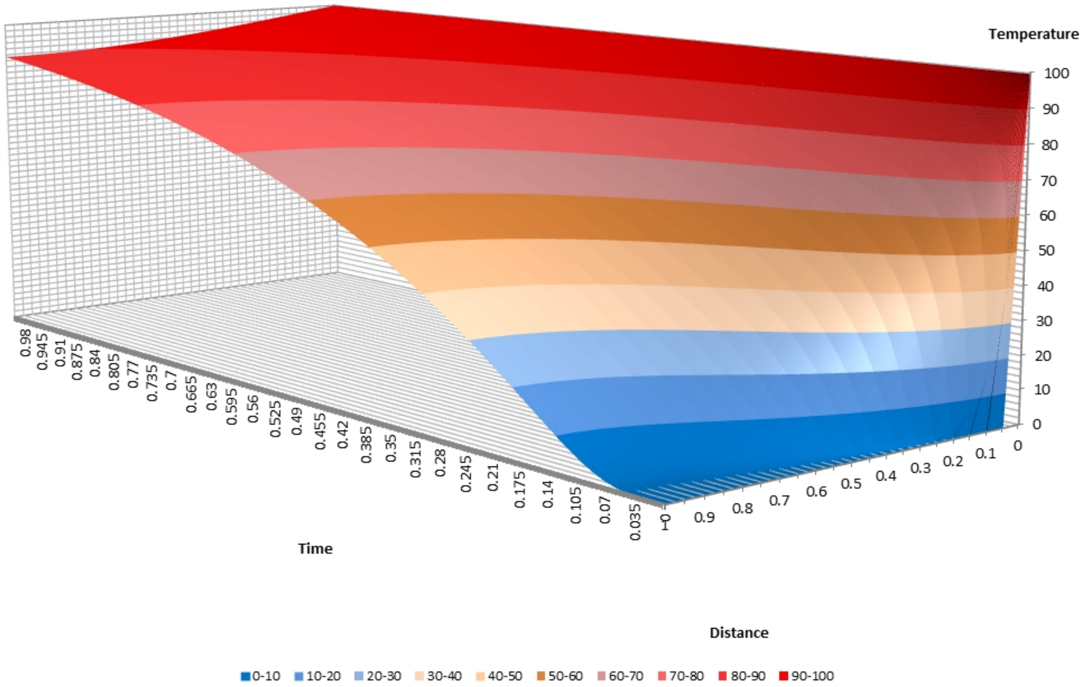

Figure 14.105: **1D Heat Equation FDM plot in Microsoft® Excel® 14.0.7172**

For readers wishing to practice with real values ... a longitudinal Iron bar of 1 [kg] has a specific heat capacity of $450\,[\mathrm{J}\cdot\mathrm{kg}^{-1}\cdot\mathrm{K}^{-1}]$, a density of almost $7.88\,[\mathrm{kg}\cdot\mathrm{m}^{-3}]$ and a thermal conductivity of $82\,[\mathrm{J}\cdot\mathrm{s}^{-1}\cdot\mathrm{m}^{-1}\cdot\mathrm{K}^{-1}]$.

However with such a file a above the reader will see that the FDM is stable after some trials and errors if and only if:

$$\alpha\frac{\Delta t}{\Delta x^2}\leq\frac{1}{2} \tag{14.1.1665}$$

This is what we will study now, first with a simple example, and afterwards with a more elaborated one:

14.1.19.1.1 Numerical instability

Numerical instability is a huge issues in numerical computing that occurs in many situation (the most know one being the finite elements method). To explain this let us consider the following companion example:

$$I_n=\int\limits_0^1\frac{x^n}{10+x}\mathrm{d}x \tag{14.1.1666}$$

with $n\in\mathbb{N}$.

An immediate calculation gives:

$$\begin{aligned}I_0&=\int\limits_0^1\frac{\mathrm{d}x}{10+x}=\ln(10+x)\Big|_0^1=\ln\left(\frac{11}{10}\right)\\I_n&=\int\limits_0^1\frac{x}{10+x}x^{n-1}\mathrm{d}x=\int\limits_0^1\left(1-\frac{10}{10+x}\right)x^{n-1}\mathrm{d}x\\&=\int\limits_0^1 x^{n-1}\mathrm{d}x-10\int\limits_0^1\frac{x^{n-1}}{10+x}\mathrm{d}x=\frac{1}{n}-10I_{n-1}\end{aligned} \tag{14.1.1667}$$

This allow us to calculate I_n by recurrence with:

$$\begin{cases}I_0=\ln\left(\dfrac{11}{10}\right)\\I_n=\dfrac{1}{n}-10I_{n-1}\end{cases} \tag{14.1.1668}$$

This problem apparently well posed mathematically leads digitally to catastrophic results. Indeed we have:

$$\Delta I_n\cong 10\Delta I_{n-1} \tag{14.1.1669}$$

even if we neglect the rounding error on $1/n$. The error on I_n explode exponentially, the initial error on I_0 being multiplied by 10^n at the step n.

14.1.19.1.2 von Neumann stability

In numerical analysis, "von Neumann stability analysis" (also known as "Fourier stability analysis") is a procedure used to check the stability of finite difference schemes as applied to linear partial differential equations. The analysis is based on the Fourier decomposition of numerical error and was developed at Los Alamos National Laboratory after having been briefly described in a 11947 (holocene calendar) article by British researchers Crank and Nicolson. This method is an example of explicit time integration where the function that defines governing equation is evaluated at the current time. Later, the method was given a more rigorous treatment in an article co-authored by John von Neumann.

The stability of numerical schemes is closely associated with numerical error. A finite difference scheme is stable if the errors made at one time step of the calculation do not cause the errors to be magnified as the computations are continued. A neutrally stable scheme is one in which errors remain constant as the computations are carried forward. If the errors decay and eventually damp out, the numerical scheme is said to be stable. If, on the contrary, the errors grow with time the numerical scheme is said to be unstable. The stability of numerical schemes can be investigated by performing von Neumann stability analysis. For time-dependent problems, stability guarantees that the numerical method produces a bounded solution whenever the solution of the exact differential equation is bounded. Stability, in general, can be difficult to investigate, especially when the equation under consideration is non-linear.

The von Neumann method is based on the decomposition of the errors into Fourier series. To illustrate the procedure, consider the one-dimensional heat equation:

$$\frac{\partial T(x,t)}{\partial t}=\alpha\frac{\partial^2 T(x,t)}{\partial x^2} \tag{14.1.1670}$$

defined on the spatial interval L, which can be discretized as we have just proved as (in a very condensed form):

$$T_j^{n+1}=T_j^n+r\left(T_{j+1}^n-2T_j^n+T_{j-1}^n\right) \tag{14.1.1671}$$

where as we have just proved earlier:

$$r=\frac{\alpha\Delta t}{\Delta x^2} \tag{14.1.1672}$$

and the solution T_j^n of the discrete equation approximates the analytical solution $T(x,t)$ of the PDE on the grid.

Let us define the round-off error ε_j^n as:

$$\varepsilon_j^n=N_j^n-T_j^n \tag{14.1.1673}$$

where T_j^n is the solution of the discretized PDE as we knot it that would be computed in the absence of round-off error, and N_j^n is the numerical solution obtained in finite precision arithmetic. Since the exact solution T_j^n must satisfy the discretized PDE exactly, the error ε_j^n must also satisfy the discretized equation (superposition principle). Here we assumed that N_j^n satisfies the PDE, too (this is only true in machine precision). Thus:

$$\varepsilon_j^{n+1}=\varepsilon_j^n+r\left(\varepsilon_{j+1}^n-2\varepsilon_j^n+\varepsilon_{j-1}^n\right) \tag{14.1.1674}$$

is a recurrence relation for the error.

Equations:

$$\begin{aligned}T_j^{n+1}&=T_j^n+r\left(T_{j+1}^n-2T_j^n+T_{j-1}^n\right)\\ \varepsilon_j^{n+1}&=\varepsilon_j^n+r\left(\varepsilon_{j+1}^n-2\varepsilon_j^n+\varepsilon_{j-1}^n\right)\end{aligned}\qquad(14.1.1675)$$

show that both the error and the numerical solution have the same growth or decay behaviour with respect to time. For linear differential equations with periodic boundary condition, the spatial variation of error may be expanded in a finite Fourier series, in the interval L, as: As we have proved it in the section Thermodynamics the solution of the PDE for the errors can be written in a condensed way for a given term:

$$\varepsilon(x,t)=\sum_{\lambda}\left(C'_1(\lambda)e^{\mathrm{i}\lambda x}+C'_2(\lambda)e^{-\mathrm{i}\lambda x}\right)e^{-\lambda^2 Dt}\qquad(14.1.1676)$$

Since the difference equation for error is linear (the behaviour of each term of the series is the same as series itself), it is enough to consider the growth of error of a typical term:

$$\varepsilon(x,t)=C'_1(\lambda)e^{\mathrm{i}\lambda x}\qquad(14.1.1677)$$

and as the reader will see with the next development we can simplify already the constant such that it remains:

$$\varepsilon(x,t)=e^{\mathrm{i}\lambda x}e^{-\lambda^2 Dt}\qquad(14.1.1678)$$

The stability characteristics can be studied using just this form for the error with no loss in generality. To find out how error varies in steps of time, substitute the relation above into:

$$\varepsilon_j^{n+1}=\varepsilon_j^n+r\left(\varepsilon_{j+1}^n-2\varepsilon_j^n+\varepsilon_{j-1}^n\right)\qquad(14.1.1679)$$

after noting that:

$$\begin{aligned}\varepsilon_j^n&=e^{\mathrm{i}\lambda x}e^{-\lambda Dt}\\ \varepsilon_j^{n+1}&=e^{\mathrm{i}\lambda x}e^{-\lambda D(t+\Delta t)}\\ \varepsilon_{j+1}^n&=e^{\mathrm{i}\lambda(x+\Delta x)}e^{-\lambda Dt}\\ \varepsilon_{j-1}^n&=e^{\mathrm{i}\lambda(x-\Delta x)}e^{-\lambda Dt}\end{aligned}\qquad(14.1.1680)$$

to yield (after simplification):

$$e^{-\lambda D\Delta t}=1+\frac{\alpha\Delta t}{\Delta x^2}\left(e^{\mathrm{i}\lambda\Delta x}+e^{-\mathrm{i}\lambda\Delta x}-2\right)\qquad(14.1.1681)$$

Using the identities (see section Trigonometry page 2532):

$$\cos(\lambda\Delta x)=\frac{e^{\mathrm{i}\lambda\Delta x}+e^{-\mathrm{i}\lambda\Delta x}}{2}\qquad\sin^2\left(\frac{\lambda\Delta x}{2}\right)=\frac{1-\cos(\lambda\Delta x)}{2}\qquad(14.1.1682)$$

Then the prior previous relation can the be written as:

$$e^{-\lambda D\Delta t}=1-\frac{4\alpha\Delta t}{\Delta x^2}\sin^2\left(\frac{\lambda\Delta x}{2}\right)\qquad(14.1.1683)$$

Let us now define the "amplification factor":

$$G = \frac{\varepsilon_j^{n+1}}{\varepsilon_j^n} \qquad (14.1.1684)$$

The necessary and sufficient condition for the error to remain bounded is that $|G| < 1$. However in our case:

$$\left|e^{-\lambda D\Delta t}\right| < 1 \Leftrightarrow \left|1 - \frac{4\alpha\Delta t}{\Delta x^2}\sin^2\left(\frac{\lambda\Delta x}{2}\right)\right| < 1 \qquad (14.1.1685)$$

this is the explicit condition for stability of the numerical scheme.

Note that the term:

$$\frac{4\alpha\Delta t}{\Delta x^2}\sin^2\left(\frac{\lambda\Delta x}{2}\right) \qquad (14.1.1686)$$

is always positive. Thus, to satisfy the prior previous relation we have:

$$\frac{4\alpha\Delta t}{\Delta x^2}\sin^2\left(\frac{\lambda\Delta x}{2}\right) < 2 \qquad (14.1.1687)$$

For the above condition to hold at all:

$$\sin^2\left(\frac{\lambda\Delta x}{2}\right) \qquad (14.1.1688)$$

we have:

$$\boxed{\frac{\alpha\Delta t}{\Delta x^2} < \frac{1}{2}} \qquad (14.1.1689)$$

It gives the stability requirement for the FTCS scheme as applied to one-dimensional heat equation. This is exactly the value we found when playing with the Microsoft® Excel® worksheet.

14.1.19.2 Space-time F.D.M (finite-volume method)

The finite-volume method (FVM) is a method for representing and evaluating partial differential equations in the form of algebraic equations. Similar to the finite difference method or finite element method, values are calculated at discrete places on a meshed geometry.

"Finite volume" refers to the small volume surrounding each node point on a mesh. In the finite volume method, volume integrals in a partial differential equation that contain a divergence term are converted to surface integrals, using the divergence theorem. These terms are then evaluated as fluxes at the surfaces of each finite volume. Because the flux entering a given volume is identical to that leaving the adjacent volume, these methods are conservative. Another advantage of the finite volume method is that it is easily formulated to allow for unstructured meshes. The method is used in many computational fluid dynamics computing packages as illustrated below:

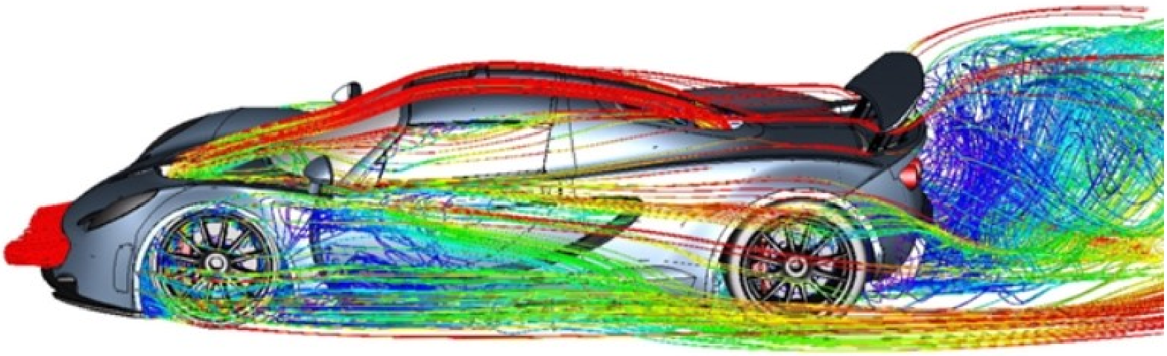

Figure 14.106: Space-time FDM for car C_x study

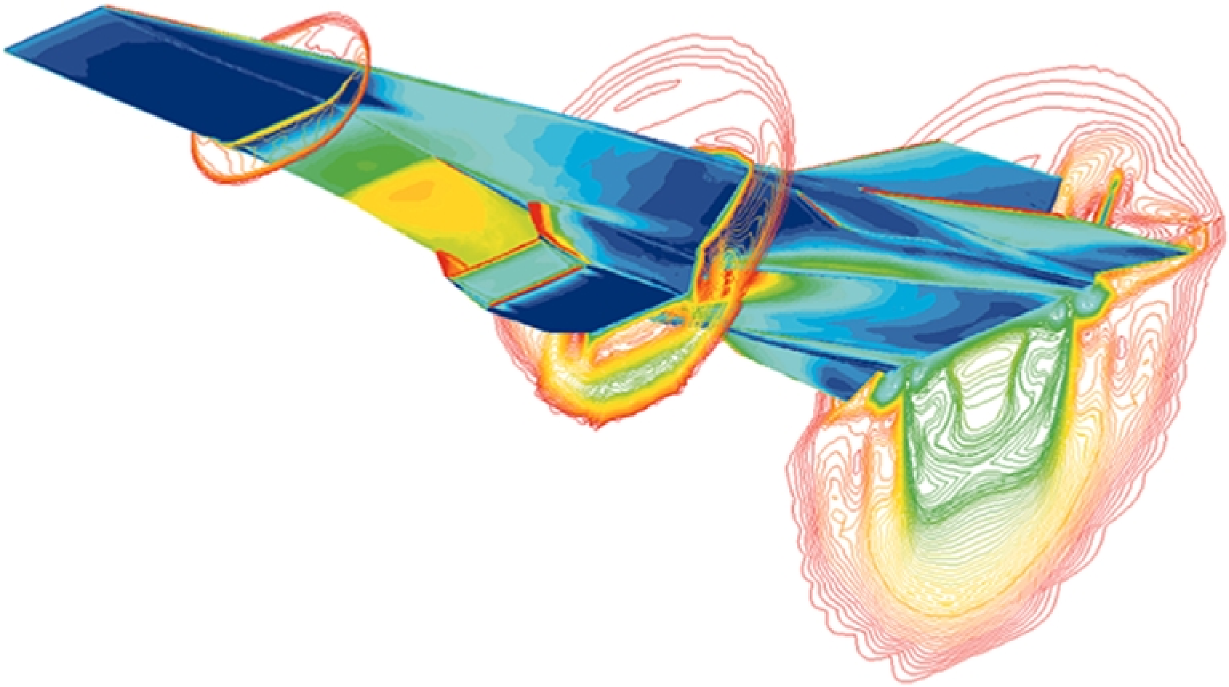

Figure 14.107: Space-time FDM for airplane wing profile study

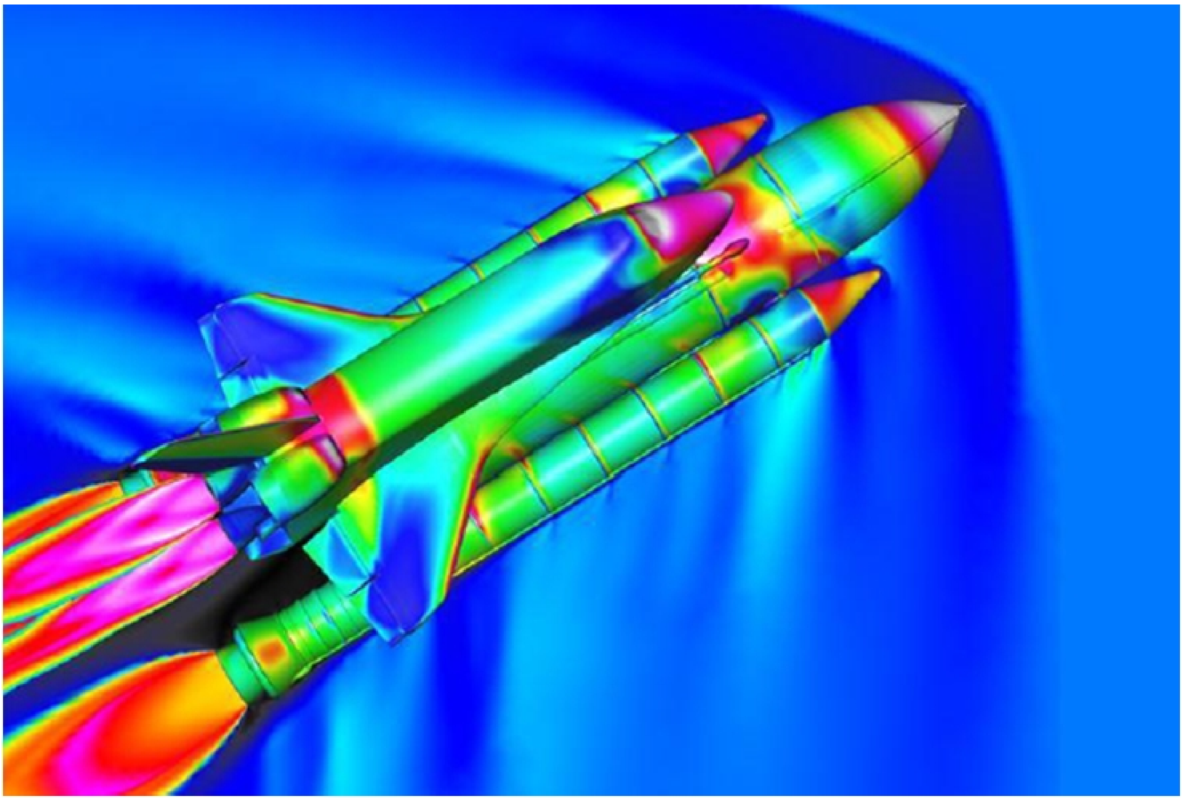

Figure 14.108: **Space-time FDM for NASA space shuttle launch (source: NASA)**

The F.D.M. is a therefore a veeeeery important numerical method in practice because it also gives the possibility to solve directly Maxwell's equations in the time domain and space (and also General Relativity situations). It is then the classified in the 3D (three-dimensional quantification of space) and temporal computational methods and finds its main industrial applications in the fields of design (antennas and circuits), of electromagnetic compatibility, of the diffraction and of the propagation and electromagnetic dosimetry (living beings and waves interactions).

We will discuss now the basics of the concept in a special case as in practice, programming the F.D.M. is a whole team job in itself (like the rest of this textbook obviously but sometimes it is useful to recall that). Indeed a loot of problems must be resolved when dealing with computer programs using F.D.M. (convergence criteria, meshing methods, boundary conditions, user input, programming language methods, etc.).

In a electrodynamics problem treated by F.D.M., the first necessary step is to define the volume V of the space and the time interval $I=[0,T]$ for which the resolution is desired (it is unrealistic at this day to hope to solve Maxwell's equations for an infinite space and for an unlimited period of time!). The volume of calculation contains the object (antenna circuit, ...) that it is desired to characterize, in response to a given excitation. Secondly, the space (meshing of V) and time should be discretized to allow a numerical implementation of the resolution (and in reality the meshing is not uniform...). The problem then becomes the one of determining the field at any point of the mesh for any discrete moment of the observation time interval. The spatial and temporal discretization will be specified in what will follow below and will naturally come from physics equations to solve. They obviously condition both the accuracy of the calculation results and the computing resources required to carry it out.

The structuring of the F.D.M. mesh and the resolution method directly result of the equations to solve.

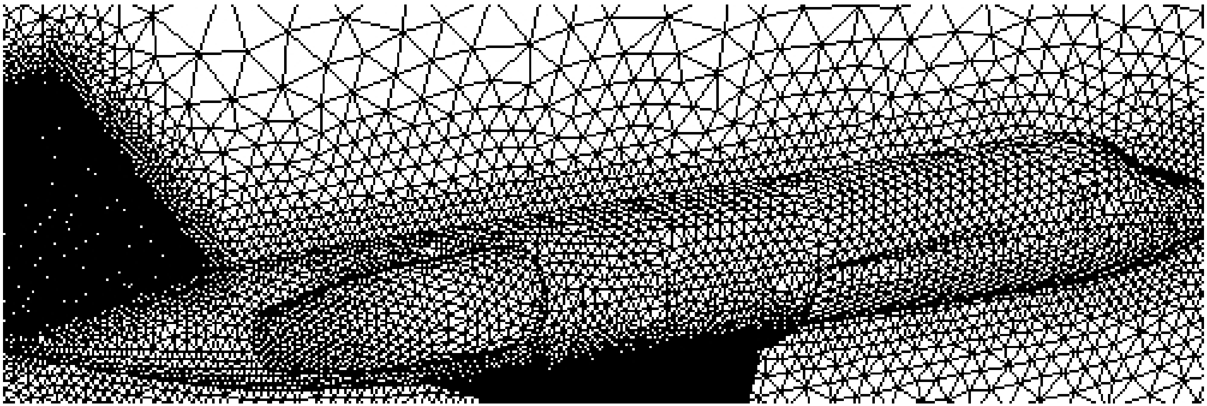

Figure 14.109: **Airplane typical FDM meshing**

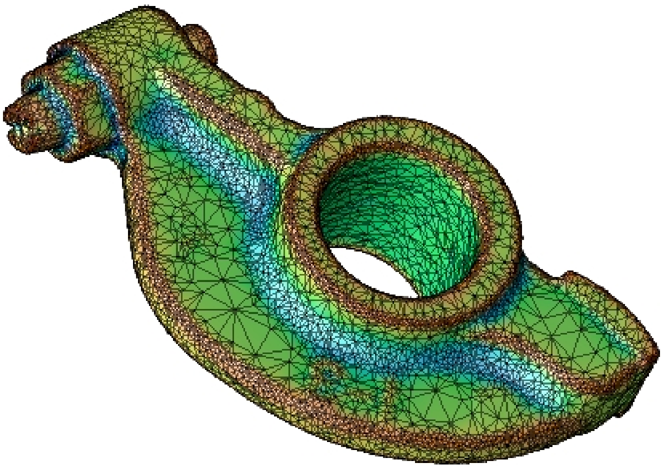

Figure 14.110: **Mechanical element FDM meshing**

In a linear, homogeneous, isotropic, non-dispersive and non-magnetic (...) material, the Maxwell equations will be written explicitly based on the third Maxwell's equation (see section Electrodynamics page 4101):

$$-\frac{\partial\vec{B}}{\partial t}=\vec{\nabla}\times\vec{E} \quad (14.1.1690)$$

Either explicitly with the negative sign put at the other side of the equality:

$$\begin{aligned}\frac{\partial B_x}{\partial t}&=-(\partial_y E_z-\partial_z E_y)\\ \frac{\partial B_y}{\partial t}&=-(\partial_z E_x-\partial_x E_z)\\ \frac{\partial B_z}{\partial t}&=-(\partial_x E_y-\partial_y E_x)\end{aligned} \quad (14.1.1691)$$

And we will also use the fourth Maxwell equation without sources:

$$\vec{\nabla}\times\vec{B}=\mu\varepsilon\frac{\partial\vec{E}}{\partial t} \quad (14.1.1692)$$

Thus explicitly and rearranged:

$$\begin{aligned}\frac{\partial E_x}{\partial t}&=\frac{1}{\mu\varepsilon}(\partial_y B_z-\partial_z B_y)\\ \frac{\partial E_y}{\partial t}&=\frac{1}{\mu\varepsilon}(\partial_z B_x-\partial_x B_z)\\ \frac{\partial E_z}{\partial t}&=\frac{1}{\mu\varepsilon}(\partial_x B_y-\partial_y B_x)\end{aligned} \tag{14.1.1693}$$

That is to say for summary:

$$\begin{aligned}&\begin{cases}\dfrac{\partial}{\partial t}B_x(\vec{r},t)=-(\partial_y E_z(\vec{r},t)-\partial_z E_y(\vec{r},t))\\ \dfrac{\partial}{\partial t}B_y(\vec{r},t)=-(\partial_z E_x(\vec{r},t)-\partial_x E_z(\vec{r},t))\\ \dfrac{\partial}{\partial t}B_z=-(\partial_x E_y(\vec{r},t)-\partial_y E_x(\vec{r},t))\end{cases}\\ &\begin{cases}\dfrac{\partial}{\partial t}E_x(\vec{r},t)=\dfrac{1}{\mu\varepsilon}(\partial_y B_z(\vec{r},t)-\partial_z B_y(\vec{r},t))\\ \dfrac{\partial}{\partial t}E_y(\vec{r},t)=\dfrac{1}{\mu\varepsilon}(\partial_z B_x(\vec{r},t)-\partial_x B_z(\vec{r},t))\\ \dfrac{\partial}{\partial t}E_z(\vec{r},t)=\dfrac{1}{\mu\varepsilon}(\partial_x B_y(\vec{r},t)-\partial_y B_x(\vec{r},t))\end{cases}\end{aligned} \tag{14.1.1694}$$

In what follows, we will only concerned with the first equation, the other leading to similar developments.

To allow a computer processing, the various derivatives present in the equation must be approximated numerically as we already know. To do this, we use the principle of centered finite difference which is based on the following Taylor series expansions for recall (see section Sequences and Series page 1696):

$$f(x)=\sum_{k=0}^{n}\frac{1}{k!}\frac{\mathrm{d}^k f(x_0)}{\mathrm{d}x^k}(x-x_0)^k=\sum_{k=0}^{n}\frac{\mathrm{d}^{(k)}f(x_0)}{k!}(x-x_0)^k \tag{14.1.1695}$$

We then have on the basis of this principle:

$$\begin{aligned}f\left(x_0+\frac{\mathrm{d}_x}{2}\right)&=f(x_0)+\frac{\mathrm{d}_x}{2}f'(x_0)+\frac{1}{2}\left(\frac{\mathrm{d}_x}{2}\right)^2 f''(x_0)+\ldots\\ f\left(x_0-\frac{\mathrm{d}_x}{2}\right)&=f(x_0)-\frac{\mathrm{d}_x}{2}f'(x_0)+\frac{1}{2}\left(\frac{\mathrm{d}_x}{2}\right)^2 f''(x_0)-\ldots\end{aligned} \tag{14.1.1696}$$

If we neglect the terms of the second order, it comes by subtracting the two series:

$$f'(x_0)=\frac{f\left(x_0+\dfrac{\mathrm{d}_x}{2}\right)-f\left(x_0-\dfrac{\mathrm{d}_x}{2}\right)}{\mathrm{d}_x}+\varepsilon(\mathrm{d}_x^2) \tag{14.1.1697}$$

where $\varepsilon(\mathrm{d}_x^2)$ is an error or order 2, neglected thereafter (we notice that this is the centering that, allowing compensation of second derivatives, minimizes the error in the approximation).

Applying this principle to temporal and spatial derivatives of:

$$\begin{aligned}\frac{\partial}{\partial t}B_x(\vec{r},t)&=-(\partial_y E_z(\vec{r},t)-\partial_z E_y(\vec{r},t))\\ \frac{\partial}{\partial t}B_y(\vec{r},t)&=-(\partial_z E_x(\vec{r},t)-\partial_x E_z(\vec{r},t))\\ \frac{\partial}{\partial t}B_z(\vec{r},t)&=-(\partial_x E_y(\vec{r},t)-\partial_y E_x(\vec{r},t))\end{aligned} \tag{14.1.1698}$$

it comes:

$$\begin{aligned}&\frac{B_x\left(x,y,z,t+\dfrac{\mathrm{d}_t}{2}\right)-B_x\left(x,y,z,t-\dfrac{\mathrm{d}_t}{2}\right)}{\mathrm{d}_t}\\ &=-\left(\frac{E_z\left(x,y+\dfrac{\mathrm{d}_y}{2},z,t\right)-E_z\left(x,y-\dfrac{\mathrm{d}_y}{2},z,t\right)}{\mathrm{d}_y}-\frac{E_y\left(x,y,z+\dfrac{\mathrm{d}_z}{2},t\right)-E_y\left(x,y,z-\dfrac{\mathrm{d}_z}{2},t\right)}{\mathrm{d}_z}\right)\end{aligned} \tag{14.1.1699}$$

or after rearrangement:

$$\begin{aligned}&B_x\left(x,y,z,t+\frac{\mathrm{d}_t}{2}\right)=B_x\left(x,y,z,t-\frac{\mathrm{d}_t}{2}\right)\\ &+\mathrm{d}_t\left(\frac{E_y\left(x,y,z+\dfrac{\mathrm{d}_z}{2},t\right)-E_y\left(x,y,z-\dfrac{\mathrm{d}_z}{2},t\right)}{\mathrm{d}_z}-\frac{E_z\left(x,y+\dfrac{\mathrm{d}_y}{2},z,t\right)-E_z\left(x,y-\dfrac{\mathrm{d}_y}{2},z,t\right)}{\mathrm{d}_y}\right)\end{aligned} \tag{14.1.1700}$$

This relation shows that if we know the components E_y, E_z of electric field at time t and the component B_x of the magnetic field at the earlier time $t-\mathrm{d}_t/2$, it is possible to determine B_x at the time $t+\mathrm{d}_t/2$. Obviously the process is exactly the same for all other components and shows the same time lag. This result suggests using an iterative numerical solution, in which the electric and magnetic fields are evaluated alternately, respectively at the discrete time $n\mathrm{d}_t$ and $(n+1/2)\mathrm{d}_t$, d_t being the time step (denoted Δt by the computer scientists). It is customary in the literature to denote by $B_x^{n+\frac{1}{2}}$ the component of the magnetic field at the time $(n+1/2)\mathrm{d}_t$.

The same analysis applies for the spatial distribution of the field on the observed points. Thus, evaluating B_x at the point (x,y,z) is based on the knowledge of E_y at the points $(x,y,z+\mathrm{d}_z/2)$ and $(x,y,z-\mathrm{d}_z/2)$ and of E_z at the points $(x,y+\mathrm{d}_y/2,z)$ and $(x,y-\mathrm{d}_y/2,z)$.

So we can summarize this geometrically in the following figure named "Yee cell":

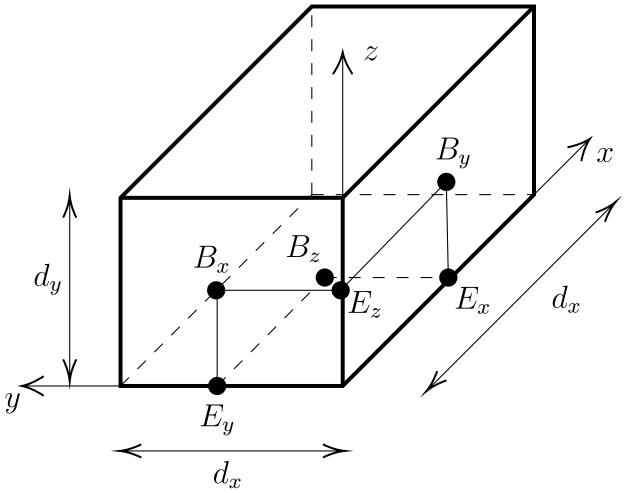

Figure 14.111: **Generic Yee cell in parallelepiped mesh element**

The electric field components are evaluated at the centers of the edges of the mesh and the components of the magnetic field at the centers of the faces so as to ensure the alternation imposed by the equations (as mentioned previously we name "Yee cell" the unit cell with this distribution of points).

In the special case of a propagating electromagnetic wave, the $\vec{E}$ and $\vec{B}$ fields are always perpendicular (see section Electrodynamics page 4138) in a homogeneous, linear, anisotropic medium (this type of media includes many things like air, water, glass without stress or tempering) and when the engineers prefers to represent the "real" magnetic field $\vec{H}$ instead of the magnetic excitation $\vec{H}$ we can find in the literature the following parallelepiped Yee cell figure:

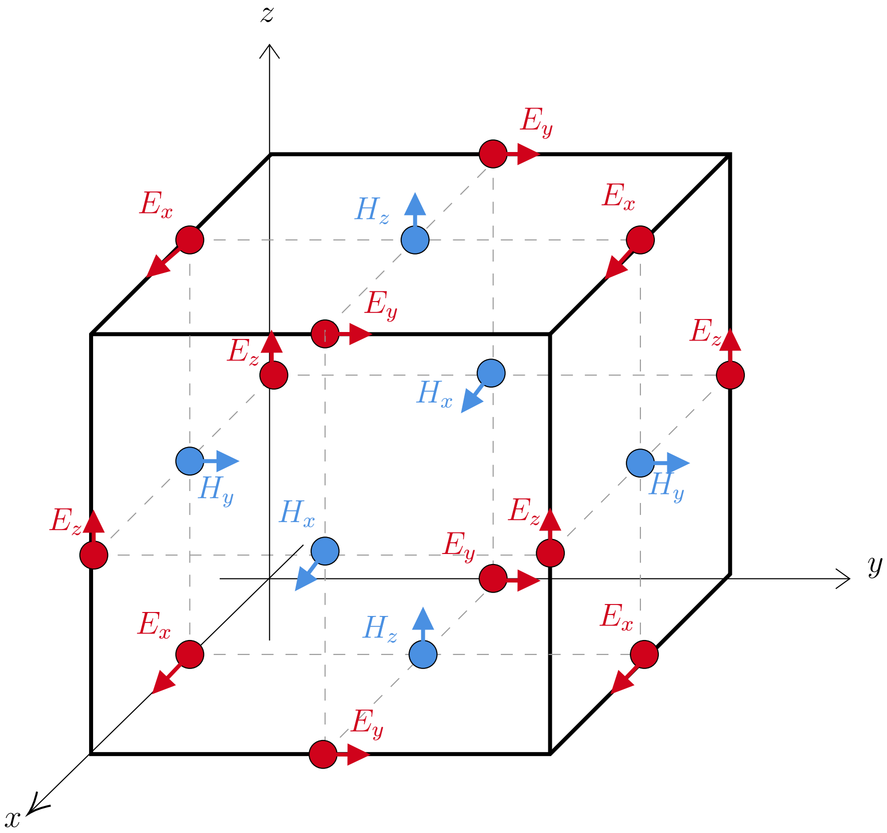

Figure 14.112: Yee cell in parallelepiped mesh element for EM wave propagating in vacuum

So globally in vacuum without the presence of any object we have a meshing of the space that can be represented as follows:

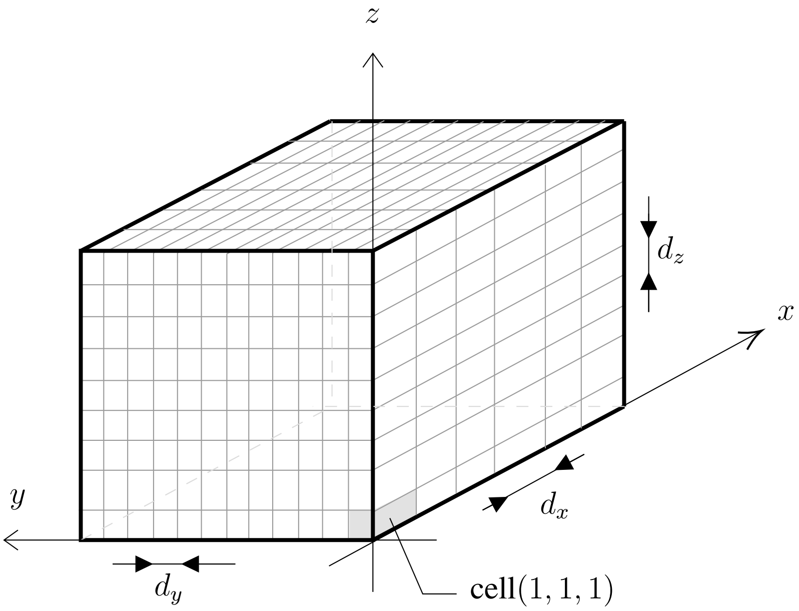

Figure 14.113: Typical simple meshing with multiple Yee cells

Obviously, we can perform the calculation routines with a value of the permittivity and permeability that are not necessarily equal in all the cells. Allowing in addition to model the propagation of electromagnetic waves in heterogeneous and non isotropic media.

Finally, it is important to notice that the spatial and temporal mesh step must be configured by the user running such simulations. This for computing resources reasons as well as accuracy goals. Indeed, we do not do the same simulations for a multi-physics system in the low frequency in vacuum than for non-isotropic material at high frequency and, either on a desktop computer or on a supercomputer.

14.1.20 Data Science & Data Mining

Definition (#14.1.567): "Data science" is an interdisciplinary business field that uses statistics, computer science, scientific methods, processes, algorithms, domain knowledge and systems to extract or extrapolate knowledge and insights from various sources of various types of datas.

Definition (#14.1.568): "Data Mining", also popularly referred to as "knowledge discovery from data" (KDD), is a subset of data science that focuses specifically on extracting patterns and knowledge from large datasets. It applies statistical and machine learning[39] algorithms to identify hidden relationships, trends, and anomalies in data. Data mining is often used for tasks such as customer segmentation, fraud detection, and predictive analytics.

Remark

Some statisticians argue that data science is not a new field, but rather another name for statistics. Others argue that data science is distinct from statistics because it focuses on problems and techniques unique to digital data. Some others argue that statistics emphasizes quantitative data and description. In contrast, data science deals with quantitative and qualitative data (e.g., from images, text, sensors, transactions, customer information, etc.) and emphasizes prediction and action. Some describe statistics as a non-essential part of data science and others that data science is not distinguished from statistics by the size of datasets or use of computing and that many graduate programs misleadingly advertise their analytics and statistics training as the essence of a data-science program. In this textbook we will consider Data Science as the set of Data investigations that don't use inferential statistics (null hypothesis testing).

quote 14.1:6768.#77

> *If you want to make big improvements in communication, my advice is—hire physicists, not communications people from normal companies...*
>
> Dominic Cummings

The following naive figure may help the reader to contextualize these both fields:

---

[39] As said by Arthur Samuel, a computer program is said to learn (i.e. machine learning) from experience E with respect to some class of tasks T and performance measure P if its performance at tasks in T, as measured by P, improves with experience E.

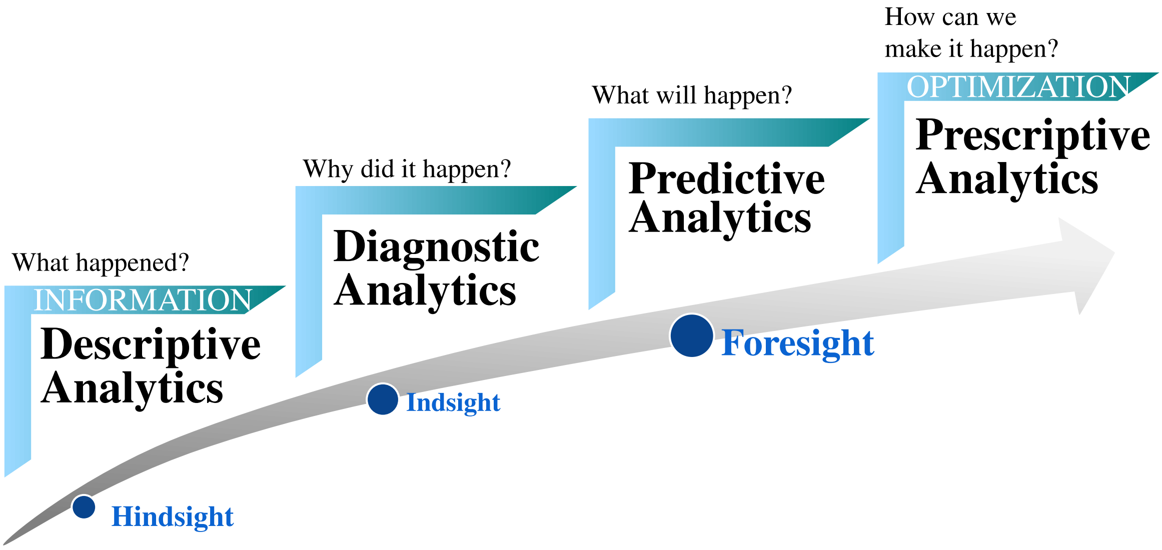
Figure 14.114: Oversimplified overview of Data Science

The main purpose of Data Mining is to ascend the following analytics levels:



What happened?
INFORMATION
Descriptive Analytics
Why did it happen?
Diagnostic Analytics
What will happen?
Predictive Analytics
How can we make it happen?
OPTIMIZATION
Prescriptive Analytics
Hindsight
Indsight
Foresight

Figure 14.115: Descriptive, Diagnostic, Predictive and Prospective analytics

Or an extended and detailed version of the above figure but instead as a table and with a slightly different vocabulary:

Analytics Steps	Typical Questions Addressed
Descriptive analytics	•What is the current situation? What's happening? •What has change? What's new? •What should we focus on? What should we worry about? •Is this the right data to use for making the prediction? •How reliable is the data we are using here?
Causal analytics	•Diagnosis, explanation, and attribution: What explains the current situation? •What can we do about it? •How would different actions change the probabilities of different future outcomes? •What decisions will this be used to make? •What's the cost of getting those decisions wrong? •How much will decisions affect the targeted people (especially the vulnerable one!)?
Predictive analytics	•If we do not change what we are doing, what will (probably) happen next? When? How likely are the different possibilities? •Given observed (or assumed) values for some variables, what are the probabilities for values of other variables? •How well can some variables be predicted from others? •How well can future outcomes be predicted now? •Are we certain that's what we want to predict? •Are we really aware of the limits of the predictions?
Prescriptive analytics	•What should we do next? •What decisions and policies implemented now will most improve probabilities of future outcomes?
Evaluation analytics	•How much will it cost to deploy and maintain the models? •How well are our current decisions and policies working? •What effects have our decisions and policies actually caused? •How do different policies affect behaviour and outcomes for different people?
Learning analytics	•What decisions or policies might work better than our current ones? •How can we use data and experimentation to find out? •By how much do different items of information improve decisions? •What is the value of information for different measurements?
Collaborative analytics	•How can we best work together to improve probabilities of future outcomes? •Who should share what information with whom, how and when? •What actions should each division of an organization or each member of a team take?

Table 14.23: **Component of risk analytics**

A second level of granularity, with their relations but poorly readable and not error proof (...), would be (we will come back on a more precise definition further below):

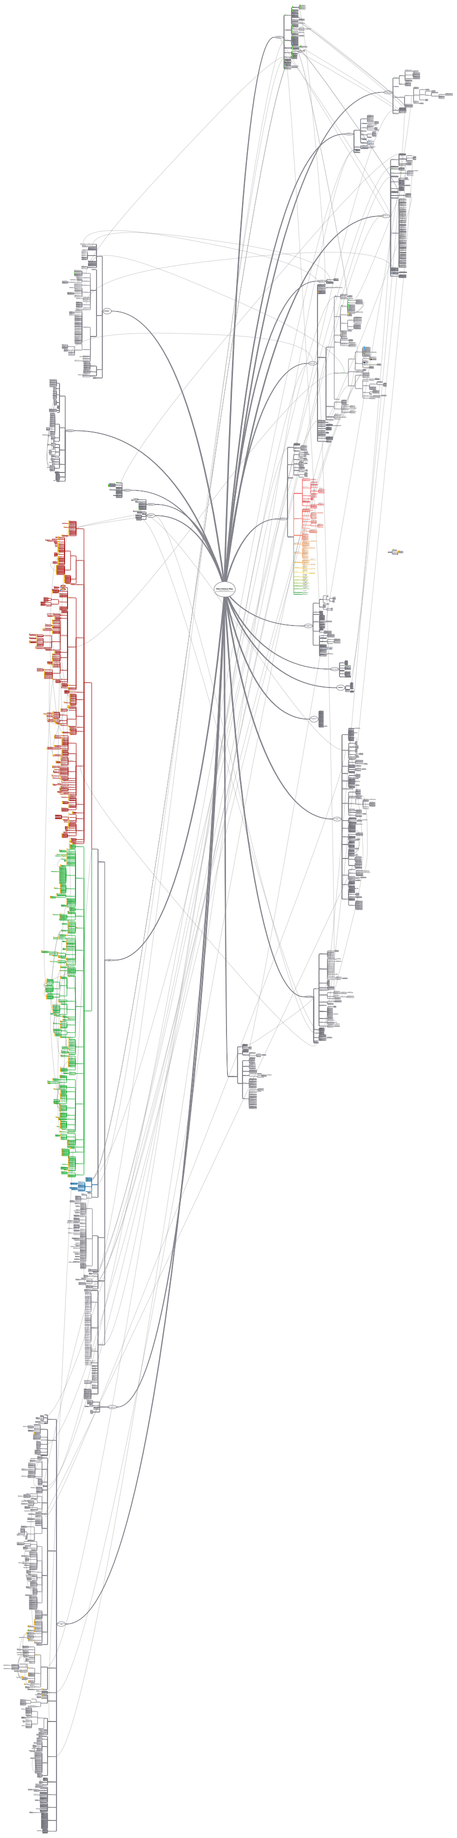


Figure 14.116: **Data Mining/Machine Learning non-exhaustive Mind Map techniques and tools**

and a third level of granularity would give[40] (sorry it's quite long but "data scientists", managers and IT staff in my teachings ask me many times to have an exhaustive one-place list):

- **Variables transformations:**
  1. Percentage ("normalization")
  2. Logarithmic transformation
  3. Center transformation (i.e. mean normalization)
  4. Z-transformation (centered-reduced / standardized)
  5. Rank transformation
  6. Percentile transformation (scaling)
  7. Range transformation (i.e. Min-Max transformation)
  8. Robust scaling
  9. Box-Cox transformation
  10. Modified Box-Cox transformation
  11. Johnson transformation (Yeo-Johnson)
  12. Variance stabilizing transformation
  13. Fisher transformation
  14. Lambert W x F transformation
  15. ORQ normalization
  16. Manly's exponential transformation
  17. John/Draper's modulus
  18. Bickel/Doksum's modified Box-Cox
  19. Whitening
  20. ...

- **Distance metrics:**
  1. Euclidean distance (special case of Hölder's distance)
  2. Mahalanobis distance
  3. Manhattan distance
  4. Canberra distance
  5. Chebyshev distance
  6. Earth mover's distance
  7. Hölder distance
  8. Cosine similarity
  9. Minkowski distance
  10. Haversine distance
  11. Hamming distance
  12. Jaccard distance
  13. Chi-squared distance
  14. Kendall rank correlation distance
  15. Heterogeneous euclidean overlap Metric (HEOM)
  16. ...

- **Sampling and validation techniques:**
  1. Simple random sampling with/without replacement (SRWR)
  2. Cluster sampling
  3. Systematic sampling
  4. Stratified random sampling
  5. Bootstrap sampling
  6. Conveniance sampling
  7. Judgemental or purposive sampling
  8. Snowball sampling
  9. Quota sampling
  10. Jackknife sampling
  11. Latin Hypercube sampling
  12. V-Fold cross-validation
  13. Leave-one-out cross-validation
  14. Monte Carlo cross-validation
  15. Group V-fold cross-validation

---

[40] this list is strongly inspired by Wikipedia, SPSS, SAS, R, Rapid Miner and Tanagra softwares options. For a neural networks list see the figure further below of Fjodor van Veen where 27 different neural networks type are given.

16. Rolling origin forecast resampling
17. Nested or double resampling
18. ...

- **Dimensionality reduction (feature extraction+feature selection):**

1. Correlation coefficients (Pearson's, Kendall, MIC, etc.)
2. Stepwise regression
3. Forward/Backward-logit
4. CFS (Correlation Feature Selection) filtering (Hall & Smith CFS)
5. FCBF filtering (Yiu & Liu Fast Correlation Based Filter)
6. mRMR (Minimum-redundancy-maximum-relevance) feature selection
7. Chi-squared feature ranking
8. Fisher Criterion Scoring
9. Battiti's MIFS (Mutual Information-based Feature Selection Method) feature filtering
10. NIMFS (Normalized mutual information feature) selection
11. MODTree (Multivalued Oblivious Decision) filtering (Lallich & Rakotomalala MODTree)
12. Non-negative matrix factorization dimension reduction
13. ReliefF (Kira & Rendell)
14. Runs filtering
15. Stepdisc (Wilk's partial lambda)
16. Oracle Minimum Description Length (MDL)
17. PCA (Principal Component Analysis)
18. SVD (Singular Value Decomposition)
19. CCA (Curvilinear Component Analysis)
20. ICA (Independent Component Analysis)/Kernel ICA
21. Parallel Factor Analysis (PARAFAC)
22. Tucker Decomposition (PARAFAC generalization)

53. Focused information criterion (FIC)
54. Mutual information criterion (MIC)
55. Bayesian predictive information criterion (BPIC)
56. Covariance inflation criterion (CIC)
57. Risk inflation criterion (RIC)
58. Relative error, Absolute error, Final prediction error (FPE)
59. Widely applicable information criterion (WAIC)
60. Quasilikelihood information criteria (QIC)
61. Shannon entropy (+perplexity)
62. Specificity
63. Log-loss (LL)

---

[42] Pseudo-correlations are used in logistic regression

64. Sensitivity
65. Jensen–Shannon divergence
66. Kullback–Leibler divergence
67. Aggregation indices (econometric)
68. Helsel's coefficient
69. Minimum message length (MML)
70. Freeman's θ
71. ε-squared
72. Pearson contingency coefficient
73. Goodman's Gamma
74. Guttman monotonicity coefficient^{np}
75. Rand index
76. Concentration coefficient
77. Uncertainty coefficient
78. Brier score loss
79. NNS (Nonlinear Nonparametric Statistic) dependence
80. ...

- **Statistical tests[43] (parametric, semi-parametric and nonparametric[44]):**

1. (Brown-)Mood's test^{np}
2. (Siegel-)Tukeys HSD test^{np}
3. Abelson-Tukey score test
4. Ahsanullah test^{np}
5. Adjacency test^{np}
6. ADF-GLS test
7. 2-AFC/3-AFC (alternative force choice) tests
8. Agostino test of skewness
9. Agresti–Pendergrast test^{np}
10. (Hodges)-Ajne's test^{np}
11. Anscombe-Glynn test of kurtosis
12. Anderson-Darling's adequation test^{np}
13. ANCOVA test
14. ANOVA/MANOVA tests (+Welch's ANOVA, Friedman's ANOVA^{np}, Kruskal-Wallis ANOVA^{np}, Scheirer-Ray-Hare ANOVA^{np}, Van der Waerden ANOVA^{np})
15. Ansari-Bradley's test^{np}
16. Anscombe-Glynn test
17. Aroian test
18. (Aspin-)Welch test
19. Auto-Regressive Conditional Heteroskedasticity (ARCH) effect test^{np}
20. Baarda's w-test
21. Bai and Ng's test
22. Banerjee-Lumsdaine-Stock test
23. Baumgartner-Weiss-Schindler test^{np}
24. Baringhaus-Henze-Epps-Pulley (BHEP) test
25. Bartholomew's likelihood ratio test
26. Barnard's test^{np}
27. Bartels rank test^{np} of randomness
28. Bartlett-(Kendall) test for variances
29. Bartlett's test for sphericity
30. Bartlett-Diananda test
31. Bayesian A/B tests
32. Beale's F test
33. Behrens-Fisher test
34. Bentler and Yuan's scree test
35. Beran's tests
36. Begg test
37. Berk-Jones tests^{np}
38. Besag-Newell's R test
39. BDS (Brock-Dechert-Scheinkman) test for non-linear serial dependence in time series
40. Bhapkar's test^{np}
41. Bieren's test
42. Bimodality test
43. (Binomial) sign test^{np}
44. Binomial exact test^{np}
45. Bithell's linear rank score test^{np}
46. Birch test^{np}
47. Bivariate sign test^{np}
48. Blumen's test^{np}
49. Blum-Kiefer-Rosenblatt independence test
50. BMP (Boehmer, Musumeci and Poulsen) cross-sectional test
51. Bonett-Seier test of kurtosis
52. Bonferroni outlier test
53. Boschloo's test^{np}

---

[43] Some of these tests are proved in the section Statistics page 542. Some items in the lists below are not really tests but more "procedures" or "methods". And obviously some tests are just special cases of others tests!!!

[44] Tests with the exponent ^{sp} are semi-parametric, those with ^{np} are nonparametric

54. Bowker's test for symmetry^{np}
55. Bowman and Shenton combination tests
56. Box's (M) test
57. Box–Pierce test
58. Brant test^{np} (proportional odds test)
59. Breitung test^{np}
60. Breslow-Day test^{np}
61. Breusch-Pagan-Godfrey's test for homogeneity of variances
62. Breusch-Godfrey stationarity test
63. Breusch-Pagan stationarity test
64. Brown–Forsythe's test
65. Brunk's^{np} test
66. Brunner-Munzel generalized Wilcoxon test^{np}
67. Buishand range and U test^{np}
68. Busetti-Taylor test
69. Buy-and-hold abnormal return test (BHAR)
70. Butler-Smirnov test
71. Canova and Hansen test^{np}
72. Capon test^{np}
73. CAR (cumulative abnormal return) test
74. Cattell's scree test
75. Chacko's test^{np}
76. Change point mean stationarity test
77. Change point variance changes stationarity test
78. Chen-Deo test
79. Chen-Wolfe test^{np}
80. Cheng-Spiring test^{np}
81. Chi-squared test for association / independence or homogeneity^{np}
82. Chi-squared test for independence with/without Yates correction
83. Chi-squared test for outlier
84. Chi-squared test for adequation^{np}
85. Chow's test^{np}
86. Cho–Gaines's test^{np}
87. Chow-Denning test
88. Chakraborti-Desu test
89. Chakraborti-Desu test^{np}
90. Chebyshev distance test^{np}
91. Circular-cone test
92. Clark-Evans' test
93. Cliff-Ord tests
94. Cochran's C-test
95. Cochran's Q-test^{np}
96. Cochran-Armitage's test^{np} (aka Chi square test for trend)
97. Cochran-Mantel-Haenszel's test^{np}
98. Cohen's d test
99. Conover-Iman squared ranks pairwise comparison test^{np}
100. Corner test for association^{np}
101. Comparing correlation coefficients of overlapping (CCO) samples
102. Corrado rank test^{np}
103. Correlation for categorical variables test
104. Cowan generalized sign test^{np}
105. Cox's F-test^{np}
106. Cox and Oakes test^{np}
107. Cox–Small test
108. Cox-Stuart trend test^{np}
109. Craddock test^{np}
110. Cramer–von Mises' test^{np}
111. Cressie tests^{np}
112. Cross sectional T-test
113. Cusum test for structural change
114. Cuzick–Edwards test
115. Cuzick's trend test^{np}
116. d-variable Hilbert Schmidt independence criterion test^{np}
117. Daniel's test for trend^{np}
118. Darroch interaction test^{np}
119. Davidson-MacKinnon test for comparing nonnested models
120. David-Barton test
121. David-Hellwig test
122. Davis-Quade's test^{np}
123. Demsar test^{np}
124. Depaulis test^{np}
125. Deshpande test^{np}
126. Dickey–Fuller's test^{np}
127. Difference between two non-overlapping dependent correlation coefficients test
128. Diggle and Chetwynd's test
129. Dixon's test
130. Doornik-Hansen test
131. Duckworth's test^{np}
132. Dudewicz-van der Meulen test^{np}
133. Duncan's multiple range comparison (MRT) test
134. Dunn's test^{np}

135. Dunnett's T, C or $T3$ test
136. Duo-Trio test
137. Durbin's rank test^{np}
138. Durbin-Watson autocorrelation test
139. Durbin-Wu-Hausman test
140. Dwass-Steele-Critchlow paired test^{np}
141. Dzhaparidze-Nikulin test^{np}
142. Egger's test
143. Euclidean distance test^{np}
144. Elliott-Rothenberg stock test
145. Enders sequential test procedure for unit roots
146. Engelman-Hartigan test
147. Engle test
148. Engle-Granger cointegration test
149. Epstein's test
150. Epps and Pulley test
151. Epps-Singleton (ES) test
152. Epsilon squared test
153. Eta squared test
154. Ewens-Watterson test^{np}
155. Excess mass test^{np}
156. Extreme rank sum test^{np}
157. Fagerland-Hosmer-Bofin test^{np}
158. Fay tests^{np}
159. Ferguson test
160. Fieller's test (A/B test)
161. Filliben's probability plot correlation test
162. Finkelstein and Schoenfeld test^{np}
163. Fisher-ADF test^{np}
164. Fisher-PP^{np}
165. Fisher-Behrens test
166. Fisher's Exact (Fisher-Irwin) test^{np}
167. Fisher-Freeman-Halton Exact test^{np}
168. Fisher's LSD (Least Significant Difference) test
169. Fisher-Hayter's LSD test
170. Fisher-Pitman's permutation test^{np}
171. Fisher's G-test for periodicity
172. Fisher's variance test
173. Fisher's cumulant test
174. Fisher-Yates test
175. Fisher-Yates-Terry-Hoeffding test^{np}
176. Fligner(-Killeen)'s test for homogeneity of variances^{np}
177. Fligner–Wolfe's test^{np}
178. Fligner–Policello's test^{np}
179. Foutz' F_n test
180. Fung-Paul test
181. Freeman–Tukey's test
182. Freund-Ansari-Bradley test for scale^{np}
183. Friedman correlation test^{np}
184. Friedman–Rafsky test^{np}
185. Frosini test
186. Fu and Li's test^{np}
187. G-test
188. Gabriel's pairwise test
189. Galton's rank order test^{np}
190. Gart's test
191. Garud tests^{np}
192. Gel-Gastwirth test
193. Generalized extreme studentized deviate test^{np} (GESD)
194. Generalized rank T-test^{np}
195. Generalized rank Z-test^{np}
196. Generalized sequential probability ratio test^{np} (GSPR)
197. Generalised sign test^{np}
198. Games-Howell test^{np}
199. Geary's test
200. Gehan's generalized Wilcoxon test^{np}
201. Gini test (Gail and Gastwirth)
202. Glejser's test
203. Gnedenko F-test^{np}
204. Goldfeld–Quandt's test
205. Goodman-Kruskal's Gamma test^{np}
206. Goodman-Kruskal's Lambda test^{np}
207. Goodman-Kruskal's tau test^{np}
208. Goodman's interaction test^{np}
209. Gore's test^{np}
210. Grambsch-Therneau test of proportionality
211. Granger causality test
212. Grazzini stationarity test^{np}
213. Greenhouse-Geisser test
214. Greenwood's test^{np}
215. Greenwood-Quesenberry-Miller test^{np}
216. Gregory–Hansen test^{np}
217. Grubbs' test
218. Gupta's test^{np}
219. Hahn-Shapiro test
220. Hadri test
221. Harrington and Fleming's Gp tests
222. Harris-Gnedenko test^{np}
223. Harrison-McCabe test for heteroskedasticity

224. Harrison-Kanji-Gadsden test
225. Hartigan's Dip (HDS) test
226. Hartley's (F-max) test
227. Harbord's test
228. Harvey-Collier test for linearity
229. Hatemi–J test^{np}
230. Haugh's test
231. Hayter-Stone test^{np}
232. Hayter-Nasimoto-Wright test
233. Hegazy-Green test^{np}
234. Henze-Zirkler test
235. Hermans–Rasson test
236. Hettmansperger–McKean test^{np}
237. Hirsch-Slack correlation test^{np}
238. Hochberg's GT2 pairwise test^{np}
239. Hodges' bivariate sign test^{np}
240. Hodges-Lehmann test^{np}
241. Hoeffding's independence test^{np}
242. Hollander's bivariate symmetry test^{np}
243. Hollander's parallelism test^{np}
244. Hollander-Proshan test^{np}
245. Hopkins-Skellam test
246. Hosmer–Lemeshow test^{np}
247. Hosmer-Le Cessie test^{np}
248. Hosking test
249. Hotelling's T2-test
250. Hsieh test^{np}
251. Hsu's MCB (multiple comparisons with the best) test
252. Hudson-Martin-Arguadé test^{np} (HKA)
253. Huynh-Feldt test
254. Imam test^{np}
255. Im, Pesaran and Shin test
256. J-tests
257. Jacquez's k-nearest neighbours test
258. Jalal and Jamshidian test
259. Jarque-Bera test
260. Jennrich test of the equality of two matrices[45]
261. Johansen cointegration test
262. Joenssen's JP-square test^{np}
263. Jonckheere-Terpstra (JT) trend test^{np}
264. Johnson-Mehrotra test^{np}
265. Joint digit Benford test^{np}
266. Judge-Schechter Mean Deviation test^{np}
267. Inannan HCT test^{np}
268. Inner-Wedge test
269. K test (Kleibergen)
270. Kallenberg-Ledwina test^{np}
271. Kao's test^{np}
272. Kattumannil-Sreedevi test^{np}
273. Kaplan-Meier test^{np}
274. Kaiser-Meyer-Olkin test
275. Keenan's test^{np}
276. Kendall rank correlation test^{np}
277. Kendall's tau-b test^{np}
278. Kendall's tau-c test^{np}
279. Kendall's concordance W test^{np}
280. Kendall's tau test^{np}
281. Kenward-Roger tests
282. Kim's ratio test
283. Kimball test^{np}
284. Kimber-Michael test
285. KPSS (Kwiatkowski, Phillips, Schmidt and Shin) test^{np}
286. Klotz scale test^{np}
287. Knox's tests
288. Kochar test^{np}
289. Kochar and Gupta tests^{np}
290. Kolmogorov-Smirnov test^{np}
291. Kowalski's bivariate line test
292. Koziol-Nemec test^{np}
293. Kruskal-Wallace test
294. Kuiper's test^{np}
295. Kurtosis test
296. LaBreque's tests
297. Lagrange multiplier (LM) score test
298. Lanzante's test^{np}
299. Larocque and Labarre sign test^{np}
300. Lawless and Landau recurrence Mean Cumulated Function (MCF) test^{np}
301. Le's test^{np}
302. Lee-Wolfe test^{np}
303. Lehmacher test^{np}
304. Lehmann's test
305. Leybourne-McCabe test
306. Leybourne-Kim-Smith-Newbold test
307. Lepage test
308. Levene's test
309. Liddell's exact test^{np}
310. Li-Mak test

- **Regression and regularization techniques[47]:**

1. Linear regression model (LSM)
2. Gaussian linear regression model
3. Non-linear regression models with binary or continuous variables
4. Polynomial regression model
5. Weighted least squares regression model
6. B-spline or of collocation polynomial regression
7. Logistic regression models (binomial, multinomial, ordinal)
8. Counting Poisson regression (Poisson MLE, PMLE, GLM, Poisson-quasi-Lindley)
9. Negative binomial (binomial MLE and QGPMLE) regression model
10. Beta regression
11. Cox proportional hazard regression
12. Threshold regression models
13. Total linear regression
14. Orthogonal linear regression model
15. Deming regression
16. Quantile regression model
17. Partial least squares regression (PLS)
18. Structural equation modelling (Two-Stage Least Squares/2SLS)
19. Moderated multiple regression
20. Mixed linear/non-linear or generalized models (nested or not, splitted or not)
21. Panel regression
22. LAD (Least Absolute Deviation) regression
23. LOESS (LOcally Estimated Scatterplot Smoothing) and LOWESS (LOcally Weighted Scatterplot Smoothing)
24. Least absolute shrinkage and selection operator (LASSO)
25. Multivariate adaptive regression splines (MARS)
26. Bayesian linear regression model
27. Logic regression
28. Ridge regression model
29. Bootstrap or Jackknife regression model
30. Backward elimination regressions
31. Forward entry regression
32. C-RT regression tree
33. DfBetas
34. Epsilon SVR (support vector regression)
35. Nu SVR
36. Least-angle regression (LARS)
37. Elastic net regularization
38. Simplex regression
39. Independent component regression
40. Theil-Sen estimator regression method
41. Isotonic regression
42. ...

- **Factor Analysis (FA):**

1. FADM (Mixed data factor analysis)
2. Bootstrap eigenvalues
3. Linear discriminant analysis (canonical LDA)/Kernel LDA
4. Correspondence analysis
5. Discriminant correspondence analysis

---

[47] see section Numerical Methods page 6316

6. Principal Component Analysis with/without Factor rotation (VariMax)
7. Harris component analysis
8. Multiple correspondence analysis
9. NIPALS (Non-linear Iterative Partial Least Squares)
10. Parallel analysis
11. Principal factor analysis
12. ...

- **Clustering (unsupervised):**

1. CatVARCHA (categorical variable hierarchical agglomerative clustering)
2. Clustering Tree (CT) with/without post-pruning
3. Fuzzy clustering tree
4. Kernel Density estimation (density based clustering)
5. Kernel PCA (Principal Component Analysis)
6. Singular Value Decomposition (SVD)
7. EM-Clustering (Expectation-Maximization)
8. HAC (Hierarchical Agglomerative Clustering)
9. k-means, k-Medians or k-Medoids clustering, Fuzzy clustering, k-Modes, k-Prototypes
10. Kernel k-means
11. Mean shift clustering
12. Spectral clustering
13. Multidimensional scaling (MDS)
14. Kohonen-SOM (Self Organization Map)
15. Kohonen-LVQ (Learning Vector Quantizer)
16. GMM (Gaussian Mixture Model)
17. VARCLUS (top down approach)
18. VARHCA (clustering variables using Hierarchical Cluster Analysis)
19. VARKMeans (clustering variable using k-means)
20. Density-based spatial clustering of applications with noise (DBSCAN)
21. Soft independent modelling of class analogies (SIMCA)
22. ...

- **Supervised (Spv) Learning:**

1. Binary logistic regression
2. BVM (Ball Vector Machine)
3. Iterative Dichotomiser 3 (ID3 Quinla algorithm)
4. C4.5 (Quinlan algorithm extension of ID3)
5. M5 (Quinlan algorithm)
6. Cubist (extension of M5)
7. C-PLS (PLS for classification)
8. C-RT (Regression Tree for classification)
9. CS-CRT (Cost Sensitive Classification RT)
10. C-MC4 (M-Estimates based and Laplace smoothed CS-CRT)
11. C-SVC (Continuous Supervised Classification)
12. CVM (Core Vector Machine)
13. Decision List (One-Rule, Zero-Rule, CN2)
14. Repeated Incremental Pruning to Produce Error Reduction (RIPPER)
15. CHAID (Chi-squared Automatic Interaction Detection)
16. Gradient Boosting
17. Gaussian processes
18. k-nn (Nearest Neigbhors)
19. Linear discriminant analysis (canonical LDA)/Kernel LDA
20. QDA (Quadratic Discriminant Analysis)
21. Log-Reg TRIRLS
22. Multilayer perceptron (MLP neural network)

23. Multinomial Logistic Regression
24. Naive bayes categorical variables classification
25. Naive bayes continuous variables classification
26. PLS-DA (PLS Discriminant Analysis)
27. PLS-LDS (PLS Linear DA)
28. Prototype-NN (Nearest Neighbours)
29. Radial basis function (RBF neural network)
30. Random Tree
31. Rule Induction, Fuzzy rule induction
32. Support Vector Machine (SVM)
33. Genetic classification
34. Locally Weighted Learning (LWL)
35. ...

- **Semi-Supervised learning:**
  1. Contrastive Pessimistic Likelihood Estimation (CPLE)
  2. semi-supervised vector machine (S3VM)
  3. Transductive Support Vector Machines (TSVM)
  4. Label propagation
  5. Label spreading
  6. ...
- **Meta Supervised learning (ensemble learning):**
  1. Random forests
  2. Extremely Randomized trees
  3. Rotation forests
  4. Mondrian forests
  5. Gradient Boosting Machines (GMB)
  6. Boosting
  7. Bootstrapped Aggregation (bagging)
  8. CatBoost, AdaBoost, XGBoost
  9. Light GBM
  10. Stacked Generalization (blending)
  11. Gradient Boosted Regression Trees (GBRT)
  12. Arcing (Arc-x4) bagging with weights
  13. Bagging with/without cost sensitivity
  14. Boosting with/without cost sensitivity
  15. MultiCost sensitive supervised learning
  16. Stacked generalization
  17. ...
- **Supervised learning assessment:**
  1. Bias-variance decomposition (Wolpert & Kohavi)
  2. Bootstrap
  3. Cross-validation
  4. Leave-One-Out
  5. Test set assessment
  6. Learning/Train assessment test
  7. ...
- **Scoring:**
  1. Lift curve
  2. ROC curve
  3. Precision-Recall curve
  4. Log-loss (and i.e. log likelihood)
  5. Log-pointwise predictive density (LPPD)
  6. Reliability diagram
  7. ...

- **Association:**

  1. A priori (MR version or not)
  2. A priori PT (Borgelt's algorithm)
  3. Assoc outlier (association rule mining principle)
  4. Frequent itemsets (Borgelt's algorithm)
  5. ECLAT (equivalence class transformation algorithm)
  6. FP-growth (frequent pattern growth)
  7. RElim (recursive elimination)
  8. SaM (Split and Merge)
  9. JIM (Jaccard Itemset Mining)
  10. Spv association rule
  11. Spv association tree
  12. ...

- **Anomaly detection:**

  1. Chauvenet's criterion
  2. Cochran C test
  3. Dixon's test
  4. Grubb test
  5. Cook's distance
  6. Peirce's criterion
  7. Studentized residual
  8. Isolation forest
  9. Control Charts[48] (P, NP, C, U, R-R, X-R, etc.)
  10. Markov modulated Poisson process (MMPP)
  11. Local outlier factor (FOL)
  12. Online Over-Sampling Principal Component Analysis
  13. ...

- **Reinforcement learning:**

  1. Markov Decisions Processes
  2. Case-Based Reasoning
  3. Genetic algorithm
  4. Asynchronous Advantage Actor Critic (A3C)
  5. State–Action–Reward–State–Action (SARSA)
  6. Q-learning
  7. TD(λ) algorithm
  8. TD(0) Actor-Critic
  9. ...

- **Imputations methods[49]:**

  1. Predictive mean matching
  2. Weighted predictive mean matching
  3. Random sample from observed values
  4. Classification and regression trees
  5. Hot or Cold deck imputation
  6. Random forest imputations
  7. Unconditional mean imputation
  8. Bayesian linear regression
  9. Linear regression ignoring model error
  10. Linear regression using bootstrap
  11. Linear regression, predicted values
  12. Imputation of quadratic terms
  13. Laplace smoothing
  14. Random indicator for non-ignorable data
  15. Logistic regression
  16. Logistic regression with bootstrap

---

[48] see section Industrial Engineering (page 8934) for the details on control charts.

[49] Be always careful when using imputation methods. For example impute missing values with mean or zero alters summary statistics significantly, changes the distribution significantly and inflate the presence of a specific value and therefore leads to inaccurate modelling and unlikely conclusions.

17. Proportional odds model
18. Polytomous logistic regression
19. Linear discriminant analysis (LDA)
20. Level-1 normal heteroscedastic
21. Level-1 logistic
22. Level-2 class mean/normal
23. Level-2 class predictive mean matching
24. Multivariate imputation by Chained Equations
25. k-NN imputer
26. ...

- **Forecastings:**
  1. Linear and polynomial regressions (see above)
  2. Moving Average
  3. Simple exponential smoothing
  4. Double exponential smoothing (Brown)
  5. Triple exponential smoothing (Holt & Winters)
  6. ETS (Error Trend Seasonal) models
  7. Logistic forecasts
  8. Croston's method / Adjusted Croston's method
  9. ARIMA[50] processes (AR, ARMA DARMA, INARMA, ARIMA, SARIMA, ARFIMA, SARFIMA, ARIMAX)
  10. GARCH (General-ARCH[51]) processes (GARCH-X, EGARCH, ARCH, sGARCH, RUGARCH, iGARCH, MGARCH)
  11. NARCH (Non-linear-ARCH) processes
  12. TARCH (Threshold-ARCH) processes
  13. Independent Component Analysis (ICA)
  14. ...

- **Sequence mining:**
  1. GSP (Generalized Sequential Patterns)
  2. SPADE (Sequential Pattern Discovery)
  3. FreeSpan
  4. HMM (hidden Markov models)
  5. ...

- **Neural Networks/Deep learning:**
  1. Perceptron
  2. Feed-Forward Neural Network (FFNN)
  3. Radial Basis Network (RBF)
  4. Recurrent Neural Network (RNN)
  5. Gated Recurrent Unit (GRU)
  6. Long Short-Term Memory (LSTM)
  7. Deep Boltzmann Machine (DBM)
  8. Deep Feed Forward Networks (DBN)
  9. Deep Belief Networks (DBN)
  10. Deep Belief Convolutional Network (DCN)
  11. Deep Residual Network (DRN)
  12. Differentiable Neural Computer (DNC)
  13. Neural Turing Machine (NTM)
  14. Capsule Network (CN)
  15. Kohonen Network (KN)
  16. Attention Network (AN)
  17. Deconvolutional Network (DN)
  18. Deep Convolutional Inverse Graphics Network (DCIGN)
  19. Liquid State Machine (LSM)
  20. Extreme Learning Machine (ELM)

  2. Latent Semantic Indexing (LSI)
  3. Latent Dirichlet allocation (LDA)
  4. Probabilistic Latent Semantic Indexing (PLSI)
  5. Vector space model (term vector model)
  6. Sentiment Analysis
  7. Language detection
  8. Pattern detection/correlation
  9. ...

Remark

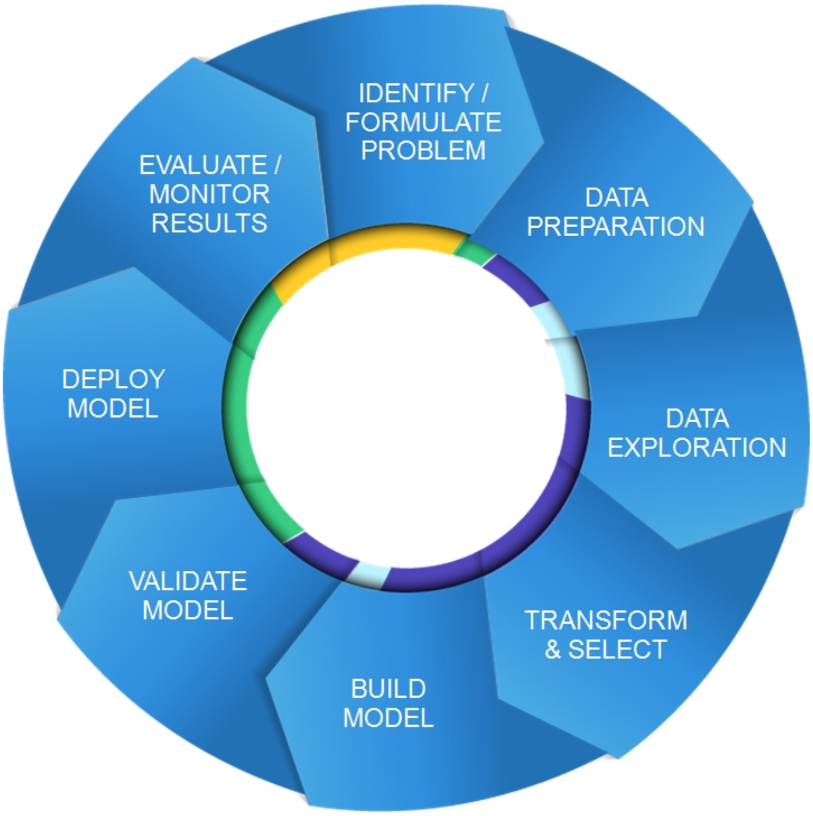
Keep in mind that Machine Learning cannot be used for everything related to statistics. Indeed, in drug assessment and approval we are limited by a set of statistical methods forming an industry standard and approved by regulatory agencies (FDA, EMA, etc.), by the accepted approach named "confirmatory data analysis" via inferential statistics, both frequentist and bayesian, by small and extremely small data (starting from 5 observations in early trial phases) by demand for interpretability (not rarely we prefer here simpler but more "transparent" methods rather than efficient ones). In clinical research (but not only!), every single possible aspect is regulated by guidelines, controlled by validation, every step of statistical analysis must be well enough justified under the threat of being rejected by regulatory or statistical reviewers and lead the whole trial to fail (that is why in practice we have to construct a "Statistical Analysis Plan (SAP)" before any well done experiment).

The reader must also keep in mind some possible limitations of predictive model based on data fitting:

- History cannot always predict future
- The issue of unknown unknowns
- Bad model choice
- Over-fitting model
- Overconfidence of humans on algorithms results
- ...

So we see through these lists that Data Mining and Machine Learning are child of statistics, computer science, and mathematical optimization. Along the way, it took inspiration from information theory, neural science, theoretical physics, and many other fields.

This was the scientist point of view of Data Mining... From the point of view of business, Data Mining is more considered as the following data life cycle:

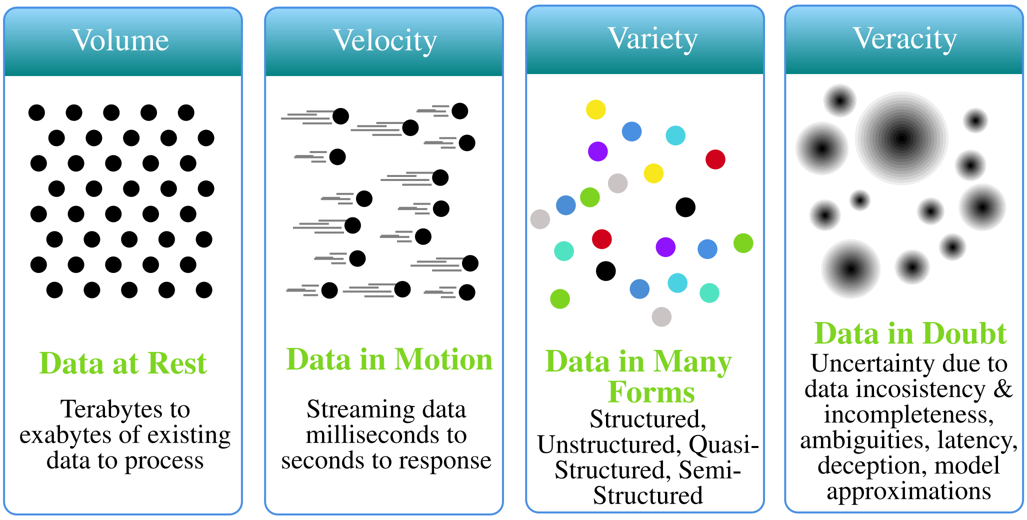


IDENTIFY / FORMULATE PROBLEM
DATA PREPARATION
DATA EXPLORATION
TRANSFORM & SELECT
BUILD MODEL
VALIDATE MODEL
DEPLOY MODEL
EVALUATE / MONITOR RESULTS

Figure 14.117: Data Mining life cycle as seen by SAS™ (source: SlideShare SAS)

Remember, as we already said it in the introduction chapter of this textbook, that statisticians do not in general exactly agree on how to analyse anything but the simplest of problems! The fact that statistical inference uses mathematics does not imply there is only one reasonable or useful way to conduct an analysis. Engineering uses math as well, but there are many ways to build a bridge. So trying multiple analyses given to multiple independent teams of researchers may be considered scientifically prudent to test the robustness of findings.

And also let us introduce the 4V's of Data Mining/Machine Learning that resume quite well the most common cases of data to which the Data Scientist is faced to:



Volume
Data at Rest
Terabytes to exabytes of existing data to process
Velocity
Data in Motion
Streaming data milliseconds to seconds to response
Variety
Data in Many Forms
Structured, Unstructured, Quasi-Structured, Semi-Structured
Veracity
Data in Doubt
Uncertainty due to data incosistency & incompleteness, ambiguities, latency, deception, model approximations

Figure 14.118: Data Mining/Machine Learning 4V's

Remarks

R1. The data scientist must take care of not becoming a "Data Pusher" and not to do just "infotainement" (almost no-sense statistics) in order to remain employed. This is ethically non-scientific and as the reader of this textbook already knows it, as going at the opposite of the Archimedes Oath!

R2. Corporations and managers have to understand that a data steward cannot be a data analyst, that a data analyst that cannot be a data scientist and that latter is also most of time not at the level of statistician. Think the opposite show an evident lack of technical and scientific knowledge from the management, especially when the data scientist is supposed alone to install Big Data servers, clean data, develop new mathematical models, do programming for implementing the models and put them in production.

R3. Data is not a currency, most data is garbage. Actionable information is currency. Extracting information form modern big data sets requires the equivalent processing infrastructure and time of extracting a nugget of gold from a mountain of dirt.

Type of Data	Description	Examples
Unstructured	Data that has no inherent structure	PDF, Text documents (txt, doc, docx), Images, Videos, Slideshows
Quasi-structured	Textual data with erratic formats that can be formatted with effort and software tools	website pages, log files, social networks post, configuration files
Semi-structured	Textual data files with an apparent pattern enabling analysis (but with some pain)	spreadhsheet (xls, xlsx), Comma separated value (csv), JSON, XML, emails
Structured	Data having a defined data model, format, structure,	Parquet files, Relational Databases (i.e. semantic model)

Table 14.24: Types of data in Data Science

Small, medium and international companies must not be surprised to be disappointed after having hired a Data Scientist that theoretically (on the paper...) should "master" various programming languages (R, Python™, C++, Java), various tools (Microsoft® Excel®, Salesforce Tableau, Microsoft Power BI) data retrieval, data wrangling, data archiving, data governance, scientific methodology and advanced statistics as it is impossible for one person to master all these subjects at the same time (or even to have an undergraduate level at the same time of each of these topics)! Furthermore when considering the four types of data below where each one required very specific high level mathematical skills (at PhD level) to be able to correctly and efficiently deal with:

So don't be surprised if by hiring only one person in your company that should do all the following jobs:

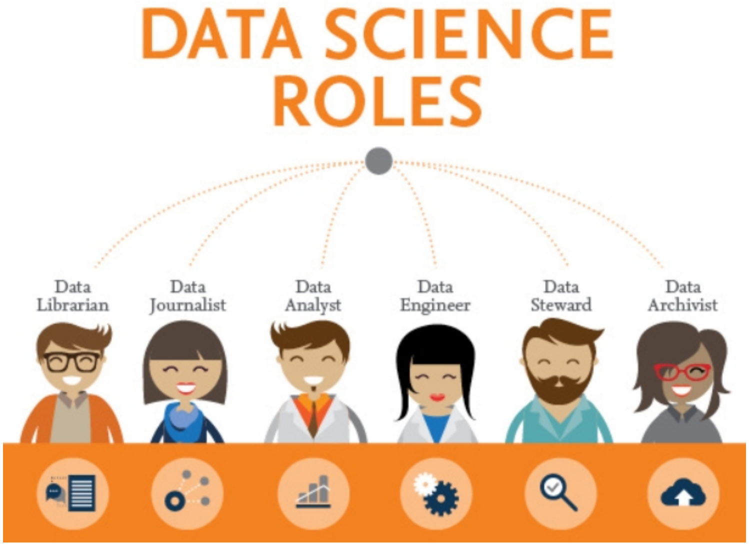


Figure 14.119: Data science roles (source: ?)

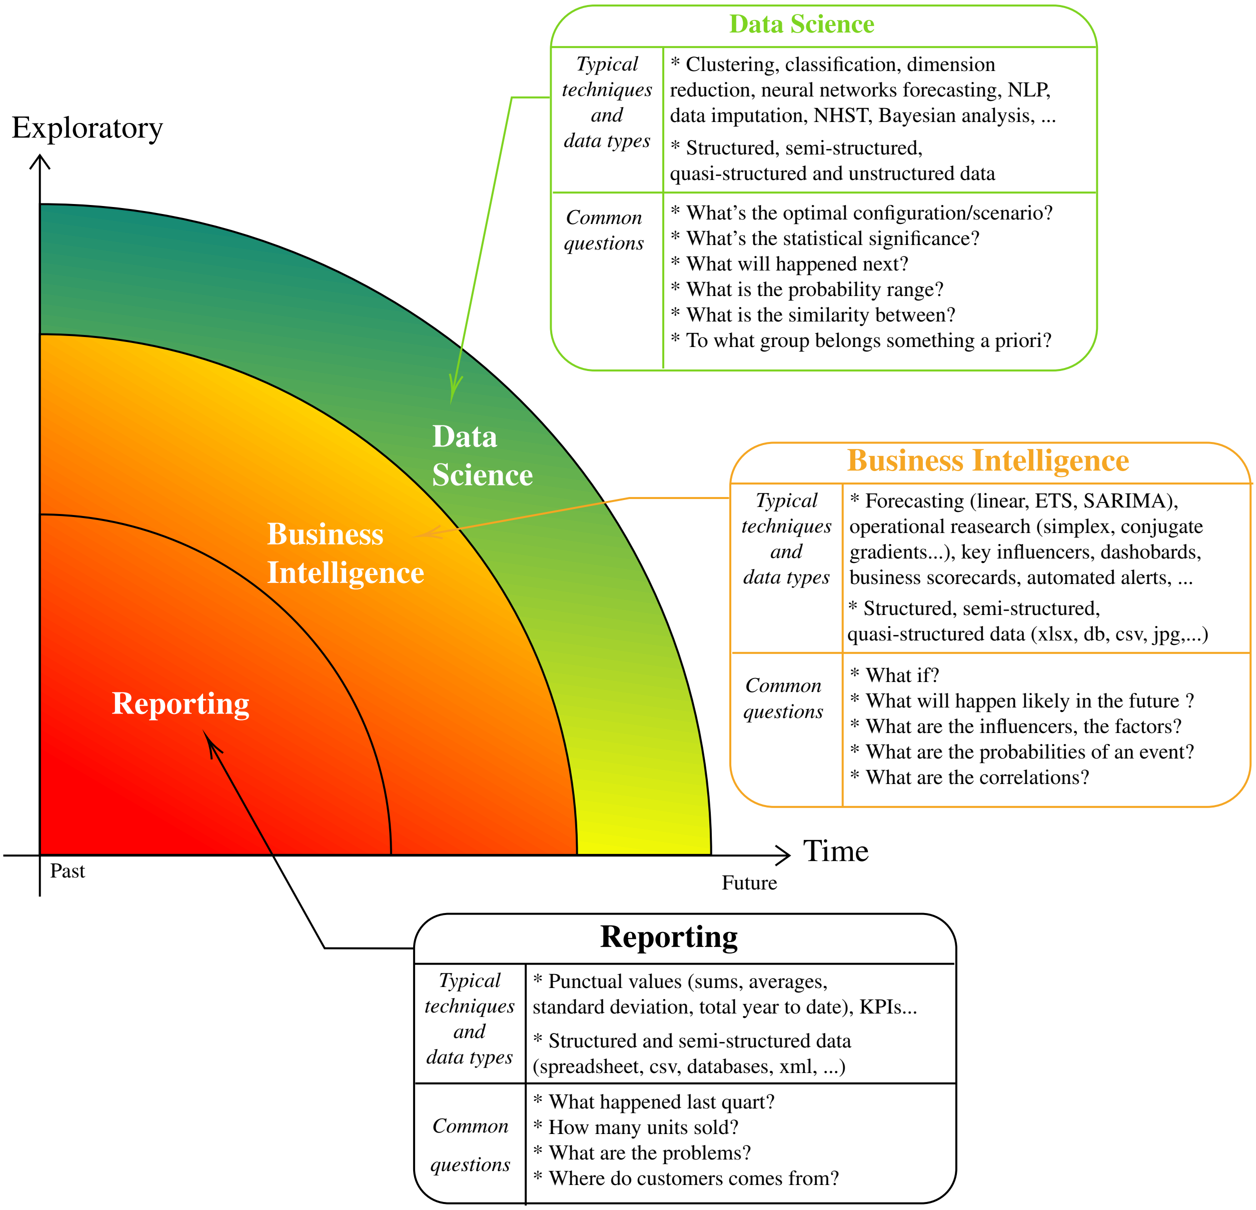
that you get garbage (unreliable) results without any strong scientific methodology.

It should be noticed that business intelligence (BI) is quite different from Data Science as illustrated below:



Data Science

Typical techniques and data types	* Clustering, classification, dimension reduction, neural networks forecasting, NLP, data imputation, NHST, Bayesian analysis, ... * Structured, semi-structured, quasi-structured and unstructured data
Common questions	* What's the optimal configuration/scenario? * What's the statistical significance? * What will happened next? * What is the probability range? * What is the similarity between? * To what group belongs something a priori?

Business Intelligence

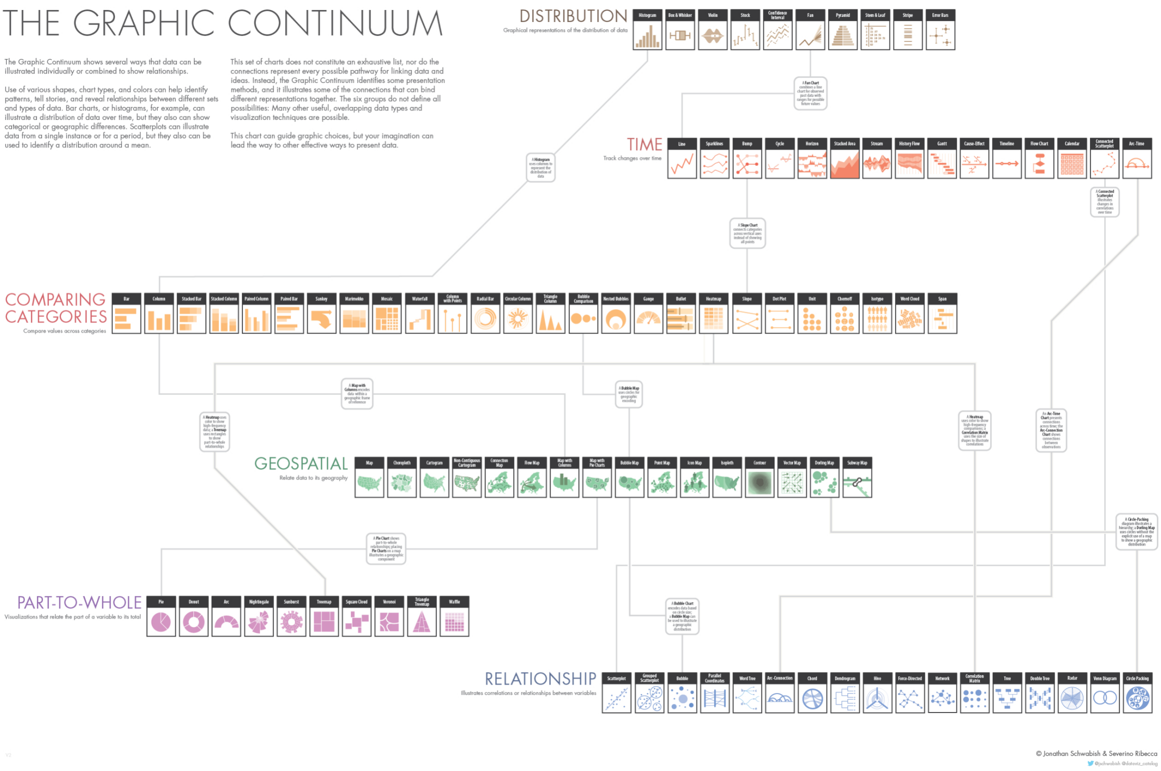
Typical techniques and data types	* Forecasting (linear, ETS, SARIMA), operational reasearch (simplex, conjugate gradients...), key influencers, dashobards, business scorecards, automated alerts, ... * Structured, semi-structured, quasi-structured data (xlsx, db, csv, jpg,...)
Common questions	* What if? * What will happen likely in the future ? * What are the influencers, the factors? * What are the probabilities of an event? * What are the correlations?

Reporting

Typical techniques and data types	* Punctual values (sums, averages, standard deviation, total year to date), KPIs... * Structured and semi-structured data (spreadsheet, csv, databases, xml, ...)
Common questions	* What happened last quart? * How many units sold? * What are the problems? * Where do customers comes from?

Figure 14.120: **Comparing Reporting and Business Intelligence with Data Science**

Finally, as requested by a customer, here is also a list of visuals (charts) used in Business Intelligence (for a more complete list including high level scientists and engineers charts, see page 2204):



THE GRAPHIC CONTINUUM

The Graphic Continuum shows several ways that data can be illustrated individually or combined to show relationships.

Use of various shapes, chart types, and colors can help identify patterns, tell stories, and reveal relationships between different sets and types of data. Bar charts, or histograms, for example, can illustrate a distribution of data over time, but they also can show categorical or geographic differences. Scatterplots can illustrate data from a single instance or for a period, but they also can be used to identify a distribution around a mean.

This set of charts does not constitute an exhaustive list, nor do the connections represent every possible pathway for linking data and ideas. Instead, the Graphic Continuum identifies some presentation methods, and it illustrates some of the connections that can bind different representations together. The six groups do not define all possibilities: Many other useful, overlapping data types and visualization techniques are possible.

This chart can guide graphic choices, but your imagination can lead the way to other effective ways to present data.

A **Histogram** uses columns to represent the distribution of data

A **Fan Chart** combines a line chart for observed past data with ranges for possible future values

A **Slope Chart** connects categories across vertical axes instead of showing all points

A **Connected Scatterplot** illustrates changes in correlations over time

A **Map with Columns** encodes data within a geographic frame of reference

A **Bubble Map** uses circles for geographic encoding

A **Heatmap** uses color to show high-frequency data; a **Treemap** uses rectangles to show part-to-whole relationships

A **Heatmap** uses color to show high-frequency comparisons; a **Correlation Matrix** uses the size of shapes to illustrate correlations

An **Arc-Time Chart** presents connections across time; the **Arc-Connection Chart** shows connections between observations

A **Circle-Packing** diagram illustrates a hierarchy; a **Dorling Map** uses circles without the explicit use of a map to show a geographic distribution

A **Pie Chart** shows part-to-whole relationships; placing **Pie Charts** on a map illustrates a geographic component

A **Bubble Chart** encodes data based on circle size; a **Bubble Map** can be used to illustrate a geographic distribution

14.1.20.1 Training vs Test Data

First, to define a problem of machine learning, we have to decide what type of modelization function we want to consider.

Definition (#14.1.569): We name "hypothesis space", the set of functions $\mathcal{F} \subseteq \mathcal{Y}^{\mathcal{X}}$ describing the modelization functions that we will consider. This space is chosen depending on our convictions (return on experience) relatively to the problem we are faced to.

We typically split the input data into learning and testing datasets. We then run the Machine Learning algorithm on the learning dataset to generate the prediction model. Later, we use the test dataset to evaluate our model.

Definition (#14.1.570): Given a dataset $\mathcal{D}=\{(\vec{x}^i, y^i)\}_{i=1,\ldots,n}$, partitioned into two sets $\mathcal{D}_{\text{tr}}$ and $\mathcal{D}_{\text{te}}$, we name "training set" the set $\mathcal{D}_{\text{tr}}$ used to train a predictive model, and test set the set $\mathcal{D}_{\text{te}}$ used for its evaluation.

It is important that the test data is separate from the one used in training otherwise we will be kind of cheating because may for example the generated model memorizes the data and hence if the test data is also part of the training data then our evaluation scores of the model will be higher than they actually are.

The data is usually split 75% training and 25% data or $2/3$ training and $1/3$ testing. It is important to note that: the smaller the training set the more challenging it is for the algorithm to discover the rules.

In addition, when splitting the dataset, we need to maintaining class proportions and population statistics otherwise we will have some classes that are under represented in the training dataset and over represented in the test dataset.

A crucial step when building our Machine Learning model is to estimate its performance on that the model hadn't seen before. We want to make sure that the model generalizes well to new unseen data.

Now consider the situation where we want to choose between K models. We can then train each of the models on the training dataset, thus obtaining K decision functions $f_1, f_2, \ldots, f_K$, then calculate the error of each of these models on the test set. We can then choose as a model the one that has the smallest error on the test set:

$$\hat{f}=\underset{k=1,\ldots,K}{\arg\min}\frac{1}{|\mathcal{D}_{\text{te}}|}\sum_{\vec{x},y\in\mathcal{D}_{\text{te}}} L\left(y, f_k(\vec{x})\right) \qquad (14.1.1701)$$

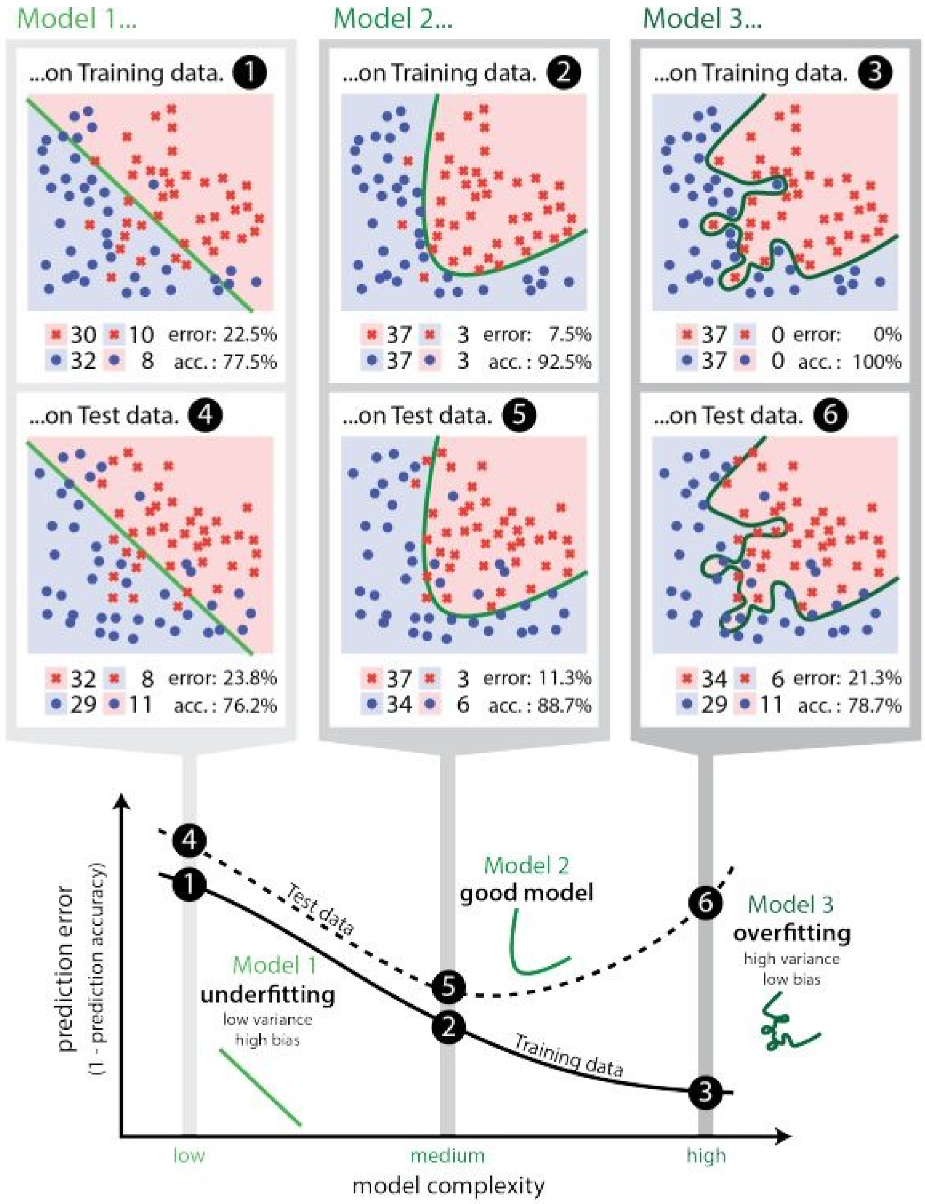

Figure 14.123: **Underfitting and overfitting errors**

In statistics and Machine Learning, the "bias–variance tradeoff" (or dilemma) is the problem of simultaneously minimizing two sources of error that prevent supervised learning algorithms from generalizing beyond their training set:

- The bias is an error from erroneous assumptions in the learning algorithm. High bias can cause an algorithm to miss the relevant relations between features and target outputs (underfitting).
- The variance is an error from sensitivity to small fluctuations in the training set. High variance can cause an algorithm to model the random noise in the training data, rather than the intended outputs (overfitting).

This tradeoff applies to all forms of supervised learning: classification, regression (function fitting), and structured output learning. It may has also been invoked to explain the effectiveness of heuristics in human learning.

The bias-variance tradeoff is a central problem in supervised learning. Ideally, one wants to choose a model that both accurately capture the regularities in its training data, but also generalizes well to unseen data. Unfortunately, it is typically impossible to do both simultaneously. High-variance learning methods may be able to represent their training set well but are at risk of overfitting to noisy or unrepresentative training data. In contrast, algorithms with high bias typically produce simpler models that don't tend to overfit but may underfit their training data, failing to capture important regularities.

Models with low bias are usually more complex (e.g. higher-order regression polynomials), enabling them to represent the training set more accurately. In the process, however, they may also represent a large noise component in the training set, making their predictions less accurate - despite their added complexity. In contrast, models with higher bias tend to be relatively simple (low-order or even linear regression polynomials) but may produce lower variance predictions when applied beyond the training set.

Suppose that we have a training set consisting of a set of points $x_1,\ldots,x_n$ and real values y_i associated with each point x_i. We assume that there is a function with noise $y=f(x)+\varepsilon$, where the noise, ε, has zero mean and variance σ_ε^2.

We want to find a function $\hat{f}$, that approximates the true function $f(x)$ as well as possible, by means of some learning algorithm. We make "as well as possible" precise by measuring the mean squared error between y and $\hat{f}(x)$: we want $(y-\hat{f}(x))^2$ to be minimal, both for $x_1,\ldots,x_n$ and for points outside of our sample. Of course, we cannot hope to do so perfectly, since the y_i contain noise ε; this means we must be prepared to accept an irreducible error in any function we come up with.

Theorem 14.7. Finding an $\hat{f}$ that generalizes to points outside of the training set can be done with any of the countless algorithms used for supervised learning. It turns out that whichever function $\hat{f}$ we select, we can decompose its expected error on an unseen sample x as follows:

$$\text{PE}=\text{E}\left[\left(y-\hat{f}(x)\right)^2\right]=\sigma_\varepsilon^2+\underbrace{\text{V}\left[\hat{f}(x)\right]+\text{Bias}\left[\hat{f}(x)\right]^2}_{\text{model estimation error (to minimize)}} \tag{14.1.1702}$$

named "bias-variance tradeoff", where:

$$\text{Bias}\left[\hat{f}(x)\right]=\text{E}\left[\hat{f}(x)-f(x)\right] \tag{14.1.1703}$$

and:

$$\text{V}\left[\hat{f}(x)\right]=\text{E}\left[\hat{f}(x)^2\right]-\text{E}\left[\hat{f}(x)\right]^2 \tag{14.1.1704}$$

and where PE denotes the "prediction error" also sometimes named the "expected loss".

Proof 14.7.1. The derivation of the bias-variance decomposition for squared error proceeds as follows. For notational convenience, abbreviate $f=f(x)$ and $\hat{f}=\hat{f}(x)$. First, recall that, by definition, for any random variable X, we have:

$$\text{V}(X)=\text{E}(X^2)-\text{E}(X)^2 \tag{14.1.1705}$$

Rearranging, we get:

$$\mathrm{E}(X^2)=\mathrm{V}(X)+\mathrm{E}(X)^2 \tag{14.1.1706}$$

If we assume a model where f is deterministic:

$$\mathrm{E}(f)=f \tag{14.1.1707}$$

This, given $y=f+\varepsilon$ and $\mathrm{E}(\varepsilon)=0$, implies:

$$\mathrm{E}(y)=\mathrm{E}[f+\varepsilon]=\mathrm{E}(f)=f \tag{14.1.1708}$$

Also, since $\mathrm{V}(\varepsilon)=\sigma_\varepsilon^2$:

$$\mathrm{V}(y)=\mathrm{E}\left[(y-\mathrm{E}(y))^2\right]=\mathrm{E}\left[(y-f)^2\right]=\mathrm{E}\left[((f+\varepsilon)-f)^2\right]=\mathrm{E}(\varepsilon^2)=\mathrm{V}[\varepsilon]+\mathrm{E}[\varepsilon]^2=\sigma_\varepsilon^2 \tag{14.1.1709}$$

Thus, since ε and $\hat{f}$ are independent, we can write:

$$\begin{aligned}\mathrm{E}\left[(y-\hat{f})^2\right]&=\mathrm{E}\left(y^2+\hat{f}^2-2y\hat{f}\right)=\mathrm{E}(y^2)+\mathrm{E}(\hat{f}^2)-\mathrm{E}(2y\hat{f})\\&=\left(\mathrm{V}(y)+\mathrm{E}(y)^2\right)+\left(\mathrm{V}(\hat{f})+\mathrm{E}(\hat{f})^2\right)-2f\mathrm{E}(\hat{f})\\&=\mathrm{V}(y)+\mathrm{V}(\hat{f})+\left(f^2-2f\mathrm{E}(\hat{f})+\mathrm{E}(\hat{f})^2\right)\\&=\mathrm{V}(y)+\mathrm{V}(\hat{f})+\left(f-\mathrm{E}(\hat{f})\right)^2\\&=\sigma_\varepsilon^2+\mathrm{V}(\hat{f})+\mathrm{Bias}(\hat{f})^2=\text{noise}+\mathrm{V}(\hat{f})+\mathrm{Bias}(\hat{f})^2\end{aligned} \tag{14.1.1710}$$

So we get finally the bias-variance tradeoff relation:

$$\boxed{\mathrm{E}\left[(y-\hat{f})^2\right]=\text{noise}+\mathrm{V}(\hat{f})+\mathrm{Bias}(\hat{f})^2=\sigma_\varepsilon^2+\mathrm{E}\left[\hat{f}(x)^2\right]-\mathrm{E}\left[\hat{f}(x)\right]^2+\mathrm{E}\left[\hat{f}(x)-f(x)\right]} \tag{14.1.1711}$$

That latter is sometimes denoted as following in some textbooks (the letter D denotes the known data):

$$\mathrm{E}_{D,(y_*,x_*)}\left[(y_*-f(x_*\,|\,D))^2\right]=\underbrace{\mathrm{E}_{\varepsilon_*}\left[(y_*-h(x_*))^2\right]}_{\text{noise}}+\underbrace{\mathrm{E}_D\left[(f(x_*\,|\,D)-\mathrm{E}_D[f(x_*\,|\,D)])^2\right]}_{\text{variance}}+\underbrace{(h(x_*)-\mathrm{E}_D[f(x_*\,|\,D)])^2}_{\text{bias}^2} \tag{14.1.1712}$$

■ Q.E.D.

The trade-off between bias and variance is that:

- Simple Models: High Bias, Low Variance (over-fitting)
- Complex Models: Low Bias, High Variance (under-fitting)

We will derive later the bias and variance for the (vanilla) k nearest neighbours clustering but also for the bagging and bootstrap of random forests (when we will introduce these topics!). Let us however see right now as an example how to derive the prediction error for the linear regression!

✍**Example:**

Our goal is first to derive the bias of the ordinary least square regression:

$$f\left(\vec{x}_* \mid D\right) = \vec{x}_*^T \hat{\vec{\theta}}_{\text{MLE}} \tag{14.1.1713}$$

For that we assume obviously the true model to be:

$$h\left(\vec{x}_*\right) = \vec{x}_*^T \vec{\theta} \tag{14.1.1714}$$

Therefore:

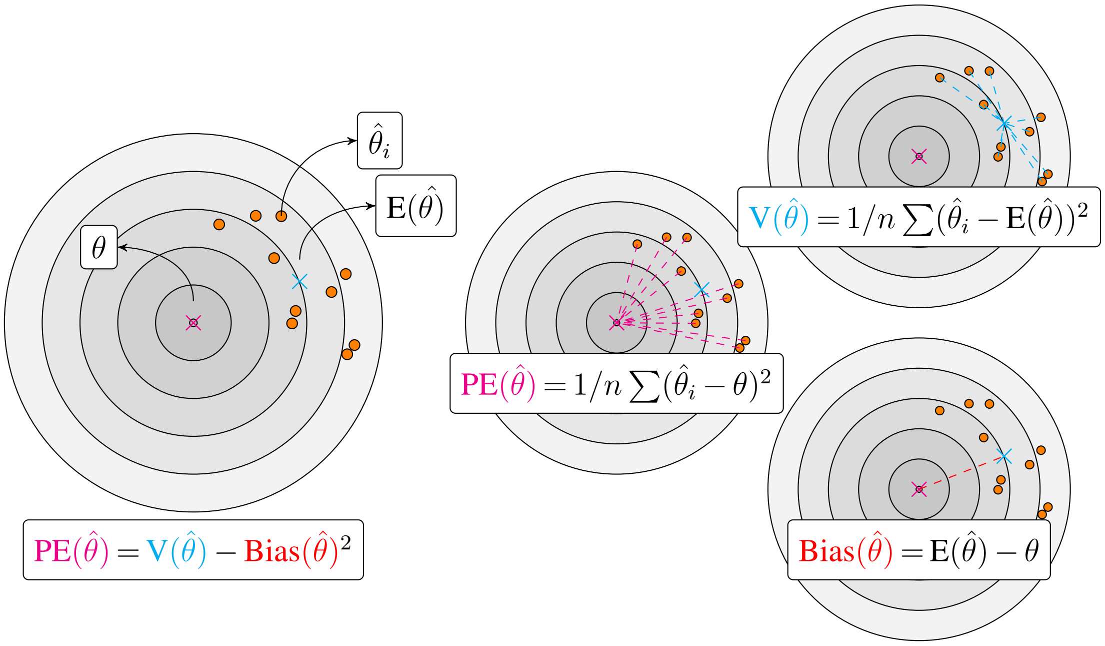
$$\begin{aligned}
\text{Bias} &= h\left(\vec{x}_*\right) - \mathrm{E}_D\left[f\left(\vec{x}_* \mid D\right)\right] = \vec{x}_*^T \vec{\theta} - \mathrm{E}_D\left[\vec{x}_*^T \hat{\vec{\theta}}_{\text{MLE}}\right] = \vec{x}_*^T \vec{\theta} - \mathrm{E}_D\left[\vec{x}_*^T \left(X^T X\right)^{-1} X^T Y\right] \\
&= \vec{x}_*^T \vec{\theta} - \mathrm{E}_D\left[\vec{x}_*^T \left(X^T X\right)^{-1} X^T (X\vec{\theta} + \vec{\varepsilon})\right] \\
&= \vec{x}_*^T \vec{\theta} - \mathrm{E}_D\left[\vec{x}_*^T \left(X^T X\right)^{-1} X^T X \vec{\theta} + \vec{x}_*^T \left(X^T X\right)^{-1} X^T \vec{\varepsilon}\right] \\
&= \vec{x}_*^T \vec{\theta} - \mathrm{E}_D\left[\vec{x}_*^T \vec{\theta} + \vec{x}_*^T \left(X^T X\right)^{-1} X^T \vec{\varepsilon}\right] \\
&= \vec{x}_*^T \vec{\theta} - \vec{x}_*^T \vec{\theta} + \vec{x}_*^T \left(X^T X\right)^{-1} X^T \mathrm{E}_D[\vec{\varepsilon}] = \vec{x}_*^T \vec{\theta} - \vec{x}_*^T \vec{\theta} = 0
\end{aligned} \tag{14.1.1715}$$

Hence $\hat{\theta}_{\text{MLE}}$ is unbiased! Let's compute the variance now:

$$\begin{aligned}
\text{Variance} &= \mathrm{E}\left[\left(f\left(\vec{x}_* \mid D\right) - \mathrm{E}_D\left[f\left(\vec{x}_* \mid D\right)\right]\right)^2\right] = \mathrm{E}\left[\left(\vec{x}_*^T \hat{\vec{\theta}}_{\text{MLE}} - \vec{x}_*^T \vec{\theta}\right)^2\right] \\
&= \mathrm{E}\left[\left(\vec{x}_*^T \left(X^T X\right)^{-1} X^T Y - \vec{x}_*^T \vec{\theta}\right)^2\right] = \mathrm{E}\left[\left(\vec{x}_*^T \left(X^T X\right)^{-1} X^T (X\vec{\theta} + \vec{\varepsilon}) - \vec{x}_*^T \vec{\theta}\right)^2\right] \\
&= \mathrm{E}\left[\left(\vec{x}_*^T \vec{\theta} + x_*^T \left(X^T X\right)^{-1} X^T \vec{\varepsilon} - \vec{x}_*^T \vec{\theta}\right)^2\right] = \mathrm{E}\left[\left(\vec{x}_*^T \left(X^T X\right)^{-1} X^T \vec{\varepsilon}\right)^2\right] \\
&= \mathrm{E}\left[\left(\vec{x}_*^T \left(X^T X\right)^{-1} X^T \vec{\varepsilon}\right)\left(\vec{x}_*^T \left(X^T X\right)^{-1} X^T \vec{\varepsilon}\right)^T\right] \\
&= \mathrm{E}\left[\vec{x}_*^T \left(X^T X\right)^{-1} X^T \vec{\varepsilon}\vec{\varepsilon}^T \left(\vec{x}_*^T \left(X^T X\right)^{-1} X^T\right)^T\right] \\
&= \vec{x}_*^T \left(X^T X\right)^{-1} X^T \mathrm{E}\left[\vec{\varepsilon}\vec{\varepsilon}^T\right] \left(\vec{x}_*^T \left(X^T X\right)^{-1} X^T\right)^T \\
&= \vec{x}_*^T \left(X^T X\right)^{-1} X^T \sigma_\varepsilon^2 I \left(\vec{x}_*^T \left(X^T X\right)^{-1} X^T\right)^T \\
&= \sigma_\varepsilon^2 \vec{x}_*^T \left(X^T X\right)^{-1} X^T X \left(\vec{x}_*^T \left(X^T X\right)^{-1}\right)^T \\
&= \sigma_\varepsilon^2 \vec{x}_*^T \left(\vec{x}_*^T \left(X^T X\right)^{-1}\right)^T = \sigma_\varepsilon^2 \vec{x}_*^T \left(X^T X\right)^{-1} \vec{x}_*
\end{aligned} \tag{14.1.1716}$$

With the above example we see therefore that:

$$\begin{aligned}\text{PE}_{\text{OLS}} &= \underbrace{\text{E}_{\varepsilon_*}\left[(\vec{y}_* - h(\vec{x}_*))^2\right]}_{\text{noise}} + \underbrace{\text{E}_D\left[(f(\vec{x}_* \mid D) - \text{E}_D[f(\vec{x}_* \mid D)])^2\right]}_{\text{variance}} + \underbrace{(h(\vec{x}_*) - \text{E}_D[f(\vec{x}_* \mid D)])^2}_{\text{bias}^2}\\ &= \sigma_\varepsilon^2 + \sigma_\varepsilon^2 \vec{x}_*^T \left(X^TX\right)^{-1} \vec{x}_* + 0 = \sigma_\varepsilon^2\left(1 + \vec{x}_*^T\left(X^TX\right)^{-1}\vec{x}_*\right)\end{aligned} \tag{14.1.1717}$$



$\hat{\theta}_i$
$\text{E}(\hat{\theta})$
θ
$\text{PE}(\hat{\theta}) = \text{V}(\hat{\theta}) - \text{Bias}(\hat{\theta})^2$
$\text{PE}(\hat{\theta}) = 1/n\sum(\hat{\theta}_i - \theta)^2$
$\text{V}(\hat{\theta}) = 1/n\sum(\hat{\theta}_i - \text{E}(\hat{\theta}))^2$
$\text{Bias}(\hat{\theta}) = \text{E}(\hat{\theta}) - \theta$

One case, the Machine Learning algorithm has different parameters and we want to tune these parameters to achieve the best performance (the parameters of the Machine Learning algorithm are named "hyperparameters" as we will see further below[52]). Another case, sometimes we want to try out different algorithms and choose the best performing one. Here is a typical technique:

We simply split the data into training and testing datasets. Then, the training data is further split into training and validation sets.

The training data is used to train different models. Then the validation data is used to compute performance of each of them and we select the best one. Finally, the model is then used for the test set to evaluate performance. The next figure illustrates this idea:

---

[52] The double problem in Data Mining to find the best algorithm + its better hyperparameters is named the "CASH problem", where CASH stands for "Combined Algorithm Selection and Hyperparameters"

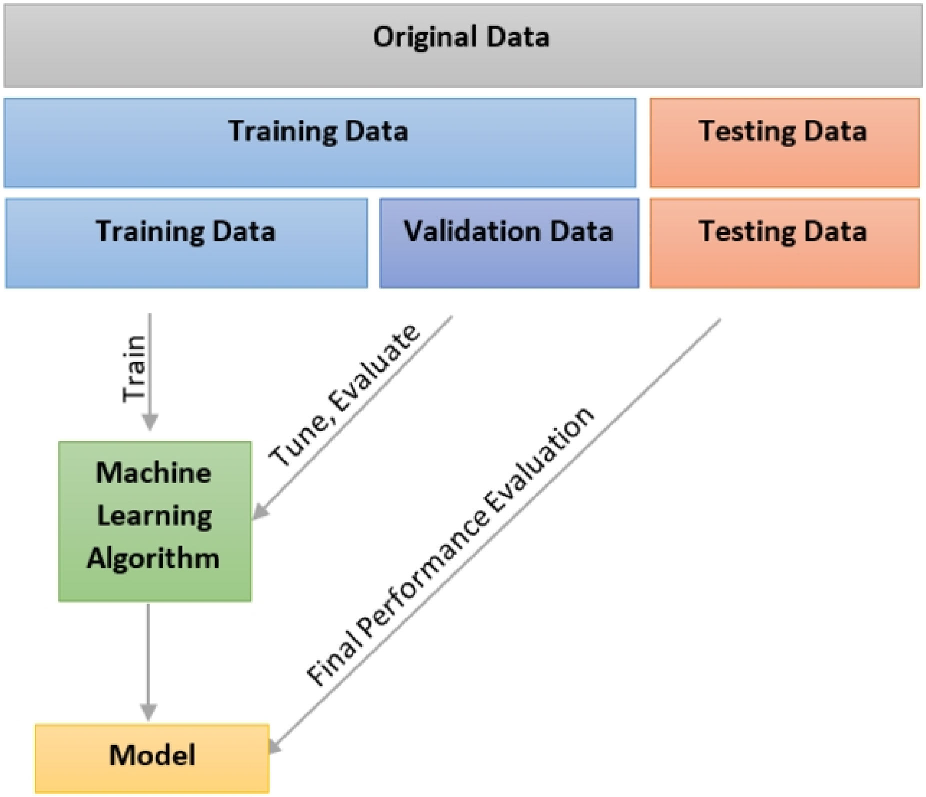


Figure 14.124: Holdout Validation in Machine learning

However, because we use the validation set multiple times, Holdout validation is sensitive to how we partition the data and that is what K-fold cross validation tries to solve.

Initially, we split the data into training and testing dataset. Furthermore, the training dataset is split into K chunks.

Suppose we will use 5-fold cross validation, the training data set is split into 5 chunks and the training phase will take place over 5 iterations. In each iteration we use one chunk as the validation dataset while the rest of the chunk are grouped together to form the training dataset.

This is very similar to Holdout validation except in each iteration the validation data is different and this removed the bias. Each iteration generates a score and the final score is the average score of all iteration. As before we select the best model and use the test data for the final performance evaluation.

It is interesting to know that this practice of splitting data seems to come first form an article of David Freedman [191] published in 11983 according to holocene calendar (hence sometimes the name "Freedman paradox"). Freedman shows in an impressive way the dangers of data reuse in statistical analysis. The potentially dangerous scenarios include those where the results of one statistical procedure performed on the data are fed into another procedure performed on the same data. As a concrete example Freedman considers the practice of performing variable selection first, and then fitting another model using only the identified variables on the same data that was used to identify them in the first place.

The figure below shows the distributions of the considered model statistics (variable selection and afterwards a regression) by David Freedman across the 1000 repetitions for model fits with and without data reuse (the code producing this figure is given at the bottom of this post):

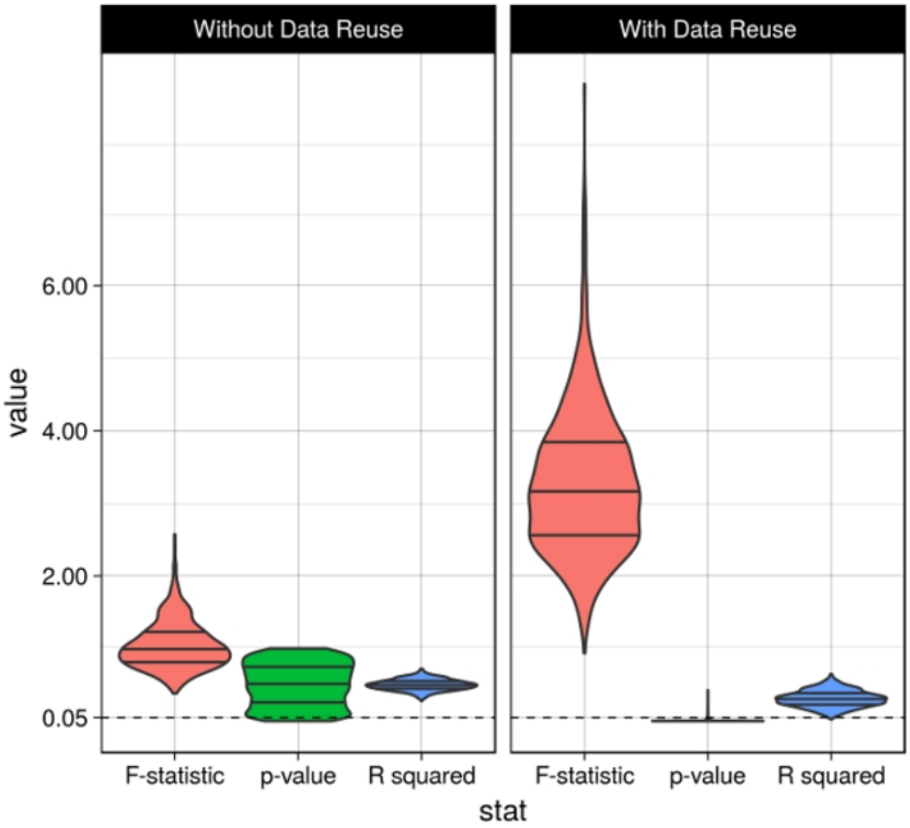

Figure 14.125: **Freedman paradox illustration**

Well, the R squared statistic shows a moderate change between models with or without data reuse (average of 0.3093018 vs. 0.5001641). The F test statistic however grows immensely to an average of 3.2806118 (from 1.0480097), and the p-values fall after data reuse to an average of 0.0112216 (from 0.5017696), below the widely used (but arbitrary) 5% significance level.

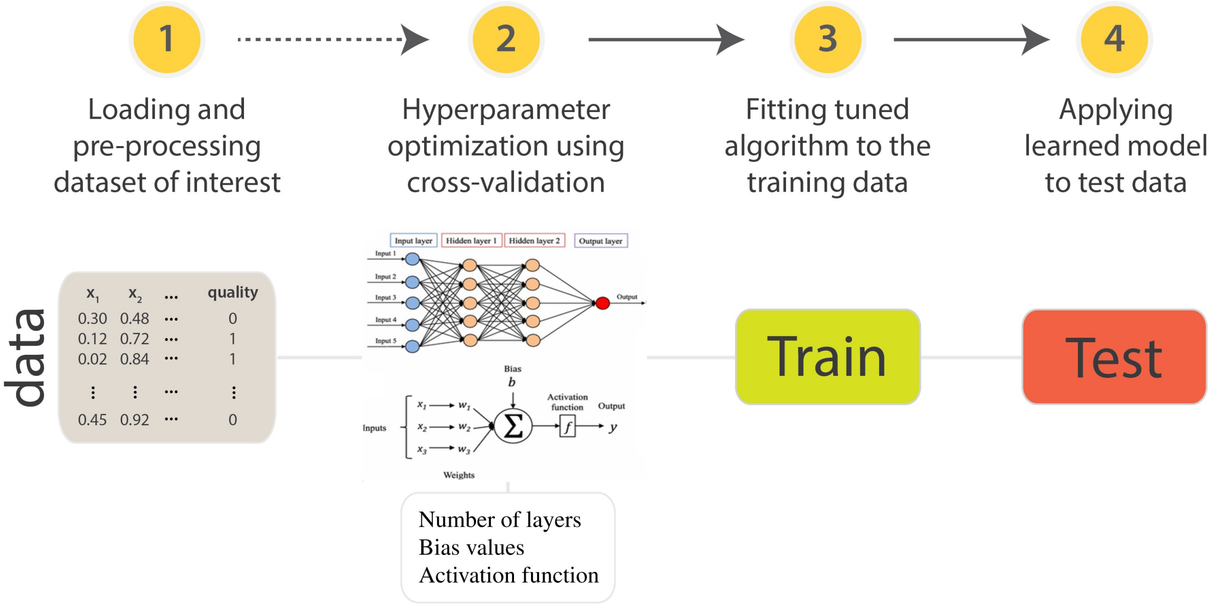
Obviously the model with data reuse is highly misleading here, because in fact there are absolutely no relationships between the predictor variables and the response (as per the data generation procedure).

OK! This done let us now begin first with the basics of clustering methods!

14.1.20.2 Hyperparameters vs Parameters

You may have heard of terms like "hyperparameter" search, autotuning (which is just a shorter way of saying hyperparameter search), or grid search (a possible method for hyperparameter search). Where do those terms fit in? To understand hyperparameter search, we have to talk about the difference between a model parameter and a hyperparameter. In brief, model parameters are the knobs that the training algorithm knows how to tweak; they are learned from data. Hyperparameters, on the other hand, are not learned by the training method, but they also need to be tuned.

A famous example are neural networks (see further below) where weights and bias are autotuned parameters, but the number of layers, the type of activation function of the bias values are hyperparameters:



1
Loading and pre-processing dataset of interest
2
Hyperparameter optimization using cross-validation

Figure 14.126: **Parameters vs Hyperparameters**

"Bagging" and "Boosting" are both ensemble methods in Machine Learning that also use hyperparameters (number of iterations/trees, sampling with or without replacement, minimum leaf size, minim parent size, maximum number of decision splits, learning rate for shrinkage, etc).

Bagging and Boosting are similar in that they are both ensemble techniques, where a set of weak learners are combined to create a strong learner that obtains better performance than a single one. So, let's start from the beginning[53].

"Ensemble learning" is a Machine Learning concept in which the idea is to train multiple models using the same learning algorithm. The ensembles take part in a bigger group of methods, named "multiclassifiers", where a set of hundreds or thousands of learners with a common objective are fused together to solve the problem.

---

[53] The whole text introducing the difference between bagging and boosting in this textbook is taken form the QuantDare blog article `https://quantdare.com/what-is-the-difference-between-bagging-and-boosting/` written by Ana Porras Garrido who works for the company ETS Asset Management Factory (`https://www.etsfactory.com/`)

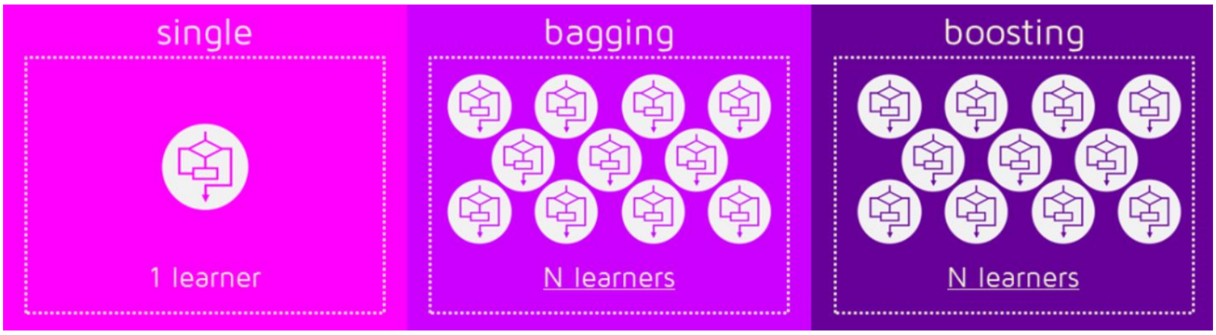
The second group of multiclassifiers contain the "hybrid methods ". They use a set of learners too, but they can be trained using different learning techniques.

The main causes of error in learning are due to noise, bias and variance. Ensemble helps to minimize these factors. These methods are designed to improve the stability and the accuracy of Machine Learning algorithms. Combinations of multiple classifiers decrease variance, especially in the case of unstable classifiers, and may produce a more reliable classification than a single classifier.

To use Bagging or Boosting you must select a base learner algorithm. For example, if we choose a classification tree, Bagging and Boosting would consist of a pool of trees as big as we want.

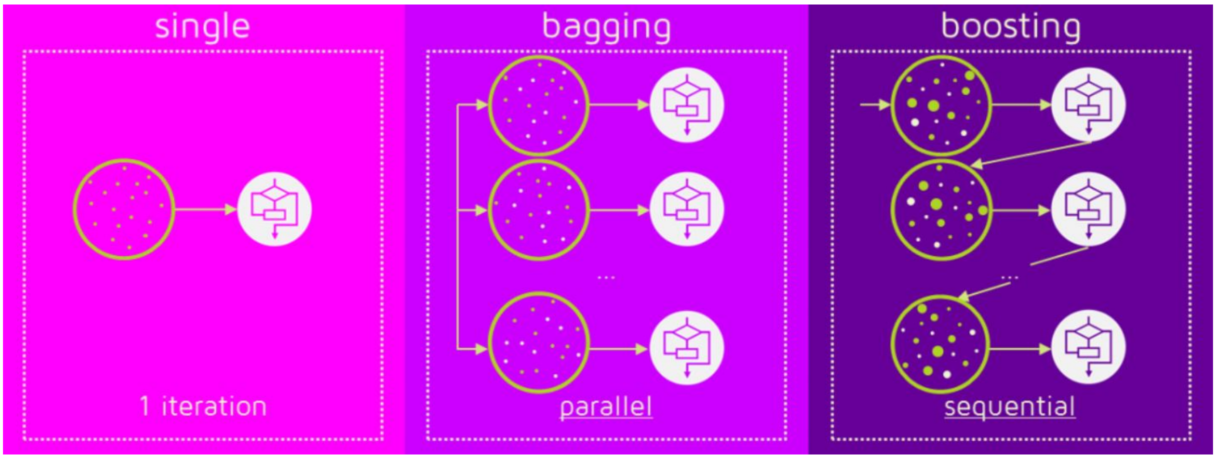
Bagging and Boosting get N learners by generating additional data in the training stage. N new training data sets are produced by random sampling with replacement from the original set. By sampling with replacement some observations may be repeated in each new training data set.

In the case of Bagging, any element has the same probability to appear in a new data set. However, for Boosting the observations are weighted and therefore some of them will take part in the new sets more often:



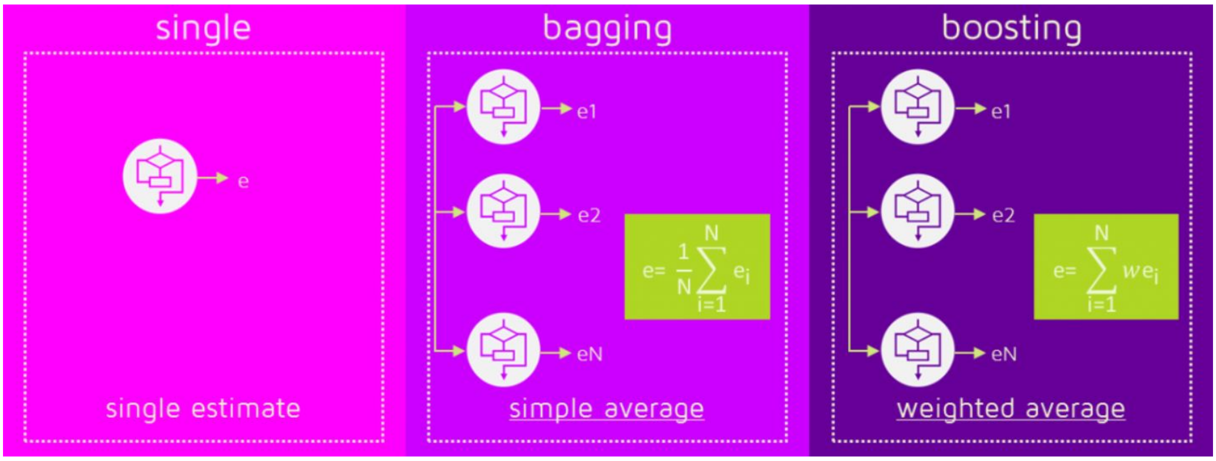
These multiple sets are used to train the same learner algorithm and therefore different classifiers are produced.

At this point, we begin to deal with the main difference between the two methods. While the training stage is parallel for Bagging (i.e., each model is built independently), Boosting builds the new learner in a sequential way:



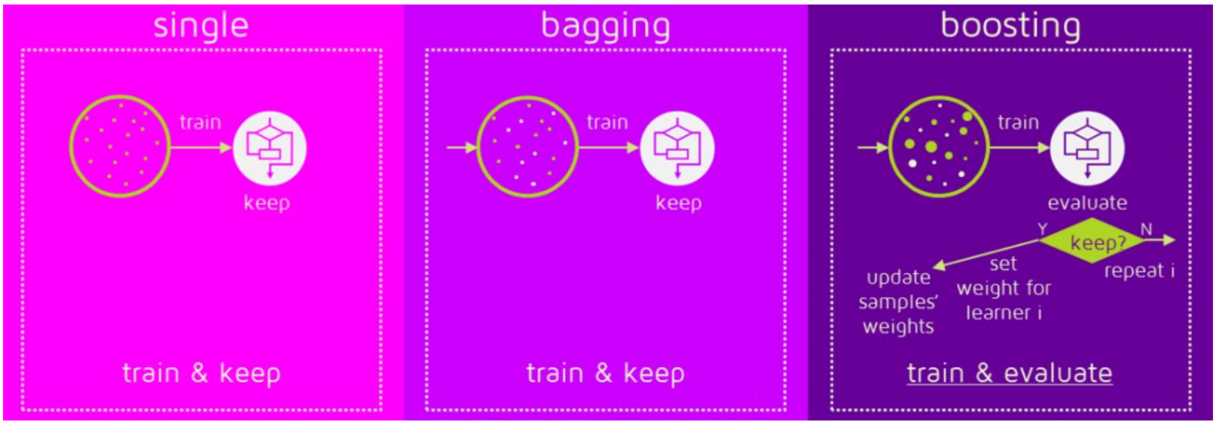
single
1 iteration
bagging
...
parallel
boosting
...
sequential

To predict the class of new data we only need to apply the N learners to the new observations. In Bagging the result is obtained by averaging the responses of the N learners (or majority vote). However, Boosting assigns a second set of weights, this time for the N classifiers, in order to take a weighted average of their estimates.



single
e
single estimate
bagging
e1
e2
eN
$e=\frac{1}{N}\sum_{i=1}^{N} e_i$
simple average
boosting
e1
e2
eN
$e=\sum_{i=1}^{N} we_i$
weighted average

In the Boosting training stage, the algorithm allocates weights to each resulting model. A learner with good a classification result on the training data will be assigned a higher weight than a poor one. So when evaluating a new learner, Boosting needs to keep track of learners' errors, too. Let's see the differences in the procedures:



single
train
keep
train & keep
bagging
train
keep
train & keep
boosting
train
evaluate
keep?
Y
N
repeat i
set weight for learner i
update samples' weights
train & evaluate

Some of the Boosting techniques include an extra-condition (hyperparamater) to keep or discard a single learner. For example, in AdaBoost, the most renowned, an error less than 50% is required to maintain the model; otherwise, the iteration is repeated until achieving a learner better than a random guess.

The previous image shows the general process of a Boosting method, but several alternatives exist with different ways to determine the weights to use in the next training step and in the classification stage (AdaBoost, LPBoost, XGBoost, GradientBoost, BrownBoost).

We may ask ourselves what is the best, Bagging or Boosting?

There's not an outright winner; it depends on the data, the simulation and the circumstances. Bagging and Boosting decrease the variance of your single estimate as they combine several estimates from different models. So the result may be a model with higher stability.

Indeed, let us recall that the bias-variance tradeoff relation that we have derived at page 6798:

$$\text{PE}=\text{noise}+\text{V}(\hat{f})+\text{Bias}(\hat{f})^2=\sigma_\varepsilon^2+\text{E}\left[\hat{f}(x)^2\right]-\text{E}\left[\hat{f}(x)\right]^2+\text{E}\left[\hat{f}(x)-f(x)\right] \quad (14.1.1718)$$

As bagging consist to average the different models, we know that averaging reduces the variance according:

$$\text{V}(\bar{X})=\frac{\text{V}(X)}{n} \quad (14.1.1719)$$

So bagging B times leads to:

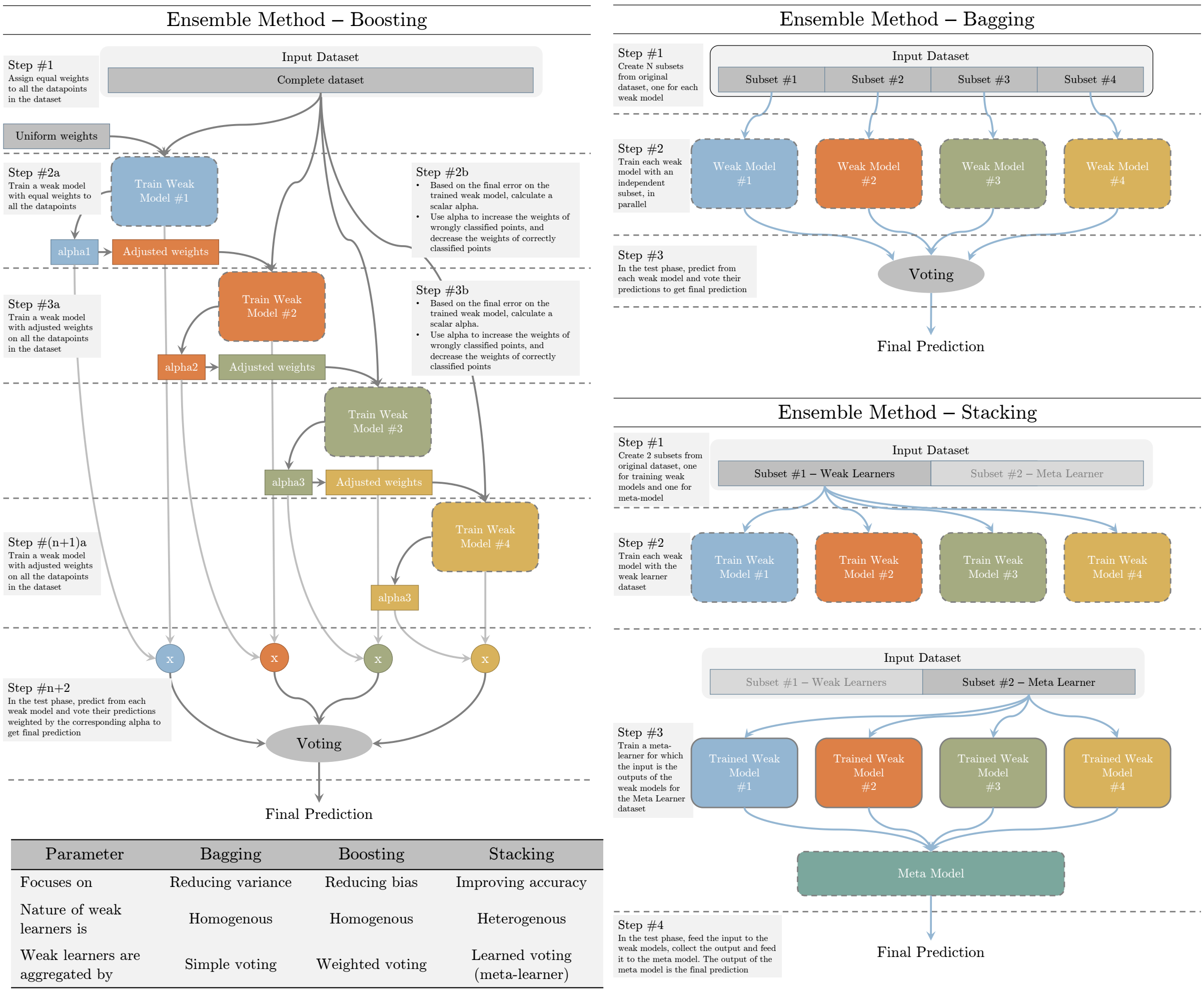
$$\text{PE}_{\text{bagging}}=\text{noise}+\frac{\text{V}(\hat{f})}{B}+\text{Bias}(\hat{f})^2 \quad (14.1.1720)$$

As we know decreasing the variance therefore increase the bias (as the sum of the both must always be equal). In practice the bagging models are correlated, and as we know it, correlation makes variance even smaller!

If the problem is that the single model gets a very low performance, Bagging will rarely get a better bias. However, Boosting could generate a combined model with lower errors as it optimises the advantages and reduces pitfalls of the single model.

By contrast, if the difficulty of the single model is over-fitting, then Bagging is the best option. Boosting for its part doesn't help to avoid over-fitting; in fact, this technique is faced with this problem itself. For this reason, Bagging is effective more often than Boosting.

Here is a very nice summary of the most three common ensemble learning method in one picture:



Ensemble Method – Boosting

Ensemble Method – Boosting

Step #1
Assign equal weights to all the datapoints in the dataset

Step #2a
Train a weak model with equal weights to all the datapoints

Step #2b
- Based on the final error on the trained weak model, calculate a scalar alpha.
- Use alpha to increase the weights of wrongly classified points, and decrease the weights of correctly classified points

Step #3a
Train a weak model with adjusted weights on all the datapoints in the dataset

Step #3b
- Based on the final error on the trained weak model, calculate a scalar alpha.
- Use alpha to increase the weights of wrongly classified points, and decrease the weights of correctly classified points

Step #(n+1)a
Train a weak model with adjusted weights on all the datapoints in the dataset

Step #n+2
In the test phase, predict from each weak model and vote their predictions weighted by the corresponding alpha to get final prediction

Ensemble Method – Bagging

Step #1
Create N subsets from original dataset, one for each weak model

Step #2
Train each weak model with an independent subset, in parallel

Step #3
In the test phase, predict from each weak model and vote their predictions to get final prediction

Ensemble Method – Stacking

Step #1
Create 2 subsets from original dataset, one for training weak models and one for meta-model

Step #2
Train each weak model with the weak learner dataset

Step #3
Train a meta-learner for which the input is the outputs of the weak models for the Meta Learner dataset

Step #4
In the test phase, feed the input to the weak models, collect the output and feed it to the meta model. The output of the meta model is the final prediction

Parameter	Bagging	Boosting	Stacking
Focuses on	Reducing variance	Reducing bias	Improving accuracy
Nature of weak learners is	Homogenous	Homogenous	Heterogenous
Weak learners are aggregated by	Simple voting	Weighted voting	Learned voting (meta-learner)

Figure 14.127: Three most common ensemble learning methods (source: https://www.cheatsheets.aqeel-anwar.com, author: Aqeel Anwar)

14.1.20.3 Association Rules

A classic story tells about the increase in beer sales after a store decided to place the beer next to the diapers. What is the relationship between baby diapers and beers? We would be wondering...

Several explanations follow to understand this observation, but that's about the purchases made by the male parents. The latter, when they go to take diapers profit to buy a few beers. This little anecdote actually reveals the existence of a rule of association between these two products which at first sight have nothing in common.

Association rule learning is a unsupervised rule-based Machine Learning method for discovering interesting relations between variables in large databases. It is intended to identify strong rules discovered in databases using some measures of interestingness.

For example, the rule $\{\text{diapeer}\}\Rightarrow\{\text{beer}\}$ or $\{\text{onions},\text{potatoes}\}\Rightarrow\{\text{burger}\}$ found in the sales data of a supermarket would indicate that if a customer buys onions and potatoes together, they are likely to also buy hamburger meat. Such information can be used as the basis for decisions about marketing activities such as, e.g., promotional pricing or product placements. In addition to the above example from "market basket analysis" association rules are employed today in many application areas including Web usage mining, intrusion detection, continuous production, and bioinformatics. In contrast with sequence mining, association rule learning typically does not consider the order of items either within a transaction or across transactions.

Here are some possible questions that association rules can answer:

- Which products tend to be purchased together?
- Of those customers who are similar to this person, what products do they tend to buy?
- Of those customers who have purchased this product, what other similar products do they tend to view or purchase?

Some well-known algorithms are OneR (OneRule), Apriori, ECLAT (Equivalence Class Transformation) and FP-Growth (first pass), but they only do half the job, since they are algorithms for mining frequent itemsets. Another step needs to be done after to generate rules from frequent itemsets found in a database.

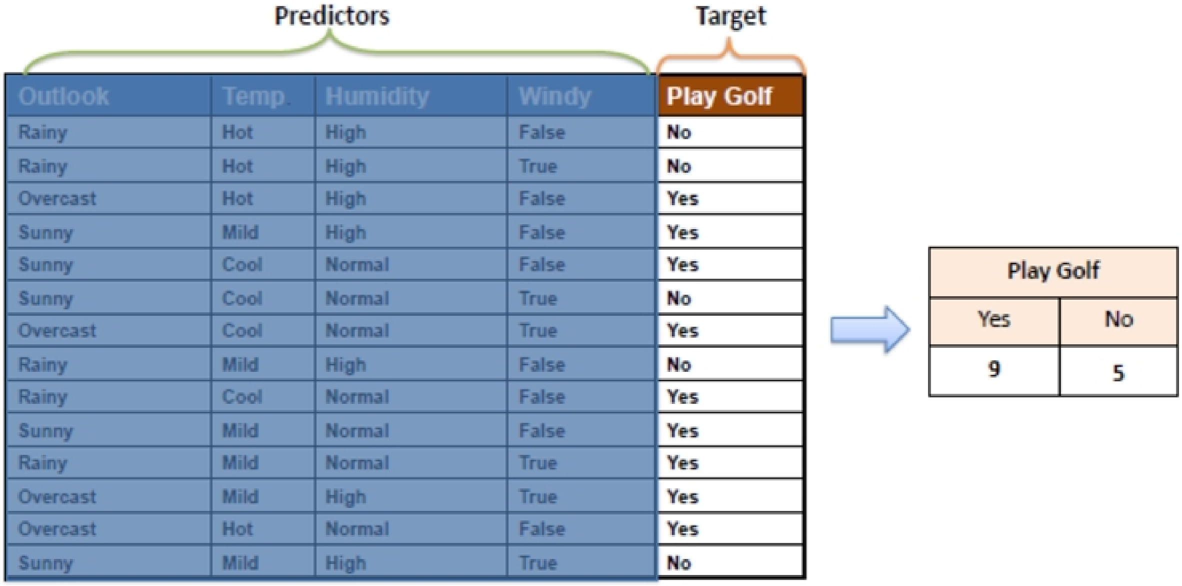
14.1.20.3.1 ZeroR

"ZeroR", short for "Zero Rule", is the simplest supervised classification method which relies on the target and ignores all predictors. ZeroR classifier simply predicts the majority category (class). Although there is no predictability power in ZeroR, it is useful for determining a baseline performance as a benchmark for other classification methods.

A nice story about ZeroR algorithm is that we use it unconsciously everyday when our brain chooses the most frequent seen item as the most probable event (ZeroR classification) or when we talk about averages (ZeroR Regression).

The ZeroR algorithm is (it's not a joke!): Construct a frequency table for the target and select its most frequent value.

The "$Play\ Golf = Yes$" in the example below[54] is the ZeroR rule for the learning table (14 rows) with an accuracy of $9/14 \cong 0.64$.



Predictors
Target

Outlook	Temp.	Humidity	Windy	Play Golf
Rainy	Hot	High	False	No
Rainy	Hot	High	True	No
Overcast	Hot	High	False	Yes
Sunny	Mild	High	False	Yes
Sunny	Cool	Normal	False	Yes
Sunny	Cool	Normal	True	No
Overcast	Cool	Normal	True	Yes
Rainy	Mild	High	False	No
Rainy	Cool	Normal	False	Yes
Sunny	Mild	Normal	False	Yes
Rainy	Mild	Normal	True	Yes
Overcast	Mild	High	True	Yes
Overcast	Hot	Normal	False	Yes
Sunny	Mild	High	True	No

Play Golf	
Yes	No
9	5

Figure 14.128: **ZeroR Data Mining (association rule) example**

There is nothing to be said about the predictors contribution to the model because ZeroR does not use any of them.

The following confusion matrix C (more complete than the one we have introduce during our study of the binomial logistic regression):

---

[54] Thanks to Dr. Saed Sayad for having authorized us to reproduce its web page: `http://www.saedsayad.com/zeror.htm`

Confusion matrix		**Play Golf**			
		Yes	No		
ZeroR	Yes	a	b	Positive Predictive Value	$\frac{a}{a+b}$
	No	c	d	Negative Predictive Value	$\frac{d}{c+d}$
		Sensitivity $\frac{a}{a+c}$	Specificity $\frac{d}{b+d}$	**Accuracy** $=\frac{a+d}{a+b+c+d}$	

Table 14.25: **Full Confusion matrix example**

gives in the case of our example:

Confusion matrix		**Play Golf**			
		Yes	No		
ZeroR	Yes	9	5	Positive Predictive Value	0.64
	No	0	0	Negative Predictive Value	0.00
		Sensitivity 1.00	Specificity 0.00	**Accuracy** =0.65	

that ZeroR only predicts the majority class correctly. As mentioned before, ZeroR is only useful for determining a baseline performance for other classification methods.

14.1.20.3.2 OneR (classification by induction)

"OneR", short for "One Rule", is a simple, yet accurate, classification algorithm that generates one rule for each predictor in the data, then selects the rule with the smallest total error as its "one rule". To create a rule for a predictor p_i among the set of all predictor $\mathbb{P}$, we construct a frequency table for each predictor against each possible value t_i of the target attribute set $\mathbb{T}$.

The OneR algorithm is the following[55]:

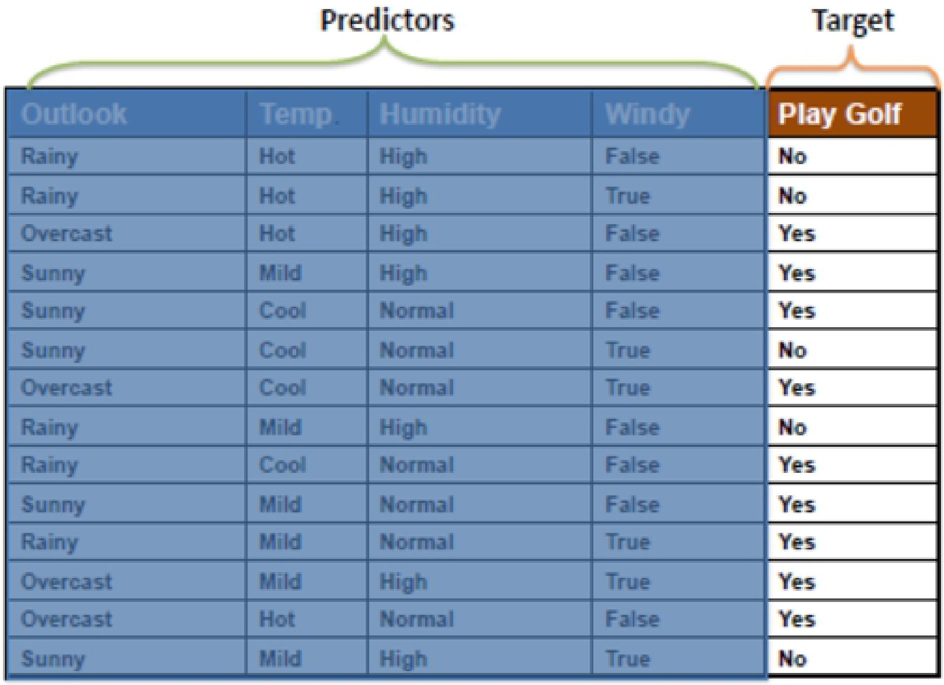
Algorithm 15: OneR (one-Rule) algorithm

```
Data: $p_i$ $a_{i,j}$,$r$, $T$
Result: $\min\{(p_i,\varepsilon_i\}$
initialization;
foreach predictor $p_i \in \mathcal{P}$ do
    foreach attribute value $a_{i,j}$ in $p_i$ do
        Count how often each value of target (class) $t_k \in \mathcal{T}$ appears in all rows $r$ for $p_i$;
        Find the most frequent class $t_k$ for $a_{i,j}$ ;
        Make the rule assign that class to this value of the predictor;
    Calculate the total error of the rules of each predictor $\varepsilon_i$
```

---

[55] Thanks again to Dr. Saed Sayad for having authorized us to reproduce its web page: `http://www.saedsayad.com/oner.htm`

As companion example let us consider again the following learning table (14 rows):



Predictors
Target

Outlook	Temp.	Humidity	Windy	Play Golf
Rainy	Hot	High	False	No
Rainy	Hot	High	True	No
Overcast	Hot	High	False	Yes
Sunny	Mild	High	False	Yes
Sunny	Cool	Normal	False	Yes
Sunny	Cool	Normal	True	No
Overcast	Cool	Normal	True	Yes
Rainy	Mild	High	False	No
Rainy	Cool	Normal	False	Yes
Sunny	Mild	Normal	False	Yes
Rainy	Mild	Normal	True	Yes
Overcast	Mild	High	True	Yes
Overcast	Hot	Normal	False	Yes
Sunny	Mild	High	True	No

Figure 14.129: **OneR Data Mining (association rule) example**

Now we create the following frequency tables for each predictor and each attribute inside each predictor:

		Play Golf	
		Yes	*No*
Outlook	*Sunny*	3	2
	Overcast	4	0
	Rainy	2	3

		Play Golf	
		Yes	*No*
Temperature	*Hot*	2	2
	Mild	4	2
	Cold	3	1

		Play Golf	
		Yes	*No*
Humidity	*High*	3	4
	Normal	6	1

		Play Golf	
		Yes	*No*
Windy	*False*	6	2
	True	3	3

Now according to the algorithm, for each predictor we keep only the attribute that has the biggest frequency (in red below[56]):

		Play Golf	
		Yes	*No*
Outlook	*Sunny*	3	2
	Overcast	4	0
	Rainy	2	3

		Play Golf	
		Yes	*No*
Temperature	*Hot*	2	2
	Mild	4	2
	Cold	3	1

		Play Golf	
		Yes	*No*
Humidity	*High*	3	4
	Normal	6	1

		Play Golf	
		Yes	*No*
Windy	*False*	6	2
	True	3	3

This means that so far we would have the rules:

- For *Outlook*:

```
IF Outlook = Sunny THEN Play Golf = Yes
IF Outlook = Overcast THEN Play Golf = Yes
IF Outlook = Rainy THEN Play Golf = No
```

- For *Temperature*:

```
IF Temperature = Hot THEN Play Golf = Yes
IF Temperature = Mild THEN Play Golf = Yes
IF Temperature = Cool THEN Play Golf = Yes
```

- For *Humidity*:

```
IF Humidity = High THEN Play Golf = No
IF Humidity = Normal THEN Play Golf = Yes
```

---

[56] We can notice that in case of equality we take the target that occurs the more for the other attributes.

- For *Windy*:

```
IF Windy = False THEN Play Golf = Yes
IF Windy = True THEN Play Golf = Yes
```

Now if we count for each attribute according to the above rules the number of error of wrongly (false) classified items, we get:

- For *Outlook*: 4 wrongly classified items (10 well classified)
- For *Temperature*: 5 wrongly classified items (9 well classified)
- For *Humidity*: 4 wrongly classified items (10 well classified)
- For *Windy*: 5 wrongly classified items (9 well classified)

We see that only like this it is quite not easy to select the best rule. Therefore a possible solution is to use again a confusion matrix $\mathcal{C}$ for each attribute:

Confusion matrix		**Play Golf** Yes	 No		
OneR	Yes	a	b	Positive Predictive Value	$\frac{a}{a+b}$
	No	c	d	Negative Predictive Value	$\frac{d}{c+d}$
		Sensitivity $\frac{a}{a+c}$	Specificity $\frac{d}{b+d}$	**Accuracy =** $\frac{a+d}{a+b+c+d}$	

Therefore after building all the confusion matrices we notice that the one with the best accuracy if for the *Outlook* attribute:

Confusion matrix		**Play Golf** Yes	 No		
OneR	Yes	7	2	Positive Predictive Value	0.78
	No	2	3	Negative Predictive Value	0.60
		Sensitivity 0.78	Specificity 0.60	**Accuracy =**0.71	

Hence the final chosen association rule:

```
IF Outlook = Sunny THEN Play Golf = Yes
IF Outlook = Overcast THEN Play Golf = Yes
IF Outlook = Rainy THEN Play Golf = No
```

ToDo: Create the confusion matrices for the other attributes

14.1.20.3.3 Apriori

Before introducing the Apriori algorithm which is the second most popular algorithm of the Association Rules, it is important to define some key concepts specific to these particular methods of learning.

Here are some vocabulary definitions:

- A "transaction" is a basket or cart of one or more items purchased by consumers.

✍**Example:**

Here is a base of five transactions or baskets:

Transaction Number	Basket composition			
1	bread	juice	jam	sugar
2	milk	bread	sugar	
3	cheese	bread	butter	milk
4	cheese	milk	sugar	flour
5	chips	bread	jam	yoghurt

- An "item" designates an article. Example: juice, bread, milk ...
- An "itemset" is a collection of items or articles. A itemset containing k items or a "k-itemset" is written between brackets $\{\text{item}\,1, \text{item}\,2, \text{item}\,3, \ldots, \text{item}\,k\}$.

✍**Examples:**

- 1-itemset: $\{\text{milk}\}$ or $\{\text{bread}\}$
- 2-itemset: $\{\text{milk}, \text{bread}\}$ or $\{\text{bread}, \text{butter}\}$
- 3-itemset: $\{\text{bread}, \text{butter}, \text{sugar}\}$
- ...

- Given a k-itemset P, the "support" of P, is the percentage of transactions containing P. This is an index of reliability.

✍**Examples:**

E1. For $S=\{\text{bread},\text{milk}\}$ then the support according to the previous set of baskets is equal to $P=2/5=0.4$, hence 40%:

Transaction Number	Basket composition			
1	bread	juice	jam	sugar
2	milk	bread	sugar	
3	cheese	bread	butter	milk
4	cheese	milk	sugar	flour
5	chips	bread	jam	yoghurt

E2. For $L=\{\text{bread}\}$ then the support of L is $P=4/5=0.8$, hence 80% of the transactions contains L:

Transaction Number	Basket composition			
1	bread	juice	jam	sugar
2	milk	bread	sugar	
3	cheese	bread	butter	milk
4	cheese	milk	sugar	flour
5	chips	bread	jam	yoghurt

- The "minimum support" is the minimum threshold of from which one qualifies a k-itemset as frequent.
- One will say of a itemset that it is a "frequent k-itemset" if its support is greater or equal to the minimum support.

✍**Examples:**

If the minimum support is 0.5, we can say that L, from the previous example, is a frequent itemset but not S whose support is only 0.4.

"Apriori" is an algorithm that was proposed by Agrawal and Srikant in 11994 (holocene calendar) for frequent item set mining and association rule learning over transactional databases. It proceeds by identifying the frequent individual items in the database and extending them to larger and larger item sets as long as those item sets appear sufficiently often in the database. The frequent item sets determined by Apriori can be used to determine association rules which highlight general trends in the database: this has applications in domains such as market basket analysis.

The "a priori" algorithm is based on the so-named a priori property which is stated as follows: *«If one itemset is considered as frequent then any other sub itemset arising from the items of P is also frequent».*

Taking again the following table as companion example:

Transaction Number	**Basket composition**			
1	bread	juice	jam	sugar
2	milk	bread	sugar	
3	cheese	bread	butter	milk
4	cheese	milk	sugar	flour
5	chips	bread	jam	yoghurt

By setting the minimum support to P_{min} to 0.35, the previous itemset $S=\{\text{bread},\text{milk}\}$ with a support of 0.4 is therefore referred to as frequent. The previous itemset $L=\{\text{bread}\}$ is a sub-item of $L\subset S$, it is according to the apriori property also frequent (support of $L=0.8>0.35$) and if one considers another new sub-itemset $D=\{\text{milk}\}$ of S, one sees that the support the 1-itemset of D is $3/5=0.6>0.35$.

If we have n different items, then we have 2^n-1 possible different itemsets (the -1 is to remove the empty itemset). Therefore in our case, we could create $2^{10}-1=1023$ different possible itemsets with:

$$\{\text{bread},\text{juice},\text{jam},\text{sugar},\text{milk},\text{cheese},\text{butter},\text{flour},\text{chips},\text{yogourt}\} \tag{14.1.1721}$$

Thus, the number of itemsets to be analysed can be considerably reduced following the pruning of low-level non-frequent itemsets.

Given a minimal support that we will denote δ, the Apriori algorithm adopts an ascending iterative approach that determines all possible 1-itemset first and then those whose support is less than δ are subject to pruning and the rest, those that are frequent are stored in an L_1 itemset collections.

For the 5 transactions of the previous illustration in the 10 possible itemsets of type 1-itemset, for a minimum support of $\delta=0.35$, only the following itemsets will be part of L_1:

1-itemset	**Support**
$\{\text{bread}\}$	0.8
$\{\text{sugar}\}$	0.6
$\{\text{milk}\}$	0.6
$\{\text{jam}\}$	0.4
$\{\text{cheese}\}$	0.4

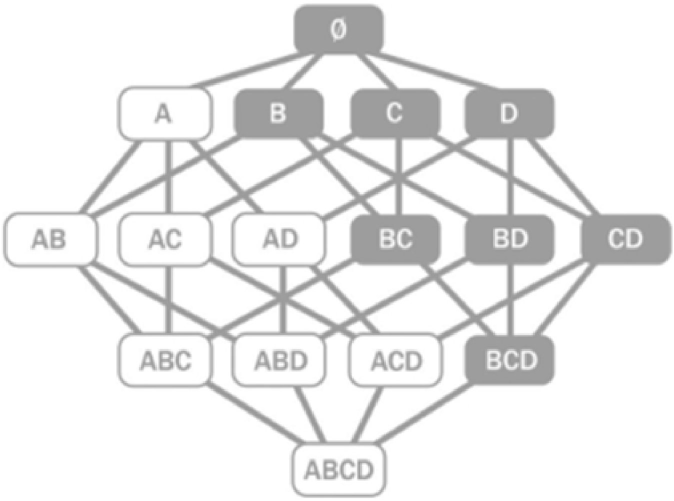
The next step consists of all possible 2-itemsets from the items contained in L_1. Again the 2-itemsets are tested, those whose support is less than δ are pruned and only the frequent 2-itemsets are kept in a collection of L_2 itemsets.

On the basis of the L_1 previously constituted, it is always possible with $\delta=0.35$ to obtain a collection L_2 consisting of:

2-itemset	**Support**
$\{\text{jam, bread}\}$	0.4
$\{\text{cheese, milk}\}$	0.6
$\{\text{sugar, milk}\}$	0.6
$\{\text{bread, sugar}\}$	0.4
$\{\text{milk, bread}\}$	0.4

This aggregation and pruning process is repeated for a collection L_k containing the possible itemsets of k-itemsets having validated the test of the minimum support δ.

So figuring the concept with transactions of a maximum of 4-itemsets $\{\mathrm{A},\mathrm{B},\mathrm{C},\mathrm{D}\}$ then with a total of $2^4-1=15$ possible combinations, this procedure would lead for example to:



The algorithm stops if for a new collection L_{k+1}, no $(k+1)$-itemsets validates the test of the minimum support δ (as is the case for the previous figure where one can not obtain 3-itemsets on the basis of L_2). Optionally, we can define an integer K which specifies either the maximum number of items that an itemset can contain or the maximum number of iterations to be performed by the algorithm.

Once the collections of itemsets are formed, it is possible to transcribe this in the form of candidate rules (for example $X\Rightarrow Y$ or: X implies Y). However, some criteria are defined to assess the relevance of an association rule:

- "Confidence" or "trust of a rule": It's the measure of certainty or confidence associated with an association rule. Formally, for a rule $X\Rightarrow Y$, it is the percentage of transaction containing both X and Y on the total of transactions containing X:

$$\text{Conf}(X\Rightarrow Y)=\frac{\text{Support}(X\cap Y)}{\text{Support}(X)}=\frac{S(X\cap Y)}{S(X)} \tag{14.1.1722}$$

✍**Example:**

What is the confidence index of the rule:

$$\{\text{milk},\text{sugar}\}\Rightarrow\text{flour}$$

As:

$$\text{Support}(\text{milk},\text{sugar})=0.4$$

and:

$$\text{Support}(\text{farine},\text{milk},\text{sugar})=0.2$$

Then:

$$\text{Conf}(\{\text{milk},\text{sugar}\}\Rightarrow\text{flour})=\frac{\{\text{milk},\text{sugar}\}}{\text{flour}}=\frac{0.2}{0.4}=0.5$$

thus a confidence index of 50%.

In practice, an acceptable threshold of confidence is defined. We are confident with regard to a rule when the index of confidence is large and moves away from the minimum.

- "Lift of an association rule": Assuming that X and Y are statistically independent (see section Probabilities page 480), the lift measures the percentage of the number of times it is more frequent to obtain X and Y:

$$\text{Lift}(X\Rightarrow Y)=\frac{\text{Support}(X\cap Y)}{\text{Support}(X)\cdot\text{Support}(Y)}=\frac{S(X\cap Y)}{S(X)\cdot S(Y)}\tag{14.1.1723}$$

Thus, if the lift is equal to 1 then X and Y are independent, which means that the rule is not at all relevant: a simple coincidence! While a lift greater than 1, shows how useful the rule is and a higher value shows how strong the rule is and therefore relevant, it is then a kind of correlation measure. A lift smaller than 1 indicates that X and Y appear less often together than expected, this means that the occurrence of X has a negative effect on the occurrence of Y or that X is negatively correlated with Y. Thus, lift is a value between 0 and $+\infty$.

Remark

We could also run (obviously) a complementary χ^2-test of independence of a 2×2 contingency table (having for entries X, Y, $\neg X$, $\neg Y$) to test if there is statistically or not independence (see section Statistics page 1238).

✍**Example:**

What is the lift of the rule:

$$\{\text{milk},\text{sugar}\}\Rightarrow\{\text{flour}\}$$

As:

$$\text{Support}(\{\text{milk}, \text{sugar}\}) = 0.4$$

and:

$$\text{Support}(\{\text{flour}, \text{milk}, \text{sugar}\}) = 0.2$$

and:

$$\text{Support}(\{\text{flour}\}) = 0.2$$

Then:

$$\text{Lift}(\{\text{milk}, \text{sugar}\} \Rightarrow \{\text{flour}\}) = \frac{\{\text{flour}, \text{milk}, \text{sugar}\}}{\{\text{milk}, \text{sugar}\} \cdot \{\text{flour}\}} = \frac{0.2}{0.4 \cdot 0.2} = 2.5$$

Of course, it is always necessary to compare these results with the values obtained with the other association rules before judging the relevance.

Lift and χ^2 are not "null-invariant". That means that they are not so good at evaluating data that contain too many null transactions.

We limited ourselves here to the two most widely used criteria for evaluating association rules, but there are other criteria (some of them are null-invariant) such as Leverage, Conviction index, Coverage, Jaccard, Cosine, Kulcynski, etc.

Measure	Definition	Range	Null-Invariant
$\chi^2(X,Y)$	$\displaystyle\sum_{i,j} \frac{(O_{ij}-E_{ij})^2}{E_{ij}}$	$[0,+\infty[$	No
$\text{Lift}(X,Y)$	$\dfrac{S(X\cap Y)}{S(X)\cdot S(Y)}$	$[0,+\infty[$	No
$\text{AllConf}(X,Y)$	$\dfrac{S(X\cap Y)}{\max\left(S(X),S(Y)\right)}$	$[0,1]$	Yes
$\text{Jaccard}(X,Y)$	$\dfrac{S(X\cap Y)}{S(X)+S(Y)-S(X\cap Y)}$	$[0,1]$	Yes
$\text{Cosine}(X,Y)$	$\dfrac{S(X\cap Y)}{\sqrt{S(X)\cdot S(Y)}}$	$[0,1]$	Yes
$\text{Kulczinsky}(X,Y)$	$\dfrac{1}{2}\left(\dfrac{S(X\cap Y)}{S(X)}+\dfrac{S(X\cap Y)}{S(Y)}\right)$	$[0,1]$	Yes
$\text{MaxConf}(X,Y)$	$\max\left(\dfrac{S(X)}{S(X\cap Y)},\dfrac{S(Y)}{S(X\cap Y)}\right)$	$[0,1]$	Yes
...	...	...	...

Table 14.26: **Some support-confidence interesting measures**

Finally, we can say that the association rules are very easily interpretable and their implementation simple and easy to transcribe into operational rules. However, a number of points are quite problematic:

- Runtime cost: Even if the Apriori algorithm eliminates several occurrences with the minimum support rule, it is easy to imagine that with a large database, occurrences that exceed the minimum support can be large.
- Fallacious or parasitic associations: This effect depends in particular on the minimum support defined, but in front of a large database, to obtain a sufficient quantity of rules it is sometimes useful to consider a low minimum support.

14.1.20.4 Equivalence CLAss Transformation (ECLAT)

The "ECLAT" algorithm, acronym for Equivalence CLAss Transformation, is an alternative way to the previous method to build the item-set that performs better in huge databases.

Let us use the companion example as before to introduce detail how ECLAT works:

Transaction Number	**Basket composition**			
1	bread	juice	jam	sugar
2	milk	bread	sugar	
3	cheese	bread	butter	milk
4	cheese	milk	sugar	flour
5	chips	bread	jam	yoghurt

The idea of ECLAT is for each item, to store a list of transaction ID's (abbreviated "tids" as acronym from "transaction ID's" or sometimes "tidlist"). It as vertical data layout at the opposite of the above one. Indeed, the transaction table above transformed into a tids will look like following for the 1-itemset:

Item Set	**TID Set**
bread	$1, 2, 3, 5$
jam	$1, 5$
cheese	$3, 4$
juice	1
milk	$2, 3, 4$
butter	3
sugar	$1, 2, 4$
flour	4
chips	5

Table 14.27: **ECLAT 1-itemset tidlist**

And the corresponding tidlist for 2-itemset:

Item Set	TID Set
{bread,jam}	1, 5
{bread,cheese}	3
{bread,juice}	1
{bread,milk}	2, 3
{bread,butter}	2, 3
{bread,sugar}	1, 2
{cheese,flour}	4
{breach, chips}	5
{jam, juice}	1
{jam, chips}	5
{cheese, milk}	4
{cheese, butter}	4
...	...

Table 14.28: **ECLAT 2-itemset tidlist**

And the corresponding tidlist for 3-itemset:

Item Set	TID Set
{bread,jam,juice}	1
{bread,jam,chips}	5
{bread,milk,sugar}	2
{bread,cheese,milk}	3
{bread,cheese,butter}	3
{jam,juice,sugar}	1
{cheese,milk,butter}	3
{cheese,milk,sugar}	4
...	...

Table 14.29: **ECLAT 3-itemset tidlist**

This process repeats, with k incremented by 1 each time, until no frequent items or no candidate itemsets can be found.

The pros are:

- Depth-first search reduces memory requirements
- Usually (considerably) faster than Apriori
- No need to scan the database to find the support of $(k+1)$-itemsets, for $k >\geq 1$

and the cons:

- The TID-sets can be quite long, hence expensive to manipulate

14.1.20.5 Clustering and Classification

In statistical data analysis, "clustering" describes empirical methods of data classification (hierarchical clustering method or data partitioning method). In other words clustering and classification are tasks for predicting the value of a categorical variable (target or class) by building a model based on one or more numerical and/or categorical variables (predictors or attributes).

These techniques typically enable the segmentation of all customers of a company based on their demography or buying patterns, to group documents for presentations, identify new animal or plant species, to group information by individuals or by interests.

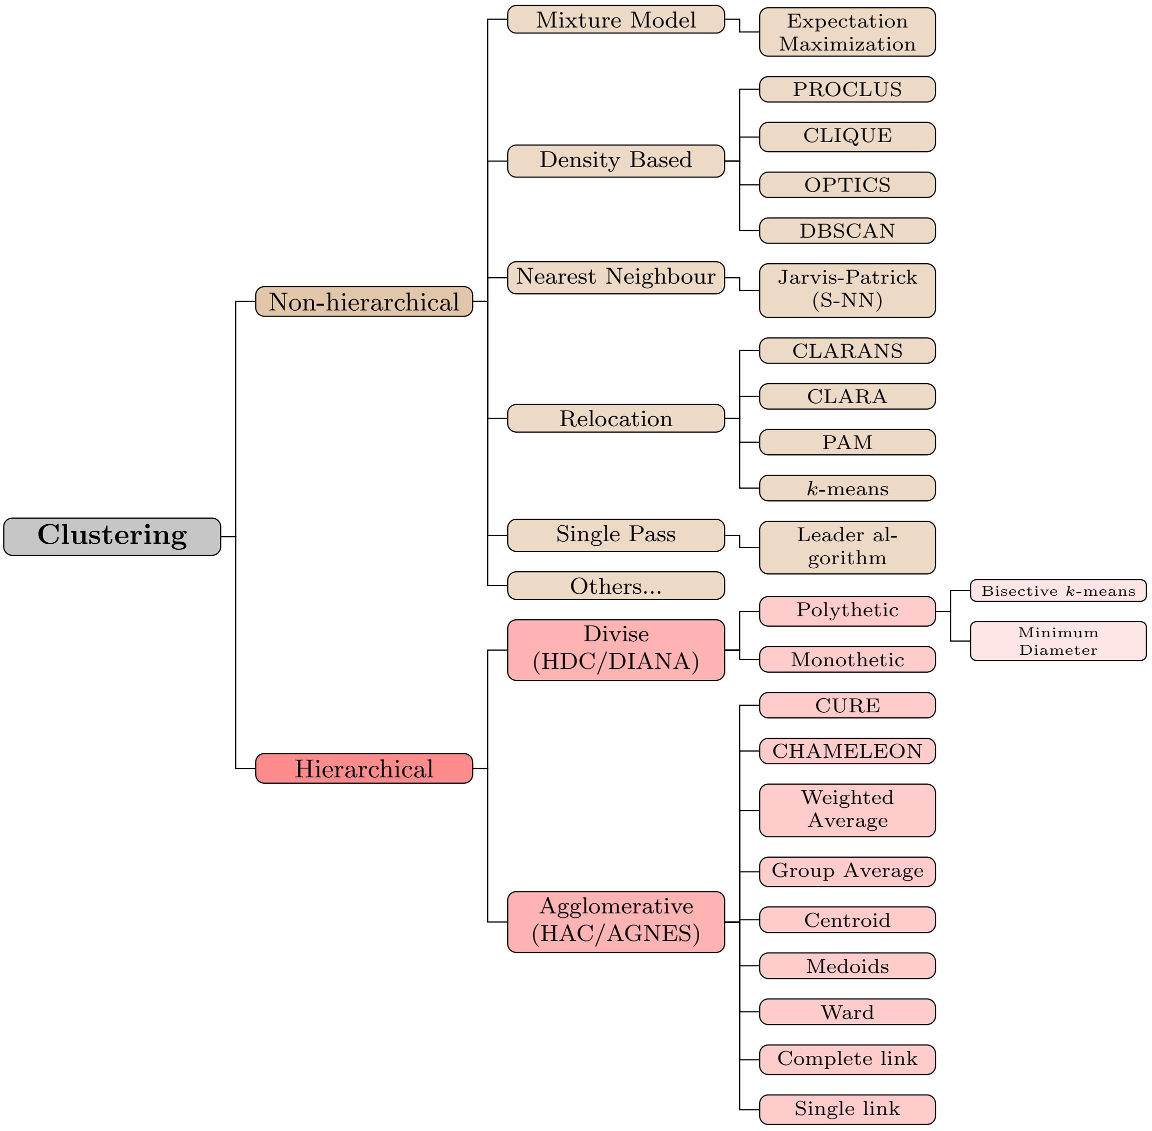
Classification	**Clustering**
Use labelled as the input	Use unlabelled as the input
The output is known	The output is unknown
Uses supervised machine learning	Uses unsupervised machine learning
A training data set is provided and used to produce classifications	A training data set is not provided and used to produce clusters
Examples of algorithms: Decision-trees, Bayesian classifiers and Support Vector Machines (SVM)	Examples of algorithms: Partition-based clustering (k-means), Hierarchical clustering (agglomerative / divisive) and DBSCAN
Can be more complex than clustering	Can be less complex than clustering
Does not specify areas for improvement	Specify areas for improvement
Known number of classes	Unknown number of classes
Interpretability High	Interpretability Low

Table 14.30: **Typical Classification vs Clustering differences**

By using some mathematical tricks, some classification techniques can be transformed into clustering techniques. That's why sometimes all these different techniques are confusing!

We see in practice two major families of clustering techniques (careful even experts in the field are unable to agree on a common classification ...!):

1. The "non-hierarchical techniques": that is to say where the final number of classes (groups) is chosen in advance.
2. The "hierarchical techniques": that is to say where it leads to a classification by successive aggregations or divisions.



Clustering
Non-hierarchical

Figure 14.130: **Non-exhaustive orgchart of clustering techniques**

Among these two families we distinguish three sub-families not highlighted in the orgchart above (this is the definition for THIS textbook - and that correspond almost to that of the SAS company - as they are no common accepted definitions until now between specialists working in this field):

1. The techniques that make use of data whose nominal classification property is known in advance to train a prediction model: "Machine Learning[57]" or "supervised learning". We find in this category the logistic regression techniques, CRT, ID3, discriminant analysis, Bayesian networks, decision lists, k-NN, neural networks, etc.

   As there are not today a consensus in the definitions, it is important that the reader also knows that "supervised" algorithms by are algorithms that have a correction mechanism of the model parameters based on generated errors.

---

[57] Oxford Dictionary definition: The capacity of a computer to learn from experience, i.e. to modify its processing on the basis of newly acquired information.

2. The techniques that make use of data whose no nominal classification is known in advance to suggest a classification and seek a possible classification (which at the business level is often more interesting): "data mining". We find in this category the, HAC, k-means, kohonen maps, K-modes, K-medoids, etc.

3. The techniques that make use of a mixture of classified and unclassified data and named "semi-supervised learning".

The first two families are quite well summarized by the following figure:

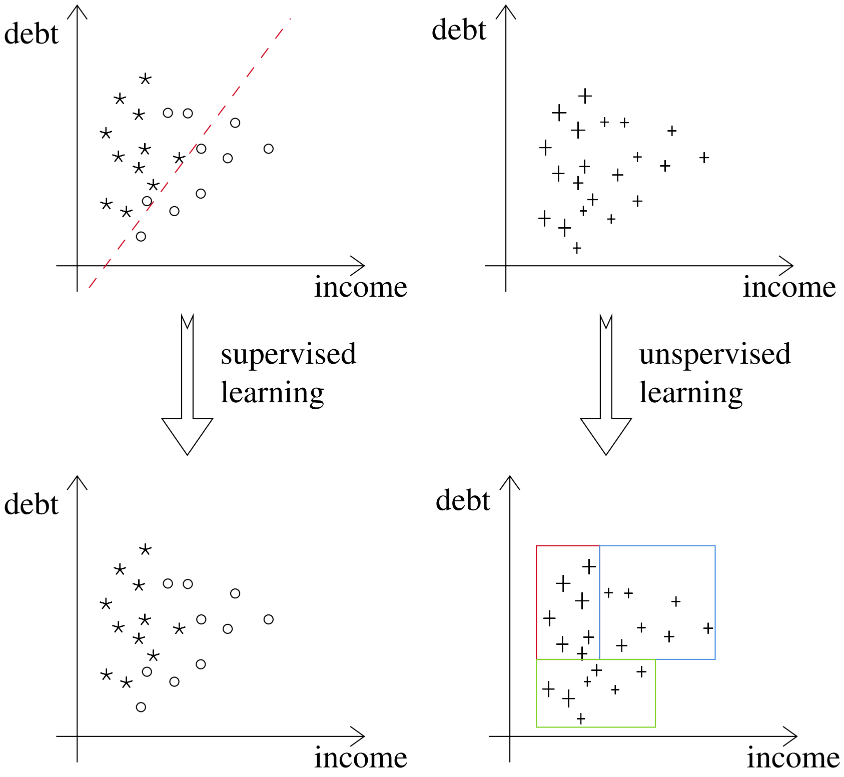

Figure 14.131: **Supervised vs Unsupervised learning idea**

are themselves divided into two sub-families: "kernel-based" (named also "soft clustering" or "fuzzy clustering") or non-kernel based (named also "hard clustering")... (that means for the latter we don't need to make any assumptions on the statistical distribution shape of the variable of interest and that an individual can only belong to one category[58]).

---

[58] Indeed, in fuzzy clustering technique like GMM (Gaussian Mixture Models) an individual has classification weights for each possible class!

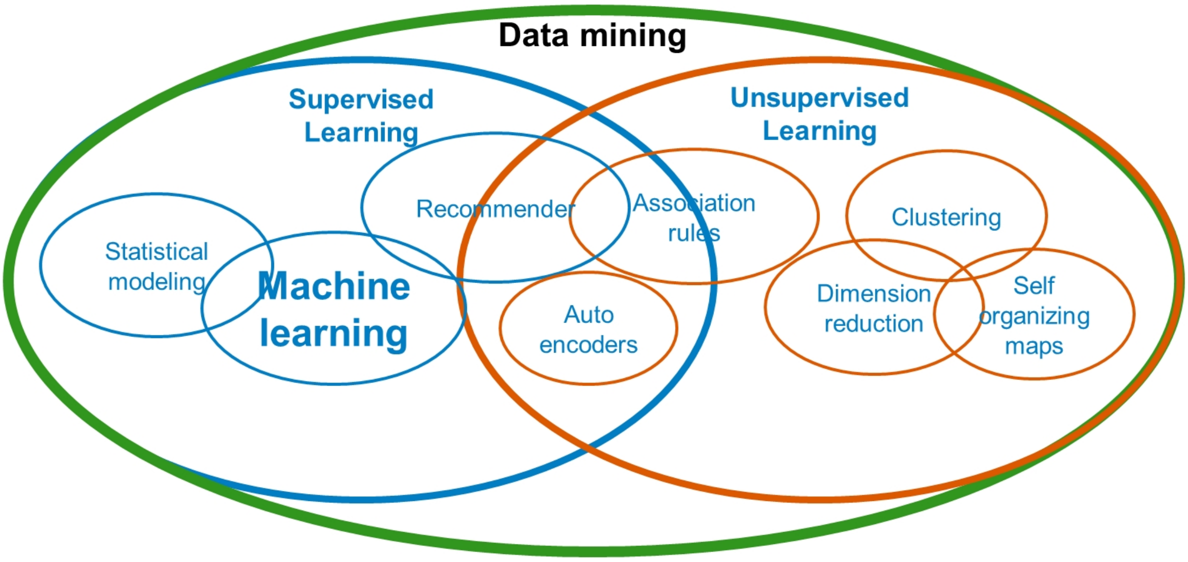

Figure 14.132: **Data Mining as seen by SAS™ (source: SlideShare SAS)**

The distinction between Machine Learning and data mining has become more and more blurred, and there is a great deal of "cross-fertilization".

The industrial or operational use of this knowledge in the professional world can solve very different problems, ranging from customer relationship management to preventive maintenance, through fraud detection and the optimization of websites, the supervision of financial markets, pro-active prospecting (customer consumption preferences), optimization of paths (analysis of road caps and left turns), or target selection (probability of acquiring a new given prospects) anticipate the identification of terrorists, pricing of products in comparison to equivalent one on the mark, etc.

Remark

Be careful to not to confuse strictly speaking the concepts of classification, segmentation and association! Although the first two are often confused (classification / segmentation) because many algorithms do both at once, classification is the prediction of one or more discrete variables based on the value of other fields in the data set as the segmentation divides the data into groups of items having the most identical properties as possible. About association it is clear that many segmentation algorithms shows what is associated with what but the idea strictly speaking of association is to quantified by a scalar the degree of association between two data sets.

We will see here some trivial techniques that we will complete with time. We tried to order them in the ascending order of pedagogical complexity (but that concept is quite subjective obviously that's why many people would argue that k-nn should be presented first)...

14.1.20.5.1 Naive Bayes classifiers

In Machine Learning, "naive Bayes classifiers" are a family of simple probabilistic classifiers based on applying Bayes' theorem with strong (naive) independence assumptions between the features (properties).

Naive Bayes has been studied extensively since the 11950s (holocene calendar). It was introduced under a different name into the text retrieval community in the early 11960s (holocene calendar), and remains a popular (baseline) method for text categorization, the problem of judging documents as belonging to one category or the other (such as spam or legitimate, sports or politics, etc.) with word frequencies as the features. With appropriate pre-processing, it is competitive in this domain with more advanced methods including support vector machines. It also finds application in automatic medical diagnosis.

14.1.20.5.1.1 Binomial Naive Bayes classifier

The "binomial naive Bayes classifier" consists by using Bayes probabilities to classify an item in two possible outcomes.

For example, the table below consisting of 4 e-mail, having 2 attributes and two possible classification outcomes that are $\{\text{No}-\text{Spam},\text{Spam}\}$:

Email	100% **Guaranteed**	**Meeting**	**Classification**
1	No	Yes	No – Spam
2	No	Yes	No – Spam
3	Yes	Yes	Spam
4	Yes	No	No – Spam

Table 14.31: **Naive Bayes spam-email companion example**

Abstractly, as already mentioned naive Bayes is a conditional probability model: given a problem instance to be classified, represented by a vector $\vec{x}=(x_1,\ldots,x_n)$ representing some n features (independent variables), it assigns a posteriori with probabilities $P(C_k/x_1,\ldots,x_n)$ to the instance C_k, or also written $P(C_k/\vec{x})$, for each of k possible outcomes or classes C_k.

Remark

Don't forget as we have seen in the section Probabilities (see section Probabilities page 497) that $P(C_k/x_1,\ldots,x_n)$ is just a convenient notation to write $P(C_k/x_1\cap\ldots\cap x_n)$. And therefore $P(\vec{x})$ is also a convenient notation for $P(x_1\cap\ldots\cap x_n)$.

With the example above it would look like this for the first e-mail (thus $n=2$):

$$P\left(C_k/\{100\%\text{ Guaranteed}\}=\text{No},\{100\%\text{ Meeting}\}=\text{Yes}\right) \qquad (14.1.1724)$$

The problem with the above formulation is that if the number of features n is large or if a feature can take on a large number of values, then basing such a model on probability tables is very hard. We therefore reformulate the model to make it more tractable. Using Bayes' theorem (see section Probabilities page 492), the conditional probability can be decomposed as:

$$P(C_k/\vec{x})=\frac{P(C_k)P(\vec{x}/C_k)}{P(\vec{x})} \tag{14.1.1725}$$

With for recall:

- $P(C_k/\vec{x})$ is the a posteriori probability to belong the class C_k knowing the features x_i (probability of the hypothetical class given the evidence ie. the features)
- $P(C_k)$ is the a priori probability (or "marginal probability") of the class C_k
- $P(\vec{x})$, the a priori probability of the feature (it is also a marginal probability)
- $P(\vec{x}/C_k)$, the a posteriori probability of the features x_i knowing the class C_k, it is also the likelihood of Y_k for $\vec{x}_i$ known (probability of evidence, i.e.. the feature, given that the hypothetical class holds).

In plain English, using Bayesian probability terminology, the above relation can be written for recall as:

$$\text{posterior}=\frac{\text{priori}\cdot\text{likelihood}}{\text{evidence}} \tag{14.1.1726}$$

In practice, there is interest only in the numerator of that fraction (equivalent to the joint probability), because the denominator does not depend on C_k and the values of the features x_i are given, so that the denominator is effectively constant whatever the k.

Hence the fact that we often can see in textbooks the following relation:

$$P(C_k/\vec{x})\propto P(C_k)P(\vec{x}/C_k) \tag{14.1.1727}$$

Theorem 14.8. A key idea in the NB model is the following assumption:

$$P(C=C_k/X_1=x_1,\ldots,X_n=x_n)\propto P(C=C_k)\prod_{i=1}^{n}P(X_i=x_i/C=C_k) \tag{14.1.1728}$$

Proof 14.8.1. This equality is derived using iteratively (don't forget that we don't care about the numerator!) the relation proved in the section of Probabilities but without the denominator (see section Probabilities page 492):

$$P(C_k/\vec{x})\propto P(C_k)P(\vec{x}/C_k) \tag{14.1.1729}$$

Indeed, let us rewrite this relation more explicitly:

$$P(C=C_k/X_1=x_1,\ldots,X_n=x_n)\propto P(C=C_k)P(X_1=x_1\ldots,X_n=x_n/C=C_k) \tag{14.1.1730}$$

Next we rewrite the second product term using the assumption of conditional independence:

$$P(X_1=x_1,\ldots,X_n=x_n/C=C_k)=P(X_1=x_1|C=C_k)\ldots P(X_n=x_n/C=C_k)=\prod_{i=1}^{n}P(X_i=x_i/C=C_k) \tag{14.1.1731}$$

Hence reinjecting in the prior-previous relation:

$$\begin{aligned}P(C=C_k/X_1=x_1,\ldots,X_n=x_n)&\propto P(C=C_k)P(X_1=x_1\ldots,X_n=x_n|C=C_k)\\&=P(C=C_k)\prod_{i=1}^{n}P(X_i=x_i/C=C_k)\end{aligned} \tag{14.1.1732}$$

In a condensed form the posterior probability of belonging to C_k knowing $\vec{x}$ is then given by:

$$\boxed{P(C_k/\vec{x})\propto P(C_k)\prod_{i=1}^{n}P(\vec{x}/C_k)} \tag{14.1.1733}$$

■ Q.E.D.

The idea now, when we have a training set of size N, is just to take for estimators:

$$\hat{P}(C_k)=\frac{\displaystyle\sum_{i=1}^{N}(\#C_i=C_k)}{N}=\frac{\text{count}(C_k)}{N} \tag{14.1.1734}$$

where obviously we define $C=C_k$ to be 1 if $C=C_k$, 0 otherwise. This estimator is simple the number of times that the label C_k is seen in the training set!

Similarly:

$$\hat{P}(\vec{x}/C_k)=\frac{\displaystyle\sum_{i=1}^{N}\#\left[(C=C_k)\cap(\vec{x}_i=\vec{x})\right]}{\displaystyle\sum_{i=1}^{N}(\#C_i=C_k)}=\frac{\text{count}(\vec{x}|C_k)}{\text{count}(C_k)} \tag{14.1.1735}$$

This is a very natural estimate: we simply count the number of times label C_k is seen in conjunction with $\vec{x}_i$ taking value $\vec{x}$ that we divide by the number of times the label C_k is seen in total.

✍**Example:**

We consider the following training set:

Email	100% **Guaranteed**	**Meeting**	**Classification**
1	No	Yes	No – Spam
2	No	Yes	No – Spam
3	Yes	Yes	Spam
4	Yes	No	No – Spam

A new e-mail arrives and contains the expression "100% *Guaranteed*" and the expression "*Meeting*". We want to predict if it is a Spam or not?

Email	100% Guaranteed	Meeting	Classification
5	Yes	Yes	?

For this purpose we will first simplify the notation by denoting the expression "100% *Guaranteed*" by the letter G and the expression "*Meeting*" by the letter M.

The posterior probabilities are in this simple case given by Bayes theorem:

$$\begin{aligned} P(\text{Spam}/G=\text{Yes},M=\text{Yes}) &= \frac{P(G=\text{Yes},M=\text{Yes}/\text{Spam})\cdot P(\text{Spam})}{P(G=\text{Yes},M=\text{Yes})} \\ P(\text{No}-\text{Spam}/G=\text{Yes},M=\text{Yes}) &= \frac{P(G=\text{Yes},M=\text{Yes}/\text{No}-\text{Spam})\cdot P(\text{No}-\text{Spam})}{P(G=\text{Yes},M=\text{Yes})} \end{aligned} \tag{14.1.1736}$$

Hence the ratio, that eliminates (as we know) the denominator that is then useless, that must be greater that 1 if the e-mail is a Spam:

$$\frac{P(G=\text{Yes},M=\text{Yes}/\text{Spam})\cdot P(\text{Spam})}{P(G=\text{Yes},M=\text{Yes}/\text{No}-\text{Spam})\cdot P(\text{No}-\text{Spam})}>1 \tag{14.1.1737}$$

According to the assumption of the independence of conditional probabilities we can write for the first factor of the numerator and respectively for that of the denominator:

$$P(G=\text{Yes},M=\text{Yes}/\text{Spam})=P(G=\text{Yes}/\text{Spam})\cdot P(M=\text{Yes}/\text{Spam}) \tag{14.1.1738}$$

$$P(G=\text{Yes},M=\text{Yes}/\text{No}-\text{Spam})=P(G=\text{Yes}/\text{No}-\text{Spam})\cdot P(M=\text{Yes}/\text{No}-\text{Spam}) \tag{14.1.1739}$$

So we can rewrite the ratio as:

$$\frac{P(G=\text{Yes}/\text{Spam})\cdot P(M=\text{Yes}/\text{Spam})\cdot P(\text{Spam})}{P(G=\text{Yes}/\text{No}-\text{Spam})\cdot P(M=\text{Yes}/\text{No}-\text{Spam})\cdot P(\text{No}-\text{Spam})}>1 \tag{14.1.1740}$$

And as we have in our training set:

$$\begin{aligned} P(G=\text{Yes}/\text{Spam}) &= \frac{1}{1} & P(G=\text{Yes}/\text{No}-\text{Spam}) &= \frac{1}{3} \\ P(M=\text{Yes}/\text{Spam}) &= \frac{1}{1} & P(M=\text{Yes}/\text{No}-\text{Spam}) &= \frac{2}{3} \\ P(\text{Spam}) &= \frac{1}{4} & P(\text{No}-\text{Spam}) &= \frac{3}{4} \end{aligned} \tag{14.1.1741}$$

Injecting in the previous ratio, we get:

$$\frac{\frac{1}{1}\cdot\frac{1}{1}\cdot\frac{1}{4}}{\frac{1}{3}\cdot\frac{2}{3}\cdot\frac{3}{4}}=1.5>1 \tag{14.1.1742}$$

That's all for this naive Bayesian example for document classification problem.

Statisticians are somewhat disturbed by use of the NBC (which they dub Idiot's Bayes) because the naive assumption of independence is almost always invalid in the real world.

However, the method has been shown to perform surprisingly well in a wide variety of contexts.

14.1.20.5.1.2 Gaussian Naive Bayes classifier

When dealing with continuous data, a typical assumption is that the continuous values associated with each class are distributed according to a Gaussian distribution. For example, suppose the training data contains a continuous attribute, x. We first segment the data by the class, and then compute the mean $\hat{\mu}$ and standard deviation $\hat{\sigma}$ of x for each class.

Let $\hat{\mu}_k$ be the mean of the values in x associated with class C_k, and let $\hat{\sigma}_k$ be the standard deviation of the values in x associated with class C_k.

Suppose we have collected some new observation value x'. Then, the probability density of x' given a class C_k, $P(x=x'/C_k)$, can be computed by plugging x' into the equation for a Normal distribution parametrized by $\hat{\mu}_k$ and $\hat{\sigma}_k^2$. That is:

$$P(x=x'/C_k)=\frac{1}{\sqrt{2\pi\hat{\sigma}_k^2}}e^{-\frac{(x'-\hat{\mu}_k)^2}{2\hat{\sigma}_k^2}} \tag{14.1.1743}$$

And after we apply again:

$$\boxed{P(C_k/\vec{x})\propto P(C_k)\prod_{i=1}^{n}P(\vec{x}/C_k)} \tag{14.1.1744}$$

✍**Example:**

We consider the following training set:

Person	Height [cm]	Weight [kg]	Foot size [cm]
male	182.88	81.64	30.48
male	180.44	86.18	27.94
male	170.07	77.11	30.48
male	180.44	74.84	25.4
female	152.4	45.35	15.24
female	167.64	68.03	20.32
female	165.20	58.96	17.78
female	175.26	68.03	22.86

The classifier created from the training set using a Gaussian distribution assumption would be (given variances are unbiased sample variances):

Person	Mean Height	Variance Height	Mean Weight	Variance Weight	Mean Foot size	Variance Foot size
male	178.45	32.59	79.94	25.28	28.58	5.91
female	165.13	90.32	60.09	114.88	19.05	10.75

We also know from the training set that we have equiprobable classes so:

$$P(\text{male})=P(\text{female})=0.5 \tag{14.1.1745}$$

Now consider a new sample to be classified as male or female:

Person	Height [cm]	Weight [kg]	Foot size [cm]
?	182.88	58.96	20.32

We wish to determine which posterior is greater, male or female. For the classification as male the posterior is given according to our boxed relation above:

$$P(C_k=\text{male}/\vec{x})\propto P(\text{male})\;P(\text{height}/\textbf{male})\;P(\text{weight}/\text{male})\;P(\text{footsize}/\text{male}) \tag{14.1.1746}$$

For the classification as female the posterior is given by:

$$P(C_k=\text{female}/\vec{x})\propto P(\text{female})\;P(\text{height}/\textbf{female})\;P(\text{weight}/\text{female})\;P(\text{footsize}/\text{female}) \tag{14.1.1747}$$

We now determine the probabilities distribution for the sex of the sample:

- $P(\text{male})=0.5$
- $P(\text{female})=0.5$
- $P(\text{height}/\text{male})=\dfrac{1}{\sqrt{2\pi\hat{\sigma}_{H,M}^2}}\exp\left(\frac{-(182.88-\hat{\mu}_{H,M})^2}{2\hat{\sigma}_{H,M}^2}\right)\cong 0.0517$
- $P(\text{height}/\text{female})=\dfrac{1}{\sqrt{2\pi\hat{\sigma}_{H,F}^2}}\exp\left(\frac{-(182.88-\hat{\mu}_{H,F})^2}{2\hat{\sigma}_{H,F}^2}\right)\cong 0.0073$
- $P(\text{weight}/\text{male})=\dfrac{1}{\sqrt{2\pi\hat{\sigma}_{W,M}^2}}\exp\left(\frac{-(58.96-\hat{\mu}_{W,M})^2}{2\hat{\sigma}_{W,M}^2}\right)\cong 1.3142\cdot 10^{-05}$
- $P(\text{weight}/\text{female})=\dfrac{1}{\sqrt{2\pi\hat{\sigma}_{W,M}^2}}\exp\left(\frac{-(58.96-\hat{\mu}_{W,M})^2}{2\hat{\sigma}_{W,M}^2}\right)\cong 0.0370$
- $P(\text{foot size}/\text{male})=\dfrac{1}{\sqrt{2\pi\hat{\sigma}_{FS,M}^2}}\exp\left(\frac{-(20.32-\hat{\mu}_{FS,M})^2}{2\hat{\sigma}_{FS,M}^2}\right)\cong 0.0005$

- $P(\text{foot size}/\text{female})=\dfrac{1}{\sqrt{2\pi\hat{\sigma}^2_{FS,F}}}\exp\left(\frac{-(20.32-\hat{\mu}_{FS,F})^2}{2\hat{\sigma}^2_{FS,F}}\right)\cong 0.1128$

Hence:

$$\begin{aligned}P(C_k=\text{male}/\vec{x})&\propto P(\text{male})\,P(\text{height}/\text{male})\,P(\text{weight}/\text{male})\,P(\text{footsize}/\text{male})\\&\cong 1.6986\cdot 10^{-10}\\P(C_k=\text{female}/\vec{x})&\propto P(\text{female})\,P(\text{height}/\text{female})\,P(\text{weight}/\text{female})\,P(\text{footsize}/\text{female})\\&\cong 1.5233\cdot 10^{-5}\end{aligned} \tag{14.1.1748}$$

Since posterior numerator is greater in the female case, we predict the new individual is female.

Most software multiplyes these two probabilities by a factor f such that:

$$f\cdot(1.6986\cdot 10^{-10}+1.5233\cdot 10^{-5})=1$$

It is easy to find that in this special case $f\cong 65646.21869$ and therefore we get:

$$P(C_k=\text{male}/\vec{x})\cong 1.11507\cdot 10^{-5}\qquad\text{and}\qquad P(C_k=\text{female}/\vec{x})\cong 0.999988849$$

14.1.20.5.2 k-nearest neighbours classifier (k-nn)

The "k-nn" is a quite simple supervised classification technique (do not confuse with the k-means that is a unsupervised clustering technique and that we will see later!). It takes a bunch of labelled points and uses them to learn how to label other points. To label a new point, it looks at the labelled points closest to that new point (those are its nearest neighbours), and has those neighbours vote, so whichever label the most of the neighbours have is the label for the new point (the "k" is the number of neighbours it checks).

In this framework, we have a learning database consisting of N input-output pairs. To estimate the output associated with a new input x, the k nearest neighbours method consists in taking into account (identically) the k learning samples whose input is closest to the new input x, according to a distance to be defined.

For example, in a classification problem, we will retain the class most represented among the k outputs associated with the k inputs closest to the new input x.

Given D the dataset composed of n pairs $(\vec{x},y)$, with $\vec{x}$ the description of an observation according to d quantitative variables, in the form of a real vector of dimensions d, and y the class of this observation. Consider the case where the descriptive variables are all quantitative and where the class variable have q modalities:

$$D=\{(\vec{x}_1,y_1),(\vec{x}_2,y_2),\ldots,(\vec{x}_n,y_n)\}\qquad\forall(x_i,y_i)_{1\leq i\leq n}:\vec{x}_i\in\mathbb{R}^d,y_i\in\{0,1,\ldots,q\} \tag{14.1.1749}$$

The space of representation of the observations must be provided with a distance necessary for the construction of the neighbourhood of a new observation. The distance is a function $d:\mathbb{R}^d\times\mathbb{R}^d\mapsto\mathbb{R}^+$, respecting the three axioms of the distance that we know well (see section Topology page 2450).

The most common distances for vectors of dimension n (corresponding therefore to the number the input attributes that must all belong to $\mathbb{R}$) in a table of size N (be careful! we know that computer scientists use some distances that doesn't respect the four axioms of distances and especially the triangular inequality as already discussed in the section Analysis at page 2454):

- Minkowski distance:

$$d_{\text{M},r}(\vec{x},\vec{y})=\sqrt[r]{\sum_{i=1}^{n}|x_i-y_i|^r} \tag{14.1.1750}$$

- Euclidean distance:

$$d_e(\vec{x},\vec{y})=d_{\text{M},2}(\vec{x},\vec{y})=\sqrt{\sum_{i=1}^{n}|x_i-y_i|^2} \tag{14.1.1751}$$

- Manhattan distance (city-block):

$$d_{\text{cb}}(\vec{x},\vec{y})=d_{\text{M},1}(\vec{x},\vec{y})=\sum_{i=1}^{n}|x_i-y_i| \tag{14.1.1752}$$

- Quadratic distance (σ is as we know a correlation matrix):

$$d_{\text{Q}}(\vec{x},\vec{y})=(\vec{x}-\vec{y})^T\Sigma(\vec{x}-\vec{y}) \tag{14.1.1753}$$

  as we can see it corresponds to the square of the Mahalanobis distance.

- Correlation distance:

$$d_\rho(\vec{x},\vec{y})=\frac{\displaystyle\sum_{i=1}^{n}(x_i-\bar{x}_i)(y_i-\bar{y}_i)}{\sqrt{\displaystyle\sum_{i=1}^{n}(x_i-\bar{x}_i)^2\sum_{i=1}^{n}(y_i-\bar{y}_i)^2}} \tag{14.1.1754}$$

- Chi-2 distance:

$$d_\chi(\vec{x},\vec{y})=\left(\sum_{i=1}^{n}\frac{1}{\displaystyle\sum_{i=1}^{n}(x_i+y_i)}\left(\frac{x_i}{\displaystyle\sum_{i=1}^{n}x_i}-\frac{y_i}{\displaystyle\sum_{i=1}^{n}y_i}\right)\right)^2 \tag{14.1.1755}$$

- Kendall rank correlation distance:

$$d_\kappa(\vec{x},\vec{y})=1-\frac{2}{n(n-1)}\sum_{i=1}^{m}\sum_{j=1}^{i-1}\text{sgn}(x_i-x_j)\text{sgn}(y_i-y_j) \tag{14.1.1756}$$

  with for recall:

$$\text{sgn}(x)=\begin{cases}-1 & x<0\\ 0 & x=0\\ +1 & x>0\end{cases} \tag{14.1.1757}$$

- Heterogeneous Euclidean Overlap Metric (HEOM) by focusing only on continuous attributes (case of the Tanagra software):

$$d_{\text{HEOM}}(\vec{x},\vec{y})=\sqrt{\sum_i\left(\frac{|x_i-y_i|}{\max_{i,a}-\min_{i,a}}\right)^2}=\sqrt{\sum_i\left(\frac{x_i-y_i}{\max_{i,a}-\min_{i,a}}\right)^2} \tag{14.1.1758}$$

  where $\max_{i,a}$ and $\min_{i,a}$ are respectively the largest and smallest value of the attribute i throughout the training sample so that the term in the parenthesis is always between 0 and 1 (normalized in other words...).

The figures below illustrate how the k nearest neighbours solves a binary supervised classification task ($y_i\in\{0,1\}$) in $\mathbb{R}^2$, depending on the Euclidean distance and for $k=3$. The first figure show (in three steps, from left to right) a new observation is attributed to class 1, its neighbour being composed of three observations belonging to class 1. The second figure shows how a new observation is attributed to class 1, its vicinity being composed of two observations belonging to the class 1 and of one observation belonging to the class 0.

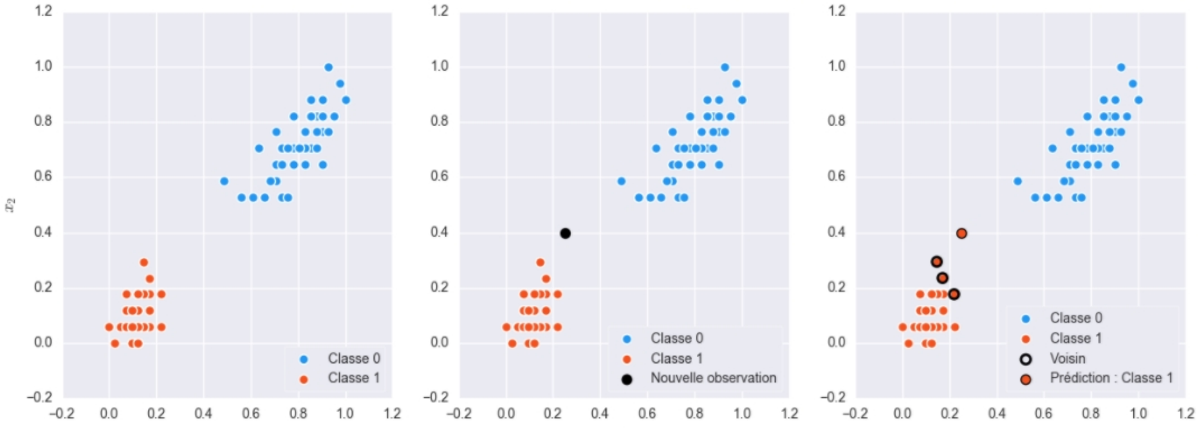

Figure 14.133: **Classification of a new observation with $k-nn$: the three nearest neighbours belong to class 1**

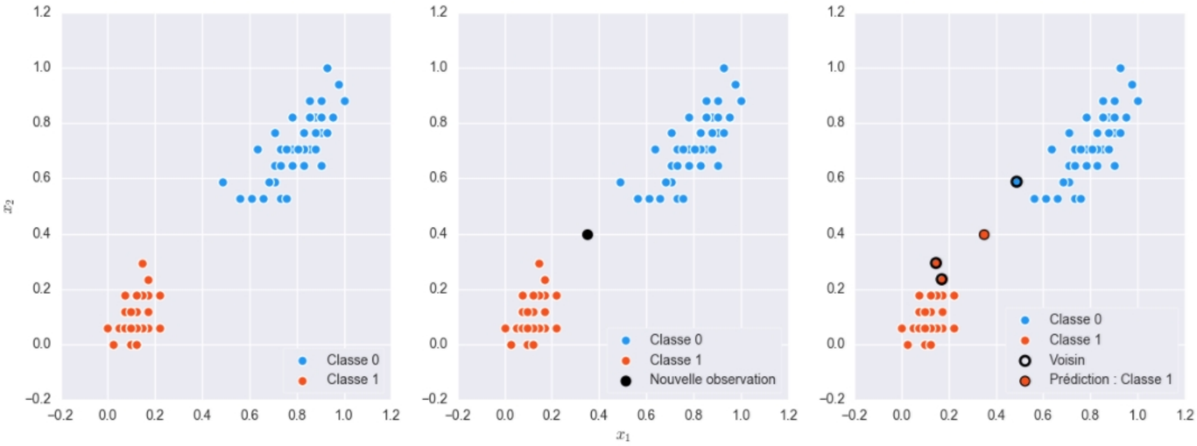

Figure 14.134: Classification of a new observation with $k-nn$: 2 of the 3 nearest neighbours belong to class 1

The distance to the kth nearest neighbour can also be seen as a local density estimate and thus is also a popular outlier score in anomaly detection. The larger the distance to the k-nn, the lower the local density, the more likely the query point is an outlier. Although quite simple, this outlier model, along with another classic data mining method, local outlier factor, works quite well also in comparison to more recent and more complex approaches, according to a large scale experimental analysis.

Remark

Obviously we may run the k-nn on the factorial space obtained after having run a PCA (Principal Component Analysis as seen on page 1213) on our data. We can also even reduce the dimensions using that latter if necessary!

14.1.20.5.3 Regression and classification trees

"Classification and Regression Tree" (CART) are a set of heuristic supervised algorithms introduced in 11984 (holocene calendar) by Leo Breiman, Jerome Friedman, Richard Olshen and Charles Stone as an umbrella term to refer to the following types of decision trees[59]":

- "Classification Trees": where the target variable is categorical and the tree is used to identify the "class" within which a target variable would likely fall into.
- "Regression Trees": where the target variable is continuous and tree is used to predict it's value.

Decision tree are non-linear, nonparametric and nonmetric classifier. Concretely, decision trees are predictive models that proceed through a tree structure of rules or a hierarchy of tests extracted from learning or training data, to partition the basic data into homogeneous subgroups from the point of view of the variable to predict. The generated rules tree easily lends itself to the human reasoning mode and it becomes more intuitive to interpret the tree and make predictions.

---

[59] A "decision stump" is a Machine Learning model consisting of a one-level decision tree

These trees are widely used in advanced marketing or social science to discriminate (categorize) a very large population. Obviously, these algorithms (that are part of hierarchical techniques) will never do better than a human being (at least in this first decade of the 121st century according to holocene calendar)... but also ask an employee to create groups in a population of 5 million customers on the basis of ten explanatory variables. You will have to wait for the response a quite long time...

While these automated classification techniques are very useful in the above situations, they nevertheless have a major problem that makes we will not focus too much on this subject:

- These techniques are very sensitive to the analysed population and give very different results.
- The various existing techniques of classifications give results that are completely different for the same population.
- Decision trees can also never predict values out of the range of the targets seen in the training dataset (i.e. classical decision trees don't extrapolate, they only retrodict).

It is better to be cautious about the conclusions that we can draw from these models and compare the results of several methods depending on the return on experience choose the one that seems the best suited.

Remark

In good practice situations, the construction of a tree is, as always in the field of Machine Learning (...), made from a set of data named the "learning sample". Once the tree is built, it is tested for its predictive power usually on a set of data named the "test sample".

14.1.20.5.3.1 Binary classification trees with quantitative variables

For companion example, let us consider a set of categorical variables $x_1,\ldots,x_p$. The recursive partitioning has for purpose to divide the p variables of the space into rectangles which do not overlap.

For example, consider the variable x_i and a value s_i of this variable, we find that the partitioning $x_i<s_i$ and $s_i<x_i$ separates well the data into two disjoint sets. Then one of the parts is in turn divided by a value x_i or by the value of another variable. We end then with three rectangles and so on...

The idea is to create n rectangles such that all data contained in a rectangle are homogeneous (that is to say contains only one family of points).

To address this issue, consider the following first practical case with only quantitative variables (it is therefore a binary regression tree):

A dealer would like for his city to find a way to classify the families that are able to buy a car (owners) and those that are not ready to buy a car (non-owners). A sample of 12 owners ("1" in the figure below) and 12 non-owners ("2" in the figure below) is selected. The two independent variables are x_1 (wage in kilo-dollars) and x_2 (area of their home). In other words, we have here a case where $x_i \in \mathbb{R}^+$ and $y_i\{1,2\}$.

	A	B	C	D
1	**Observation**	**Wedge**	**Area**	**Owner**
2	1	60	18.4	1
3	2	85.5	16.8	1
4	3	64.8	21.6	1
5	4	61.5	20.8	1
6	5	87	23.6	1
7	6	110.1	19.2	1

Figure 14.135: **Original data list of CART application with Microsoft® Excel® 14.0.7172**

We see that we have as many owners than non-owners (assumed equal appearance frequency in the whole population). Therefore the probability of belonging to a class is 50%.

Or graphically:

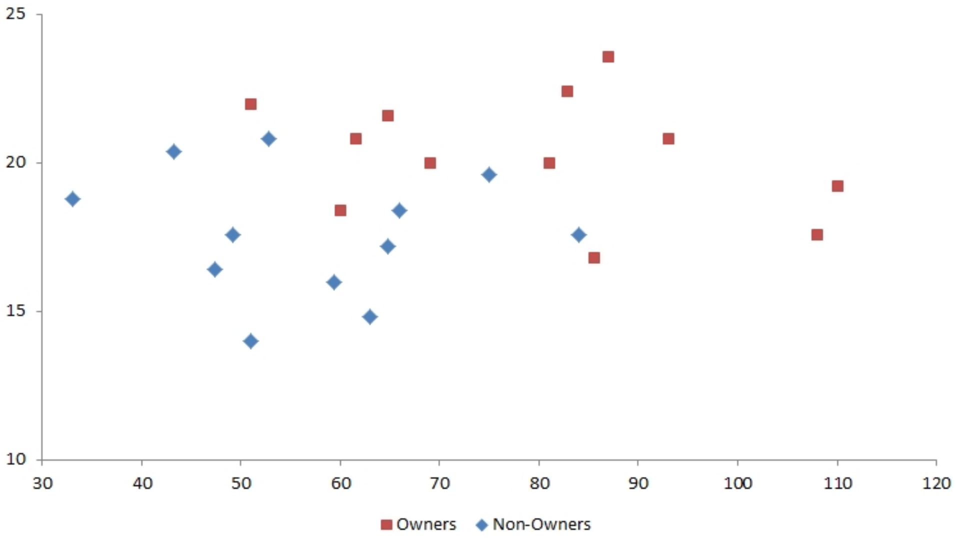

Figure 14.136: **Original plot CART application with Microsoft® Excel® 14.0.7172**

If we apply the CART algorithm on this data, we see that we must choose x_2 (Area) as the first choice of division with the division value of 19 (we will justify why!). The space (x_1, x_2) is now divided into two rectangles (it was easy to guess that discriminating step without even using mathematics):

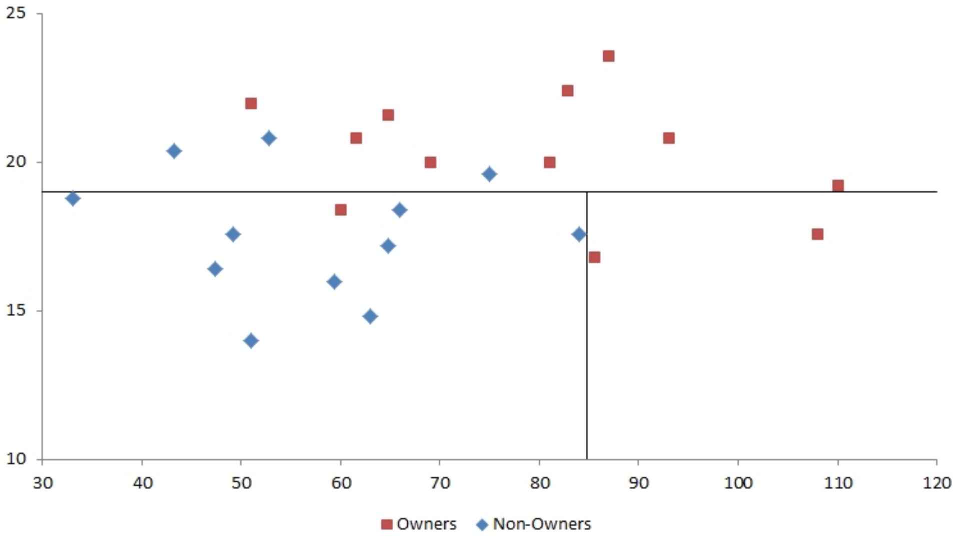

Figure 14.137: **First iteration of CART application with Microsoft® Excel® 14.0.7172**

Notice how the division into two rectangles created two zones (splits) which are more homogeneous than the original graph! The upper rectangle contains points which are more Owners while the lower rectangle contains more Non-owners.

To determine this division, the CART algorithm examines each variable and all possible values for each variable division in order to find the best division.

Thus, the possible points of division for x_1 are (notice that this is every time the average of the two related values in the table):

$$x_1 : \{38.1, 45.3, 50.1, \ldots, 109.5\}$$

and that for x_2 are:

$$x_2 : \{14.4, 15.4, 16.2, \ldots, 23\}$$

These points are ordered by the algorithm according to the way they reduce "impurity" (heterogeneous of composition) in the rectangle that generates the "split".

There are a large number of empirical ways to measure the impurity. But to start with our first example, let us use the easiest and most common "impurity measurement criterion" or "segmentation criteria" so far that is the use of an indicator inspired by the Gini coefficient (see section Quantitative Management Techniques page 8099). Thus, if we denote the classes by $k = 1, 2, 3, \ldots, C$ where C is the total number of classes to be predicted, the "Gini impurity index" for the A rectangle is defined by:

$$\boxed{I(A) = 1 - \sum_{k=1}^{C} p_k^2} \tag{14.1.1759}$$

where p_k is the fraction of observations in the rectangle A which belong to the class k.

In our example, we always have only two classes: Owners / Non-Owners.

Next, the global Gini index is defined as the weighted average of the Gini indices.

So in our example, we have two classes, therefore $C = 2$. Before the separation, we have:

$$I(A) = 1 - \sum_{k=1}^{C} p_k^2 = 1 - \left(\frac{12}{24}\right)^2 - \left(\frac{12}{24}\right)^2 = 1 - 2(0.5)^2 = 0.5 \tag{14.1.1760}$$

The separation found in 19 (see the second figure) gives for example for the top rectangle of the first subdivision:

$$\begin{aligned} I(A_{\text{sup}}) &= 1 - \sum_{k=1}^{2} p_k^2 = 1 - \left[\left(\frac{\text{blue points}}{n}\right)^2 + \left(\frac{\text{red points}}{n}\right)^2\right] \\ &= 1 - \left[\left(\frac{3}{12}\right)^2 - \left(\frac{9}{12}\right)^2\right] = 0.375 \end{aligned} \tag{14.1.1761}$$

For the inferior part:

$$\begin{aligned} I(A_{\text{inf}}) &= 1 - \sum_{k=1}^{2} p_k^2 = 1 - \left[\left(\frac{\text{blue points}}{n}\right)^2 + \left(\frac{\text{red points}}{n}\right)^2\right] \\ &= 1 - \left[\left(\frac{9}{12}\right)^2 - \left(\frac{3}{12}\right)^2\right] = 0.375 \end{aligned} \tag{14.1.1762}$$

By the hazard of the choice of this example, the impurity is the same for both rectangles (top and bottom).

The overall Gini index is then given by:

$$I(A) = \frac{12}{24}0.375 + \frac{12}{24}0.375 = 0.375 \tag{14.1.1763}$$

Notice before continuing that if the subdivision is perfect (only have one family of points in one of the boxes), then we have:

$$\begin{aligned}I(A_{\text{inf,sup}})&=1-\sum_{k=1}^{2}p_k^2=1-\left[\left(\frac{\text{blue points}}{n}\right)^2+\left(\frac{\text{red points}}{n}\right)^2\right]=1-\left[\left(\frac{12}{12}\right)^2+\left(\frac{0}{12}\right)^2\right]\\&=1-\left[\left(\frac{\text{blue points}}{n}\right)^2+\left(\frac{\text{red points}}{n}\right)^2\right]=1-\left[\left(\frac{0}{12}\right)^2+\left(\frac{12}{12}\right)^2\right]\\&=0\end{aligned}\tag{14.1.1764}$$

So the impurity is zero ... And if all the points appear in equal proportions in each of the rectangles (worst situation we could say), the value is then:

$$\begin{aligned}I(\text{A}_{\text{inf,sup}})&=1-\sum_{k=1}^{2}p_k^2\\&=1-\left[\left(\frac{\text{blue points}}{n}\right)^2+\left(\frac{\text{red points}}{n}\right)^2\right]=1-\left[\left(\frac{x^{2}}{n_1}+\frac{y}{n_2}\right)^2\right]\\&\underset{\substack{x=y\\n_1=n_2=n}}{=}1-\left[\left(\frac{x}{n}\right)^2+\left(\frac{x}{n}\right)^2\right]=1-2\left(\frac{x}{n}\right)^2\underset{x=\frac{1}{2}n}{=}=1-2\left(\frac{1}{2}\right)^2\\&=1-2\frac{1}{4}=1-\frac{1}{2}=0.5\end{aligned}\tag{14.1.1765}$$

If we generalize to C classes (C spatial dimensions), it comes immediately:

$$I(A_{\text{inf,sup}})=1-\sum_{k=1}^{C}p_k^2=1-\frac{1}{C}=\frac{C-1}{C}\tag{14.1.1766}$$

which is the maximum impurity.

So the impurity is always defined by a value in the range:

$$I(A)\in\left[0,\frac{C-1}{C}\right]\tag{14.1.1767}$$

Now, to continue with our example, even without using a computer algorithm, without even calculating the impurity, it is relatively easy to guess which will be the next discrimination: it will be $x_1=84.75$ (Income). Which will give:

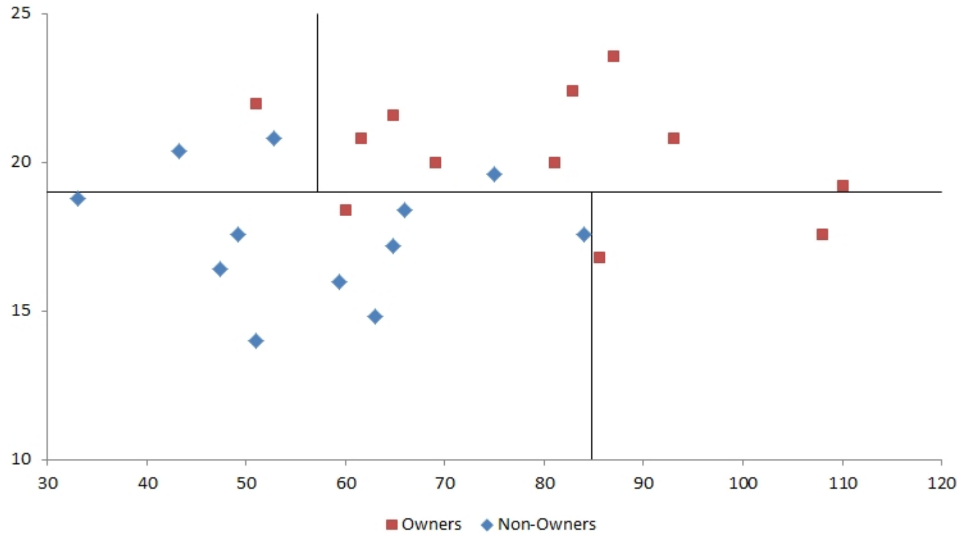

Figure 14.138: **Second iteration of CART application with Microsoft® Excel® 14.0.7172**

What was also easy to guess even without using the calculations (try your friends, you will see that very often they can find the first two discrimination).

The impurity will be calculated in the new discriminated area by:

$$\begin{aligned}I(A_{\text{left}})&=1-\sum_{k=1}^{2}p_k^2=1-\left[\left(\frac{\text{blue points}}{n}\right)^2+\left(\frac{\text{red points}}{n}\right)^2\right]\\&=1-\left[\left(\frac{9}{10}\right)^2+\left(\frac{1}{10}\right)^2\right]=0.18\\I(A_{\text{right}})&=1-\sum_{k=1}^{2}p_k^2=1-\left[\left(\frac{\text{blue points}}{n}\right)^2+\left(\frac{\text{red points}}{n}\right)^2\right]\\&=1-\left[\left(\frac{0}{2}\right)^2+\left(\frac{2}{2}\right)^2\right]=0\end{aligned} \tag{14.1.1768}$$

The overall Gini index is given by:

$$I(A)=\frac{10}{12}\cdot 0.18+\frac{2}{2}\cdot 0=0.15 \tag{14.1.1769}$$

We continue, but be aware that the result is less easy to guess.

The majority of individuals interviewed are wrong without using the mathematical definition of impurity and intuitively wrong to propose one or more of the following discrimination:

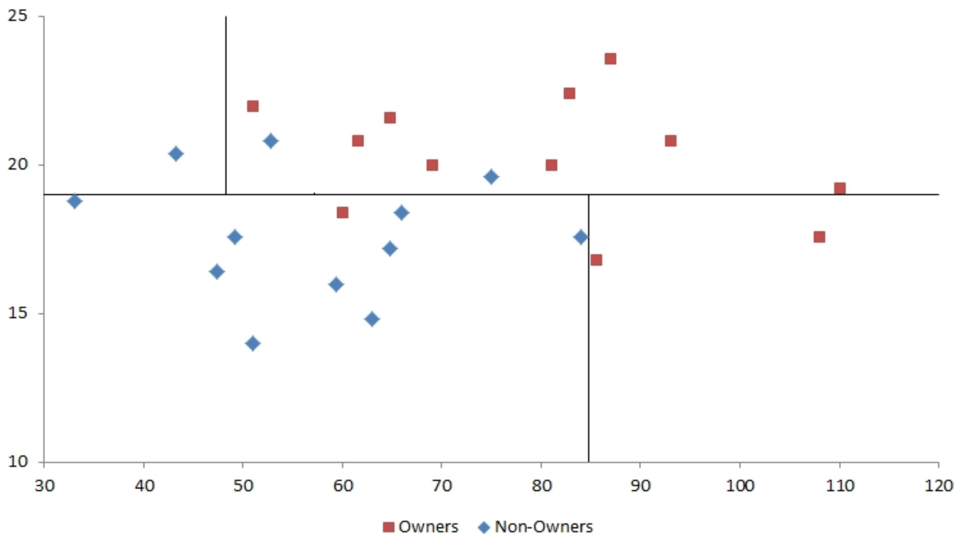

Figure 14.139: Third iteration of CART application with Microsoft® Excel® 14.0.7172

with (you can do the math) a total impurity of 0.2727. When in reality, the optimum discrimination is:

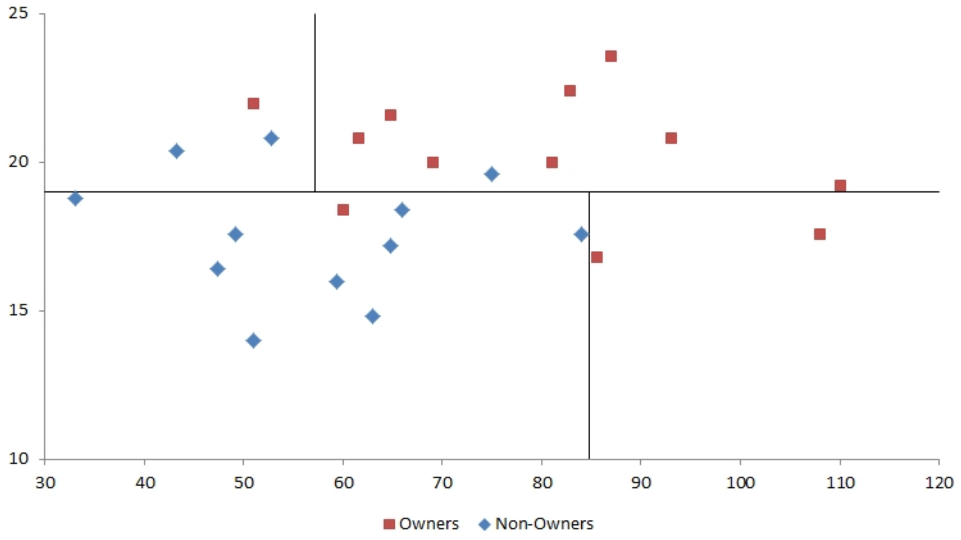

Figure 14.140: Third real iteration of CART application with Microsoft® Excel® 14.0.7172

with a total impurity of 0.2592. Indeed:

$$\begin{aligned}
I(A_{\text{left}})&=1-\sum_{k=1}^{2}p_k^2=1-\left[\left(\frac{\text{blue points}}{n}\right)^2+\left(\frac{\text{red points}}{n}\right)^2\right]=1-\left[\left(\frac{1}{3}\right)^2+\left(\frac{2}{3}\right)^2\right]=0.\bar{4}\\
I(A_{\text{right}})&=1-\sum_{k=1}^{2}p_k^2=1-\left[\left(\frac{\text{blue points}}{n}\right)^2+\left(\frac{\text{red points}}{n}\right)^2\right]=1-\left[\left(\frac{1}{9}\right)^2-\left(\frac{8}{9}\right)^2\right]\cong 0.197
\end{aligned} \tag{14.1.1770}$$

The overall Gini index is:

$$I(A)=\frac{3}{12}0.\bar{4}+\frac{9}{12}0.197\cong 0.2592 \tag{14.1.1771}$$

In the next step, we have:

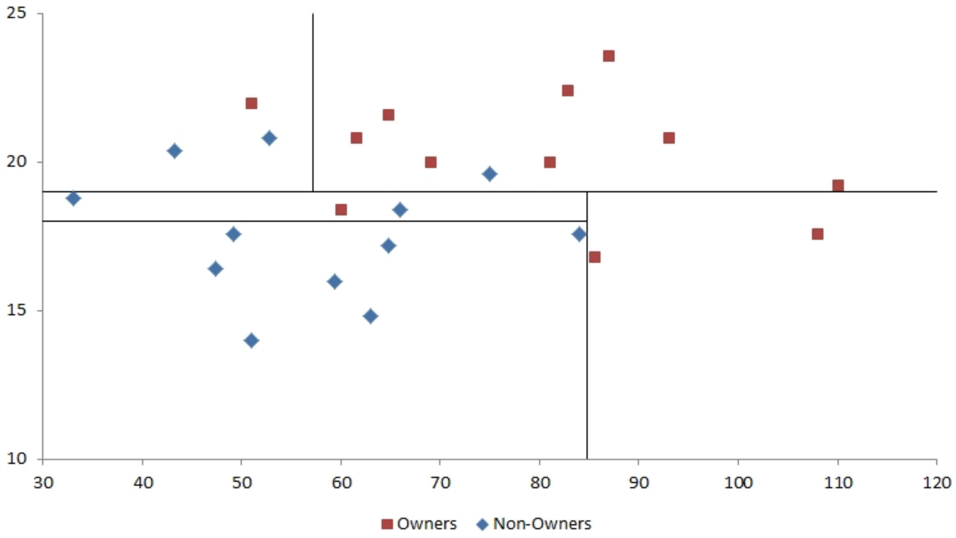

Figure 14.141: **Fourth iteration of CART application with Microsoft® Excel® 14.0.7172**

At the next step:

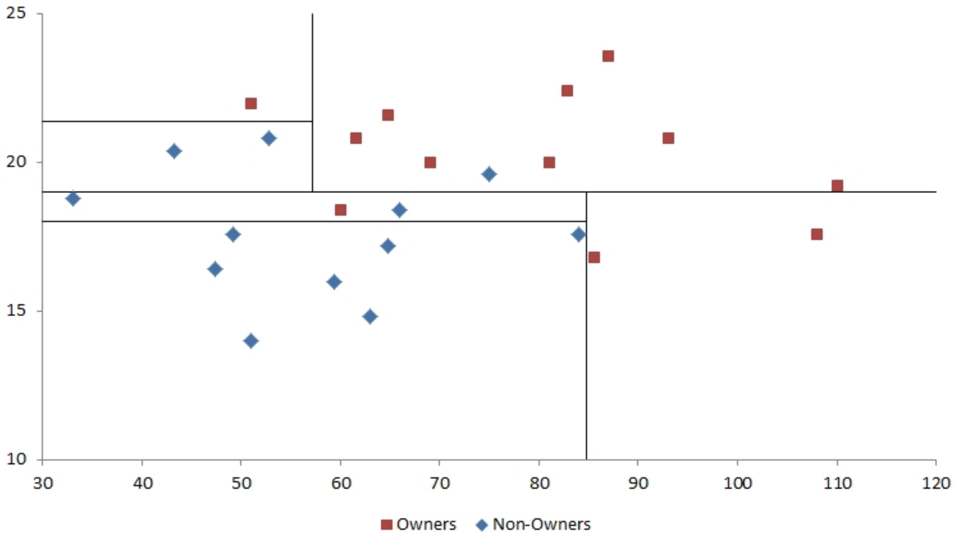

Figure 14.142: **Fifth iteration of CART application with Microsoft® Excel® 14.0.7172**

etc. until the end:

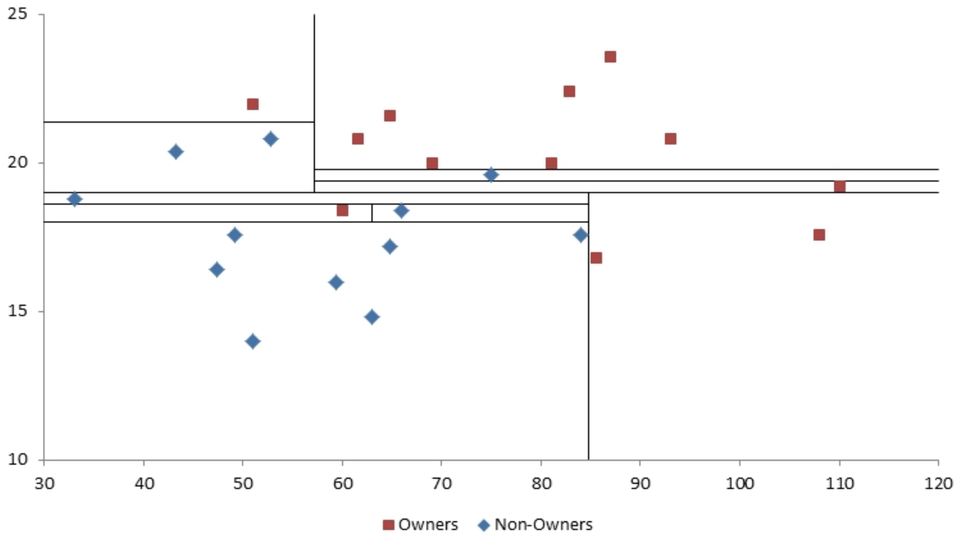

Figure 14.143: **Final iteration of CART application with Microsoft® Excel® 14.0.7172**

where each rectangle is pure (only contains data that one of the two classes).

The reason why the method is named "Classification And Regression Tree" algorithm is that each division can be represented as the division of a node into two successor nodes. The first division is shown as a branch of the tree root node. Here, for example are the first six iterations of the algorithm (only the first six one as the page size is to small to get them all):

Figure 14.146: **CART Final result in the traditional tree form with MATLAB® 2013a**

We need to be careful to pick an appropriate tree depth! Indeed:

- If the tree is too deep, we may overfit
- If the tree is too shallow, we may underfit

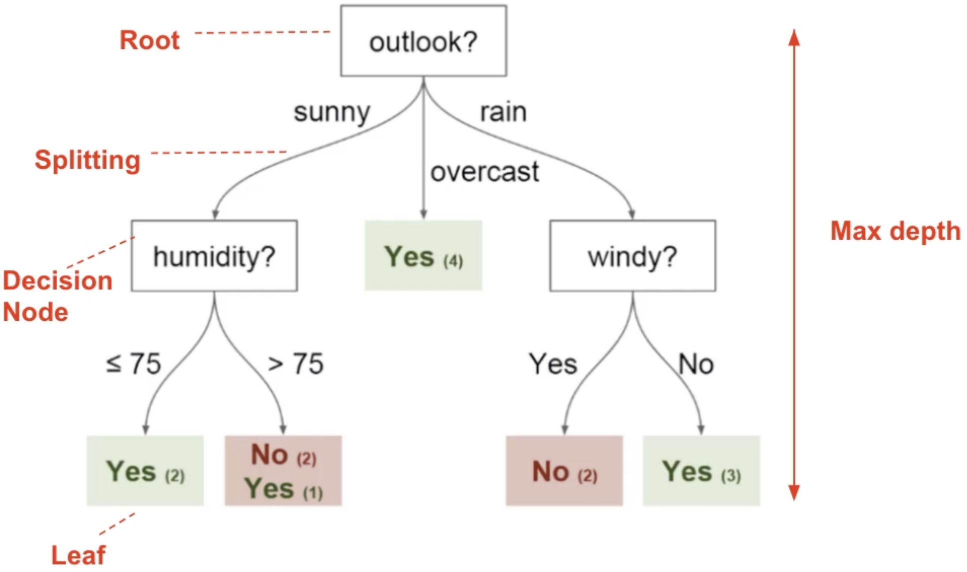

Figure 14.147: **Main vocabulary of decision trees**

Alternative strategy is to create a very deep tree, and then to prune it.

Remark

A common question for binary decision trees is: why not use logistic regression instead? The answer is quite simple! Decision trees helps you developing decision rules but in logistic regression you can not visualize a rule even though you can know which factor are more important! We will also use binary decision trees when there are too many variables, especially categorical ones and you have outliers in predictor variables and relationships are non-linear. And if we want probabilities for each case, we should go for logistic regression obviously!

14.1.20.5.3.2 Detection of significant splits

Quite often it is necessary to measure the significance of a split in a decision tree, especially when the information gain (see further below page 6851) is small.

Let N_A and N_B be the number of items of class A and class B in the parent node. Let N_{AL} represent the number of class A going to the left child node, N_{BL} represent the number of class B going to the left child node, N_{AR} represent the number of class B going to the right child node, and N_{BR} represent the number of class B going to the right child node.

Let p_L and p_B denote the proportion of data going to the left and right node, respectively:

$$\begin{aligned} p_L &= \frac{N_{AL}+N_{BL}}{N_A+N_B} \\ p_R &= \frac{N_{AR}+N_{BR}}{N_A+N_B} \end{aligned} \tag{14.1.1772}$$

The following measure computes the significance of a split. In other words, it measures how much the split deviates from what would be expected in the random data:

$$K=\frac{(N'_{AL}-N_{AL})^2}{N'_{AL}}+\frac{(N'_{BL}-N_{BL})^2}{N'_{BL}}+\frac{(N'_{AR}-N_{AR})^2}{N_{AR}}+\frac{(N'_{BR}-N_{BR})^2}{N'_{BR}} \qquad (14.1.1773)$$

where:

$$\begin{gathered}N'_{AL}=N_A\cdot p_L\\ N'_{BL}=N_B\cdot p_L\\ N'_{AR}=N_A\cdot p_R\\ N'_{BR}=N_B\cdot p_R\end{gathered} \qquad (14.1.1774)$$

We recognise here the shape of a χ^2 random variable with 4 degrees of freedom (χ^2_4).

If K is small, the information gain from the split is not significant. If K is big, it would suggest the information gain from the split is significant.

14.1.20.5.3.3 Classification (and clustering) validation

There exist many different clustering/classification methods, depending on the type of clusters/class sought and on the inherent data characteristics. Given the diversity of clustering/classification algorithms and their parameters it is important to develop objective approaches to assess clustering/classification results. Cluster/class validation and assessment encompasses three main tasks: "clustering/class evaluation" seeks to assess the goodness or quality of the clustering/classification, "clustering/class stability" seeks to understand the sensitivity of the clustering/class result to various algorithmic parameters, for example, the number of clusters/classes, and "clustering/class tendency" assesses the suitability of applying clustering/class in the first place, that is, whether the data has any inherent grouping structure. There are a number of validity measures and statistics that have been proposed for each of the aforementioned tasks, which can be divided into three main types:

- **External validation** measures employ criteria that are not inherent to the dataset. This can be in form of prior or expert-specified knowledge about the clusters/classes.
- **Internal validation** measures employ criteria that are derived from the data itself. For instance, we can use intracluster and intercluster distances to obtain measures of cluster compactness (e.g., how similar are the points in the same cluster?) and separation (e.g., how far apart are the points in different clusters?).
- **Relative validation** measures aim to directly compare different clusterings/classes, usually those obtained via different parameter settings for the same algorithm.

Remark

For the reader interested to further reading on the topic of clustering validation, we strongly recommend: *DATA MINING AND ANALYSIS: Fundamental Concepts and Algorithms* (see [592]), that has excellent detailed definitions with step by step manually calculated examples from page 425 to page 462 (all chapter 17).

To see now some other segmentation external criteria but now with qualitative variables let us consider the following first companion example based on the table below:

Color	**Shape**	**Size**	**Class**
red (R)	square (S)	big (B)	plus
blue (B)	square (S)	big (B)	plus
red (R)	round (R)	small (S)	minus
green (G)	square (S)	small (S)	minus
red (R)	round (R)	big (B)	plus
green (G)	square (S)	big (B)	minus

First let us do again the calculation with the Gini impurity index:

$$I(t)=1-\sum_{i=1}^{n}p(i/t)^2 \qquad (14.1.1775)$$

where $p(i/t)$ still represents the frequency or the probability of the i relatively to the partition t (again, a partition is "pure" if it's Gini impurity index is equal to zero).

As in the previous example we must afterwards calculate the overall Gini impurity index as the weighted average of the Gini impurity index of each partition following:

$$\boxed{I(C)=\sum_{t=1}^{n}f_t\cdot I(t)} \qquad (14.1.1776)$$

Therefore the overall Gini index for the *Color* attribute is given by (keep in mind that our dataset has 6 rows and the numerator of each fraction represent the number of occurrences of the concerned partition!):

$$I(\text{Color})=\frac{1}{6}I(B)+\frac{3}{6}I(R)+\frac{2}{6}I(G)=0.22$$

with (keep in mind that the denominator is always the number of rows of the corresponding partition, and the numerator correspond to how many of a given *Class* we have among all these rows):

- $I(B)=1-(0/1)^2-(1/1)^2=0.0$
- $I(R)=1-(1/3)^2-(2/3)^2=0.44$
- $I(G)=1-(2/2)^2-(0/2)^2=0.0$

And the overall Gini index for the *Shape* attribute is then given by:

$$I(\text{Shape})=\frac{4}{6}I(C)+\frac{2}{6}I(R)=0.5$$

with:

- $I(S)=1-(2/4)^2-(2/4)^2=0.50$
- $I(C)=1-(1/2)^2-(1/2)^2=0.50$

And finally the overall Gini index for the *Size* attribute:

$$I(\text{Size})=\frac{4}{6}I(B)+\frac{2}{6}I(S)=0.25$$

with:

- $I(B)=1-(1/4)^2-(3/4)^2=0.375$
- $I(S)=1-(2/2)^2-(0/2)^2=0.0$

As the variables with lower Gini impurity index are the one to split, then we will chose the *Color* attribute as first split in our example! So we see that in classification trees, the Gini Index can be used as "variable importance" metric for classification trees!

Now let us see a new segmentation criteria named the "information gain", used by the ID3, C4.5 and C5.0 tree-generation algorithms, and based on the measurement of information's entropy[60] from Statistical Mechanics (see page 3530).

For this purpose let us define the entropy for the partition t by the relation (named for recall "Shannon formula"):

$$S(t)=-\sum_{i=1}^{n}p(i/t)\log(p(i/t)) \tag{14.1.1777}$$

Also denoted in some textbooks as:

$$H(\mathcal{C})=-\sum_{i=1}^{r}p_{C_i}\log(p_{C_i})=-\sum_{i=1}^{r}\frac{n_i}{n}\log\left(\frac{n_i}{n}\right) \tag{14.1.1778}$$

where p_{C_i} is the probability of cluster C_i.

Thus, similarly to the Gini impurity index, the conditional entropy for a given attribute is given by the weighted information entropies:

$$\boxed{S(C,a)=\sum_{t=1}^{m}f_t\cdot S(t)=-\sum_{t=1}^{m}f_t\sum_{i=1}^{n}p(i/t)\log(p(i/t))} \tag{14.1.1779}$$

Candidate splits are determined by looking at each variable that makes up an object belonging in a given class. In the example above all objects can either be *plus* or *minus*.

Now for all possible split, we determine fist the entropy before the split which is found using the classification of each object (keep in mind that our dataset has 6 rows and the numerator of each fraction represent the number of occurrences of the concerned partition!):

$$S(\text{Class})=\frac{3}{6}S(\text{plus})+\frac{3}{6}S(\text{minus})=-\frac{3}{6}\log\left(\frac{3}{6}\right)-\frac{3}{6}\log\left(\frac{3}{6}\right)\cong 0.301$$

---

[60] ID3, C4.5 and C5.0 uses entropy information gain (IG) when CART uses the Gini impurity (see page 6839)

Now the conditional entropy for the *Class* given the *Color* attribute is given by :

$$S(C=\text{Class}, a=\text{Color}) = -\left(\frac{1}{6}S(B)+\frac{3}{6}S(R)+\frac{2}{6}S(G)\right)\cong 0.138$$

with (keep in mind that the denominator is always the number of rows of the corresponding partition, and the numerator correspond to how many of a given *Class* we have among all these rows):

- $S(B)=-(1/1)\cdot\log(1/1)=0$
- $S(R)=-(1/3)\cdot\log(1/3)-(2/3)\cdot\log(2/3)\cong 0.276$
- $S(G)=-(2/2)\cdot\log(2/2)=0$

The above definition of $S(C,a)$ is also sometimes defined is some textbooks with the following notation (where $\mathcal{T}$ is the partitioning):

$$\begin{aligned}H(\mathcal{T}\,|\,\mathcal{C}) &= \sum_{i=1}^{r}\frac{n_i}{n}H\left(\mathcal{T}\,|\,C_i\right) = -\sum_{i=1}^{r}\sum_{j=1}^{k}\frac{n_i}{n}\frac{n_{ij}}{n_i}\log\left(\frac{n_{ij}}{n_i}\right) = -\sum_{i=1}^{r}\sum_{j=1}^{k}\frac{n_{ij}}{n}\log\left(\frac{n_{ij}}{n_i}\right)\\ &= -\sum_{i=1}^{r}\sum_{j=1}^{k}p_{ij}\log\left(\frac{p_{ij}}{p_{C_i}}\right)\end{aligned}\tag{14.1.1780}$$

where $p_{ij}=\frac{n_{ij}}{n}$ is the probability that a point in cluster i also belongs to partition j. The more a cluster's members are split into different partitions, the higher the conditional entropy. For a perfect clustering, the conditional entropy value is zero, whereas the worst possible conditional entropy value is $\log(k)$. Further, expanding the previous relation, we can see that:

$$\begin{aligned}H(\mathcal{T}\,|\,\mathcal{C}) &= -\sum_{i=1}^{r}\sum_{j=1}^{k}p_{ij}\left[\log(p_{ij})-\log(p_{C_i})\right]\\ &= -\left(\sum_{i=1}^{r}\sum_{j=1}^{k}p_{ij}\log(p_{ij})\right)+\sum_{i=1}^{r}\left(\log(p_{C_i})\sum_{j=1}^{k}p_{ij}\right)\\ &= -\sum_{i=1}^{r}\sum_{j=1}^{k}p_{ij}\log(p_{ij})+\sum_{i=1}^{r}p_{C_i}\log(p_{C_i}) = H(\mathcal{C},\mathcal{T})-H(\mathcal{C})\end{aligned}\tag{14.1.1781}$$

where $H(\mathcal{C},\mathcal{T})=-\sum_{i=1}^{r}\sum_{j=1}^{k}p_{ij}\log(p_{ij})$ is the joint entropy of $\mathcal{C}$ and $\mathcal{T}$. The conditional entropy $H(\mathcal{T}\,|\,\mathcal{C})$ thus measures the remaining entropy of $\mathcal{T}$ given the clustering $\mathcal{C}$. In particular, $H(\mathcal{T}\,|\,\mathcal{C})=0$ if and only if $\mathcal{T}$ is completely determined by $\mathcal{C}$, corresponding to the ideal clustering. On the other hand, if $\mathcal{C}$ and $\mathcal{T}$ are independent of each other, then $H(\mathcal{T}\,|\,\mathcal{C})=H(\mathcal{T})$, which means that $\mathcal{C}$ provides no information about $\mathcal{T}$.

Remark

The "mutual information" tries to quantify the amount of shared information between the clustering $\mathcal{C}$ and partitioning $\mathcal{T}$, and it is defined as:

$$I(\mathcal{C},\mathcal{T})=\sum_{i=1}^{r}\sum_{j=1}^{k}p_{ij}\log\left(\frac{p_{ij}}{p_{C_i}\cdot p_{T_j}}\right) \tag{14.1.1782}$$

It measures the dependence between the observed joint probability p_{ij} of $\mathcal{C}$ and $\mathcal{T}$, and the expected joint probability $p_{C_i}\cdot p_{T_j}$ under the independence assumption. When $\mathcal{C}$ and $\mathcal{T}$ are independent then $p_{ij}=p_{C_i}\cdot p_{T_j}$, and thus $I(\mathcal{C},\mathcal{T})=0$. However, there is no upper bound on the mutual information.

Expanding this relation we observe that $I(\mathcal{C},\mathcal{T})=H(\mathcal{C})+H(\mathcal{T})-H(\mathcal{C},\mathcal{T})$. Using $H(\mathcal{T}\,|\,\mathcal{C})=H(\mathcal{C},\mathcal{T})-H(\mathcal{C})$ prove just earlier, we get the two equivalent expressions:

$$\begin{aligned}I(\mathcal{C},\mathcal{T})&=H(\mathcal{T})-H(\mathcal{T}\,|\,\mathcal{C})\\ I(\mathcal{C},\mathcal{T})&=H(\mathcal{C})-H(\mathcal{C}\,|\,\mathcal{T})\end{aligned} \tag{14.1.1783}$$

The "information gain" (IG) is then be defined by finding the difference in the prior entropy and the conditional entropy for the class C given a specific attribute variable a:

$$\boxed{\text{IG}(C,a)=S(C)-S(C,a)=\left(-\sum_{t=1}^{m}f_t\log(f_t)\right)-\left(-\sum_{t=1}^{m}f_t\sum_{i=1}^{n}p(i/t)\log(p(i/t))\right)} \tag{14.1.1784}$$

We also recognize here that the information gain is simply the relation derived in the remark box above:

$$I(\mathcal{C},\mathcal{T})=H(\mathcal{C})-H(\mathcal{C}\,|\,\mathcal{T}) \tag{14.1.1785}$$

Therefore in our example here the information gain for colors is:

$$\text{IG}(\text{Class},\text{Color})=S(\text{Class})-S(\text{Class},\text{Color})\cong 0.301-0.459=-0.158$$

And now the conditional entropy for the *Class* given the *Shape* attribute is then given by (we change to notation for the entropy from H to S in the second term to avoid having to write an ugly $S(S)$...):

$$S(\text{Class},\text{Shape})=\frac{4}{6}S(R)+\frac{2}{6}H(S)=1$$

with:

- $S(R)=-(2/4)\cdot\log(2/4)-(2/4)\cdot\log(2/4)$
- $S(S)=-(1/2)\cdot\log(1/2)-(1/2)\cdot\log(1/2)$

Therefore the information gain for *Shape* is:

$$\text{IG}(\text{Class},\text{Shape})=S(\text{Class})-S(\text{Class},\text{Shape})\cong 0.301-1=-0.699$$

And finally the conditional entropy for the *Class* given the *Size* attribute is then given by:

$$S(\text{Class, Size})=\frac{4}{6}S(B)+\frac{2}{6}H(S)=0.541$$

with:

- $S(B)=-(1/4)\cdot\log(1/4)-(3/4)\cdot\log(3/4)$
- $S(S)=-(2/2)\cdot\log(2/2)$

Therefore the information gain for sizes is:

$$\text{IG}(\text{Class, Size})=S(\text{Class})-S(\text{Class, Size})\cong 0.301-0.541=-0.24$$

As the variables with lower conditional entropy (respectively highest information gain) are the one to split, then we will chose the *Color* attribute as first split in our example! So here the split choice is the same as with the Gini impurity index. So we see that in classification trees, the overall information entropy can be used as "variable importance" metric for classification trees!

The problem with information gain as a measure to select the attribute for partition is that in the quest of pure partition, it may select attributes that are meaningless from the Machine Learning point of view. This drawback is due to the inherent deficiency in the measure information gain that gives preference to the attribute that can divide the parent dataset to datasets with the least amount of entropy.

Remark

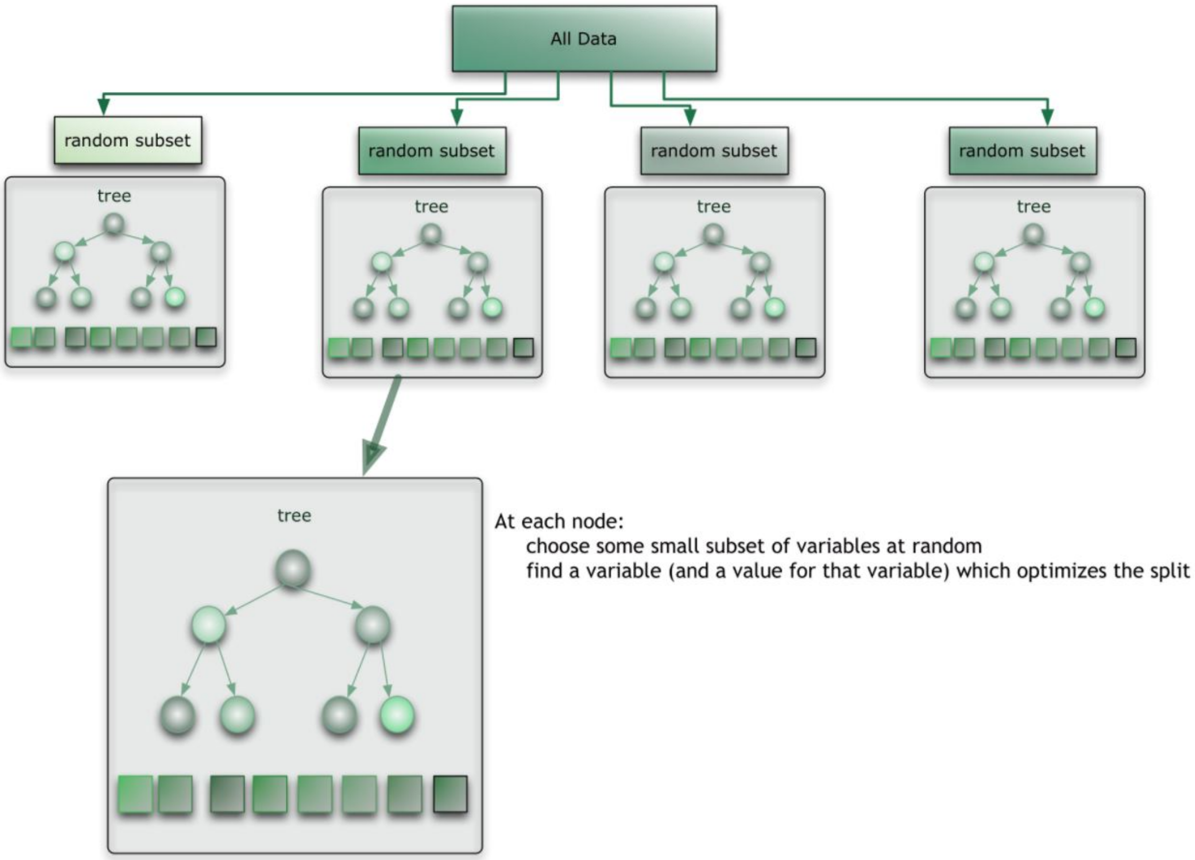
Notice that there are a lot of other segmentation criteria as the likelihood-ratio chi-squared statistic, the DKM criterion, the Twoing criterion, the Orthogonal criterion (ORT), the Kolmogorov-Smirnoff criterion, the AUC-Splitting criterion, ...

And as mentioned above, we will stop here about our study of CART because the study of the corresponding empirical variations techniques are a full time job as they are numerous (and almost none gives the same results...).

14.1.20.5.3.4 Random Forests

The random forest (see figure below) takes the notion of binary decision tree to the next level by combining trees with the notion of an ensemble. Thus, in ensemble terms, the standard decision trees are weak learners and the random forest is a strong learner (in the sense of a statistical crows sourcing).

In other words "random forests" or "random decision forests" are an ensemble learning method for classification, regression and other tasks, that operate by constructing a multitude of decision trees at training time and outputting the class that is the mode of the classes (classification) or mean prediction (regression) of the individual trees. Random decision forests correct for decision trees' habit of overfitting to their training set.



At each node:
choose some small subset of variables at random
find a variable (and a value for that variable) which optimizes the split

Figure 14.148: Random Forster illustration (author: ?)

Here is how such a system is trained; for some number of trees:

1. Sample N cases at random with replacement to create a subset of the data (see top layer of figure above). The subset should be about 66% of the total set.
2. At each node:
   (a) For some number m, m predictor variables are selected at random from all the predictor variables.
   (b) The predictor variable that provides the best split, according to some objective function, is used to do a binary split on that node.
   (c) At the next node, choose another m variables at random from all predictor variables and do the same.

For prediction with a new entered input into the system, it is run down all of the trees. The result may either be an average or weighted average of all of the terminal nodes that are reached, or, in the case of categorical variables, a voting majority.

Note that:

- With a large number of predictors, the eligible predictor set will be quite different from node to node.

- The greater the inter-tree correlation, the greater the random forest error rate, so one pressure on the model is to have the trees as uncorrelated as possible.
- As m goes down, both inter-tree correlation and the strength of individual trees go down. So some optimal value of m must be discovered.

Random forest runtimes are quite fast, and they are able to deal with unbalanced and missing data. Random Forest weaknesses are that when used for regression they cannot predict beyond the range in the training data, and that they may over-fit data sets that are particularly noisy. Of course, the best test of any algorithm is how well it works upon your own data set.

To understand why random forest works quite good you must first remember the bias-variance tradeoff relation (see earlier above page 6798) that is given by:

$$\text{E}\left[(y-\hat{f})^2\right]=\sigma_\varepsilon^2+\text{V}(\hat{f})+\text{Bias}(\hat{f})^2 \tag{14.1.1786}$$

So first, if the trees are sufficiently deep, they have very small bias!

Now let us recall the variance of the mean of identically correlated i.i.d variables (see section Statistics 620):

$$\text{V}(\bar{X})=\rho\sigma^2+\frac{1-\rho}{B}\sigma^2 \tag{14.1.1787}$$

So to improve the variance over that of a single tree, we see that de-correlation gives better accuracy as a small ρ decrease the first term, but we also see that the second term decrease if the number of trees B increase (independently of ρ)! So the idea in random forests is to improve the variance reduction of bagging by reducing the correlation between the trees, without increasing the variance too much. This is achieved in the tree-growing process through random selection of the input variables.

Why would anyone use logistic regression when machine learning models like Random Forest often predict better?

Because sometimes, prediction isn't the main goal! If we want to assess whether a treatment or a biomarker has a real effect on a health outcome, we need to quantify the relationship and test whether it's statistically significant. That's where logistic regression becomes more relevant than Random Forests.

14.1.20.5.4 k-means clustering

The "k-means" algorithm or "mobile centers", also sometimes named "classification method with dynamic clouds" is in statistics and Machine Learning (specifically unsupervised learning), a data partitioning algorithm, i.e. a method that aims to divide observations in K clusters in which each observation belongs to the partition with the nearest average (mean).

The basic steps of the algorithm are as follows:

1. We choose a partitioning into K groups

2. We generate K averages (centers c_i) randomly
3. The data are assigned to the group whose center is closest to them
4. We calculated the average of each group using the affected data (new centers)
5. We return to step 3

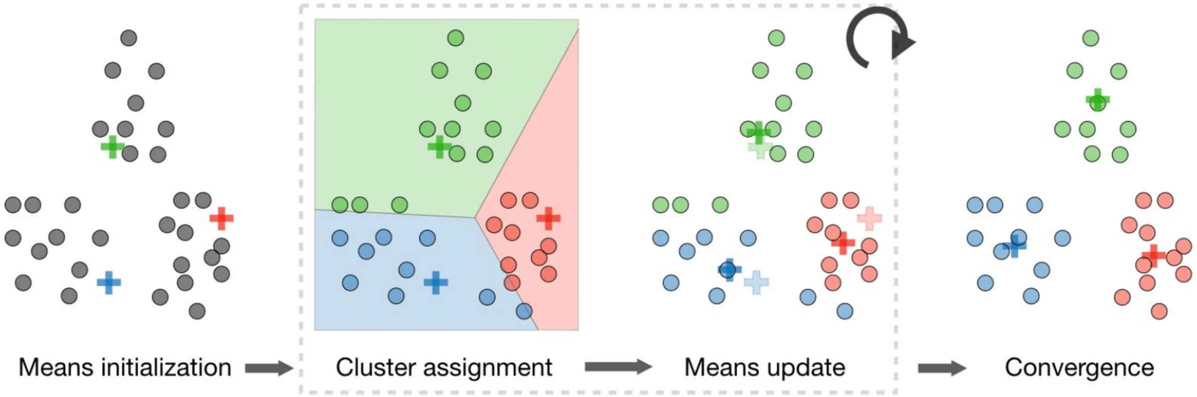


Figure 14.149: k-means iterative algorithm (authors: Afshine Amidi, Shervine Amidi)

To make more explicit the algorithm each step will be illustrated by means of the following small dataset:

Object	Weight	Length
a	12	10
b	15	25
c	30	55
d	50	100
e	35	70
f	45	70
g	35	60

we determine k temporary centers of k clusters generally by randomly dragging k individuals from the database. These k individuals form the center of the k clusters. To achieve the first clustering, we assign each individual to the cluster of which it is closest. Here the notion of proximity is understood in a measure of the Euclidean distance:

$$d(\vec{x}_i,\vec{c}_k)=\sqrt{\sum_{j=1}^{n}(x_{ij}-c_{kj})^2} \tag{14.1.1788}$$

For $k=2$, we will randomly select k individuals, here the object a and the object d for example:

Clusters	Objects	Centers
Cluster c_1	$c_1\{\text{a}\}$	$(12,10)$
Cluster c_2	$c_2\{\text{d}\}$	$(50,100)$

Now we must calculate the Euclidean distance of each individual with respect to the centers and assign each to the cluster that is closer to it:

Objects	**Distance Cluster 1**	**Distance Cluster 2**	**Affectation To**
a	0.00	97.69	Cluster c_1
b	15.30	82.76	Cluster c_1
c	48.47	49.24	Cluster c_1
d	97.69	0.00	Cluster c_2
e	64.26	33.54	Cluster c_2
f	68.48	30.41	Cluster c_2
g	55.04	42.72	Cluster c_2

Then, we again determine the k centers of the k last partitions performed. The distances of each individual with respect to these centers are recalculated and each is reallocated according to the cluster that is close to it.

Following the last clustering we obtain the center (point of gravity or barycenter) of each partitions like this:

Clusters	**Objects**	**Centers**
Cluster c_1	$c_1\{\mathrm{a, b, c}\}$	$(19, 30)$
Cluster c_2	$c_2\{\mathrm{d, e, f, g}\}$	$(41.25, 75)$

Again, it is necessary to calculate the Euclidean distance of each individual with respect to the centers and reassign each to the cluster that is closer to it:

Objects	**Distance Cluster 1**	**Distance Cluster 2**	**Affectation To**
a	21.19	71.28	Cluster c_1
b	6.40	56.47	Cluster c_1
c	27.31	22.95	Cluster c_2
d	76.56	26.49	Cluster c_2
e	43.08	8.00	Cluster c_2
f	47.71	6.25	Cluster c_2
g	34.00	16.25	Cluster c_2

We see at this level that the object c change the group (centroid) he belongs to before.

This last step is repeated as many times as necessary until the process is stabilized. The algorithm can be stopped either:

- Because we do not observe changes anymore in the composition of each cluster after two successive iterations
- Because an empirical control criterion is verified (number of iteration fixed for example)

In the previous illustration, it is rather the first reason that will decide the end of the clustering. Indeed, at the 3rd iteration there is no change in the composition of the clusters.

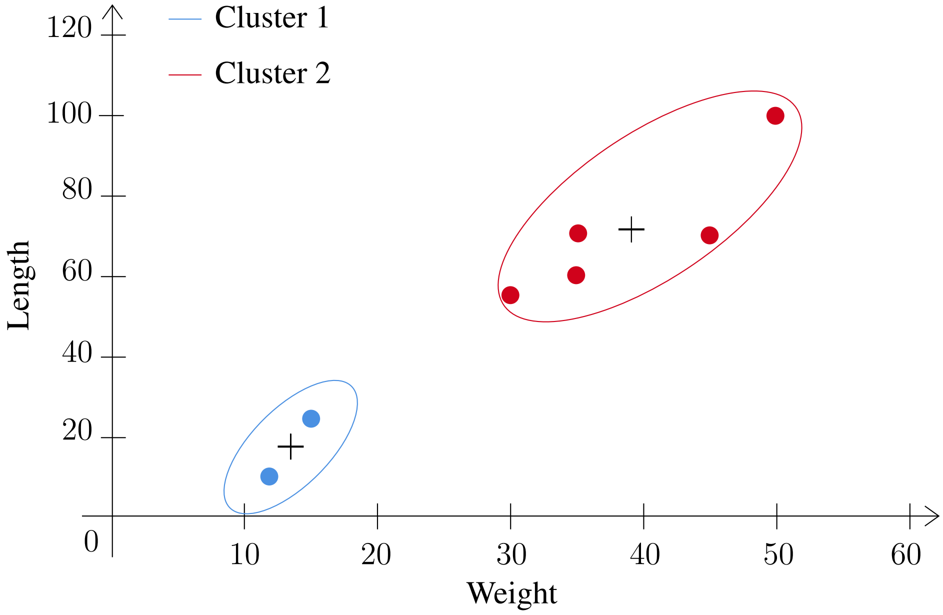
New centers following last assignment:

Clusters	**Objects**	**Centers**
Cluster c_1	$c_1\{\mathrm{a},\mathrm{b}\}$	$(13.5, 17.5)$
Cluster c_2	$c_2\{\mathrm{d},\mathrm{e},\mathrm{f},\mathrm{g}\}$	$(39, 71)$

Distance calculation and reallocation:

Objects	**Distance Cluster 1**	**Distance Cluster 2**	**Affectation To**
a	7.65	66.71	Cluster c_1
b	7.65	51.88	Cluster c_1
c	40.97	18.36	Cluster c_2
d	90.21	31.02	Cluster c_2
e	56.73	4.12	Cluster c_2
f	61.22	6.08	Cluster c_2
g	47.63	11.70	Cluster c_2

It is clear that the composition of the clusters does not change anymore and a projection of the clusters on a chart gives:



So we see with this small previous example that our problem is the same as minimizing the enlarged criterion:

$$K_{\text{means}} \min \sum_{k=1}^{K} \sum_{C(i)=k} ||\vec{x}_i - \vec{c}_k||^2 \qquad (14.1.1789)$$

over bother clusterings C and $c_1, \ldots, c_K \in \mathbb{R}^p$. That is to say, minimize the "within-cluster sum of squares" (WCSS).

Remark

k-means is as we have already mentioned it a hard assignment version of the soft assignment variant of EM (see above page 6697), with the assumptions that clusters are spherical (plus all variables must have same variance and the prior probability for all clusters are the same, i.e. each cluster has roughly equal number of observations). Here "spherical" means identical variance-covariance matrices for each cluster (assuming gaussian distribution), which is also known as "model-based clustering". Furthermore notice that there is no "k-means algorithm". There is MacQueens algorithm for k-means, the Lloyd/Forgy algorithm for k-means, the Hartigan-Wong method, ...

The procedure describe above is the Lloyds algorithm (the one assumed by default in most cheap books on Data Science, it is sometimes also referred to as "naive k-means", because there exist much faster alternatives) that consists of two step given a set of k-means $m_1^{(1)}, \ldots, m_k^{(1)}$ and therefore of $S = \{S_1, S_2, \ldots, S_k\}$ clusters:

- the E-step (assignment step), where each object is assigned to the centroid such that it is assigned to the most likely cluster using the shortest euclidean distance):

$$S_i^{(t)} = \{x_p : \left\|x_p - m_i^{(t)}\right\|^2 \leq \left\|x_p - m_j^{(t)}\right\|^2 \forall j, 1 \leq j \leq k\} \quad (14.1.1790)$$

- the M-step (update step), where the model (=centroids) are recomputed (= least squares optimization):

$$m_i^{(t+1)} = \frac{1}{\left|S_i^{(t)}\right|} \sum_{x_j \in S_i^{(t)}} x_j \quad (14.1.1791)$$

... iterating these two steps, as done by Lloyd, makes this effectively an instance of the general EM scheme.

We see also well through the previous step-by-step example that the k-means algorithm (which therefore belongs to non-hierarchical clustering techniques) however does not necessarily converge to an optimal solution. Let us recall that a global optimization calculation is inconsistent with the data volumes used, regardless of the power of computers. Thus, the k-means will use iterative algorithms to reach a local optimum. It is also an algorithm that will try to find the best K initial points.

Some software gives you the ability to set the initial values and this will affect the final quality of the typology, knowing that there is ONE no good initial choice. This varies depending on the configuration of data, on the return of experience (REX) and even the chance...

There are three common solutions:

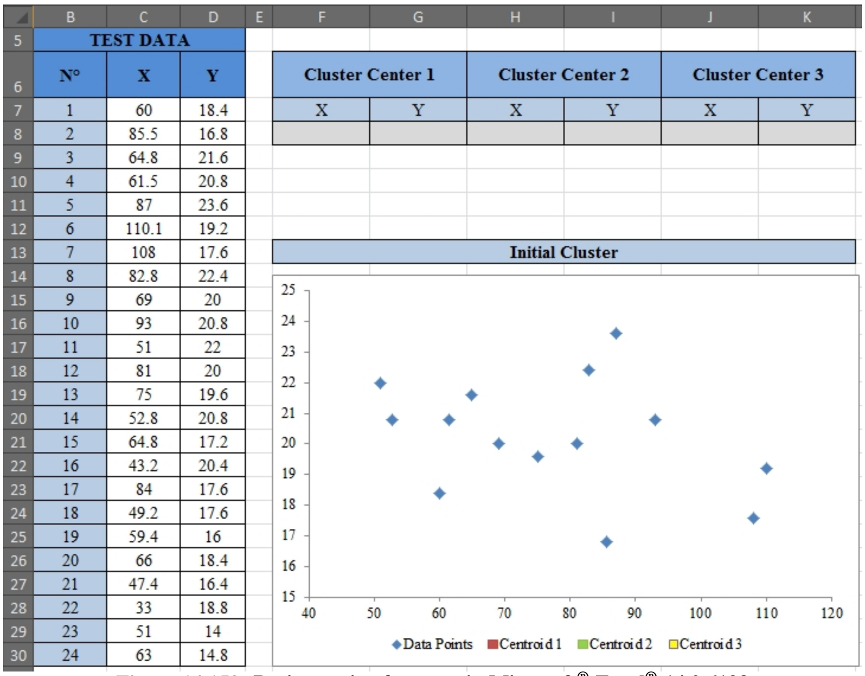
1. The software determines the K initial points randomly. It can perform a number of tests and he will choose the most conclusive one.

2. We use the expert opinion that suppose someone has a fairly good knowledge of the study population for attaching to each class an ideal type. This may or not be a real individual.

3. The software distribute the K initial points not randomly but according to some empirical algorithms.

Let us see a further step that is instructive to show how to implement this technique in a spreadsheet software like Microsoft® Excel® 14.0.6123 with genetic algorithms (see further below).

For this, we will first consider the following structure for which the idea is to establish three centers (so it is a 3-means):



TEST DATA		
N°	X	Y

Figure 14.155: k**-means final associations with Minitab 15.1.1 values**

The huge difference between Microsoft® Excel® and any other statistical software is quite simple to explain! Software such as Microsoft® Excel® 14.0.6123 minimizes the distance points to the centers but is unable simultaneously to maximize the distance between the centers. Again the statistical software have algorithms implemented for this purpose. More in details the idea is the following:

The quality/assessment of a clustering[61] is many times measured as following:

- We use the "cluster cohesion", also named "with sum of squares", already introduced earlier (we just generalize the notation without expliciting the type of distance/metric):

$$\text{WSS}=\sum_{k=1}^{K}\sum_{C(i)=k} d^2(\vec{x}_i-\vec{c}_k) \qquad (14.1.1792)$$

  In practice the purpose is to minimize it.

- We introduce the "cluster separation", also named "between sum of squares", defined by:

$$\text{BSS}=\sum_{k=1}^{K} n_k d^2(\vec{c}_k,\vec{C}) \qquad (14.1.1793)$$

  where n_k is the number of points in cluster number k and C is the barycenter of all clusters. In practice the purpose is to maximize it.

Using the properties of the barycenter (see section Geometry page 2635), we can then write the total sum of squares:

$$\boxed{\underbrace{\sum_{i=1}^{n} d^2(\vec{x}_i,C)}_{\text{TSS}}=\underbrace{\sum_{k=1}^{K}\sum_{C(i)=k} d^2(\vec{x}_i-\vec{c}_k)}_{\text{WSS}}+\underbrace{\sum_{k=1}^{K} n_k d^2(\vec{c}_k,\vec{C})}_{\text{BSS}}} \qquad (14.1.1794)$$

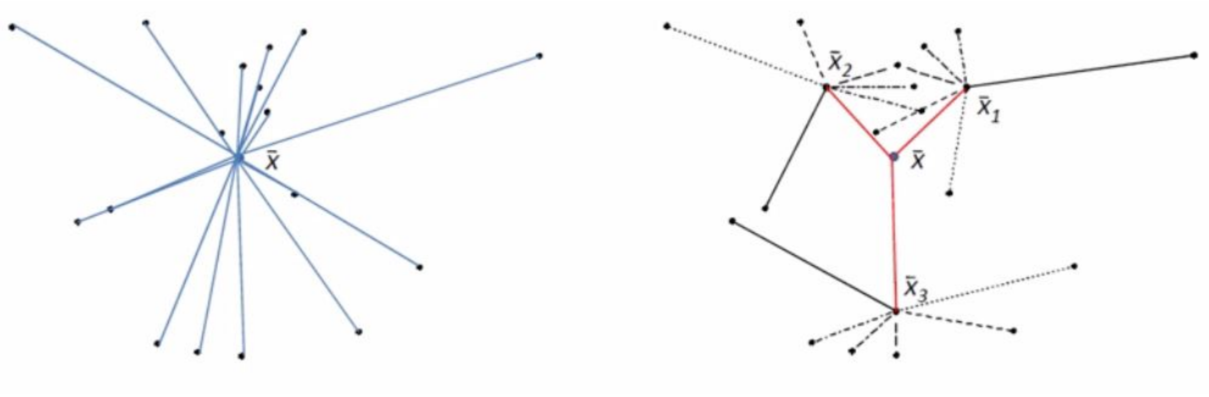
---

[61] In an unsupervised learning setting, it is often hard to assess the performance of a model since we don't have the ground truth labels as was the case in the supervised learning setting.

That latter relation is also often written as:

$$\underbrace{\sum_{q=1}^{Q}\sum_{i=1}^{I}(x_{iq}-\bar{x})^2}_{\text{Total inertia}}=\underbrace{\sum_{q=1}^{Q}\sum_{i=1}^{I}(x_{iq}-\bar{x}_q)^2}_{\text{Intra inertia}}+\underbrace{\sum_{q=1}^{Q}\sum_{i=1}^{I}(\bar{x}_q-\bar{x})^2}_{\text{Inter inertia}} \tag{14.1.1795}$$

with the following companion illustration:



$\bar{x}$
$\bar{x}_2$
$\bar{x}_1$
$\bar{x}$
$\bar{x}_3$

Figure 14.156: k-means BSS and WSS

So in practice, the k-means method is fully encompassed based on the above fundamental relation. It is then quite easy to understand that if Intra-cluster inertia decreases the inter-cluster inertia increases and vice versa.

Therefore with Tanagra 1.4.44 we get for example:

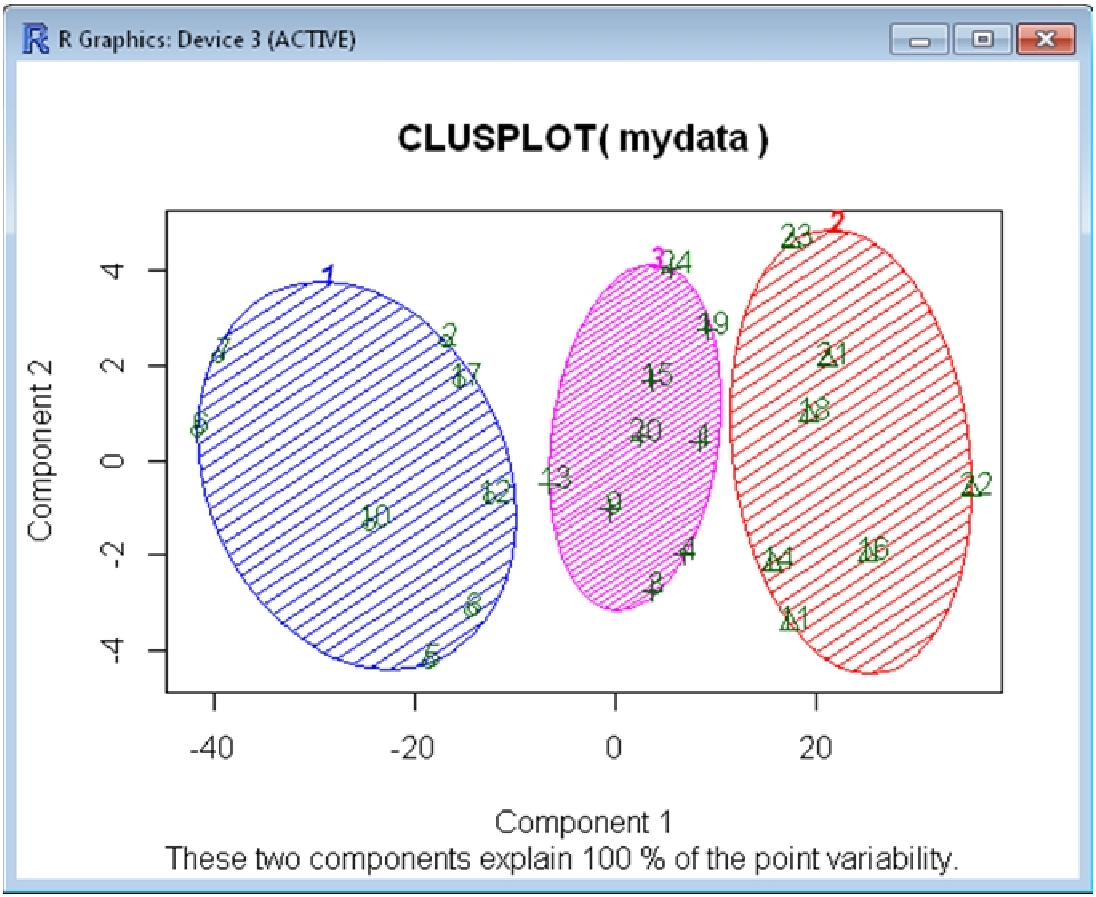

Figure 14.158: k-means final associations in `R` 3.0.2

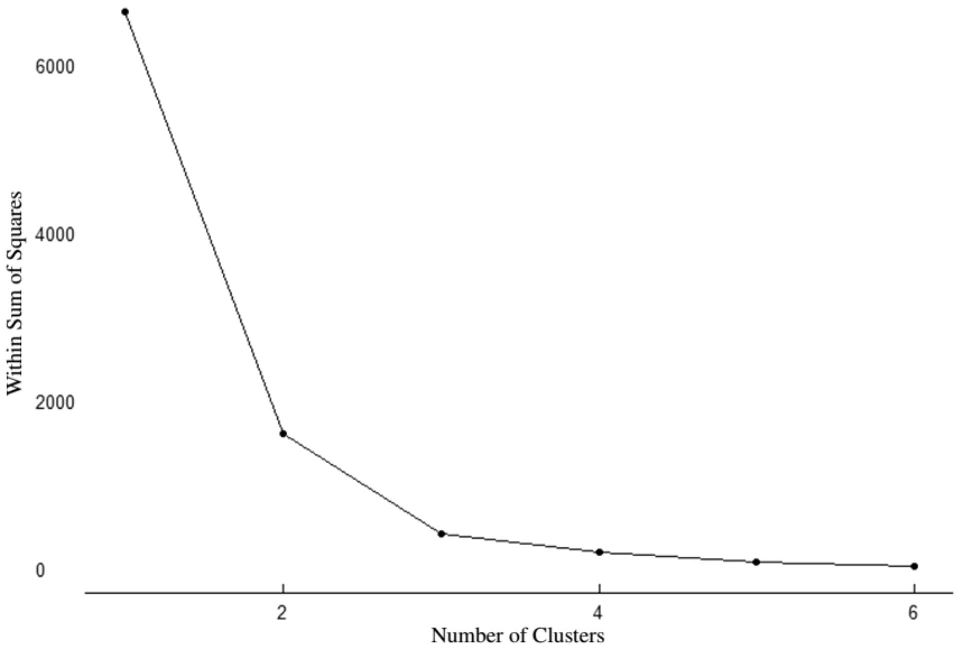
A major difficulty with the k-means is to choose the number of clusters. For this let us recall the fundamental relation of k-means:

$$\underbrace{\sum_{i=1}^{n} d^2(x_i,C)}_{\text{TSS}}=\underbrace{\sum_{k=1}^{K}\sum_{C(i)=k} d^2(\vec{X}_i-\vec{c}_k)}_{\text{WSS}}+\underbrace{\sum_{k=1}^{K} n_k d^2(\vec{c}_k,\vec{C})}_{\text{BSS}} \tag{14.1.1796}$$

The strategy commonly chosen to choose the right K is to make vary WSS as a function of k and to take the last of k which induces a considerable reduction of WSS. Geometrically speaking, at this optimal point, we observe a kind of "elbow" (or "knee") forming on the plot of $\text{WSS}=f(K)$:



In the case of our first k-means clustering, the partition in $K=2$ is more interesting, because not only does it induce a considerable gain in information (according to the figure above), thus a significant loss or reduction of WSS, but also it offers clusters having more than 2 individuals. Beyond this, for example, for $K=3$, the gain in information is no longer significant and we will obtain a cluster with only 1 individual (not very relevant for a group analysis...).

In addition to homogeneity of the observations within each group, we also seek heterogeneity of the groups; hence, intuitively, an F -like statistic as a ratio of the between-group dissimilarity to the within-group dissimilarity could be used to indicate the goodness of a given clustering. We define a "pseudo F":

$$\widetilde{F}_K=\dfrac{\text{BSS}/(K-1)}{\text{WSS}/(n-K)} \tag{14.1.1797}$$

This measure is also named the "Calinski-Harabasz index". The larger that ratio, the better the clustering at any fixed number of clusters.

A practical approach to the problem is to vary K, as $K_0,K_0+1,\ldots$, computing $\widetilde{F}_K$, which will initially increase fairly rapidly, and to choose the value of K as the point at which $\widetilde{F}_{K+1}-\widetilde{F}_K$ is relatively small. This is similar to the type of approach in a different context; that is, choosing the number of principal components.

Remarks

R1. In some applications we want each center to be one of the point itself. This is where "K-medoids" (partition around medoids) comes in an algorithm similar to the k-means algorithm, except when fitting the centers $c_1,\ldots,c_K$, we restrict our attention to the point themselves. Generally K-medoids obviously return a higher value of K_{means}. There is also on example in our R companion book.

R2. Obviously as for the k-nn, we may run the k-means on the factorial space obtained after having run a PCA (Principal Component Analysis as seen on page 1213) on our data. We can also even reduce the dimensions using that latter if necessary!

A very common simple assessment metric is the "silhouette coefficient" given as graphical output in most statistical software and defined as given an observation $\vec{x} \in \mathcal{D}$ by:

$$\boxed{s(\vec{x}) = \frac{b(\vec{x}) - a(\vec{x})}{\max(a(\vec{x}), b(\vec{x}))}} \tag{14.1.1798}$$

where $a(\vec{x})$ is the average distance of $\vec{x}$ to all other elements in the cluster it belongs to and $b(\vec{x})$ is the smallest value that could take $a(\vec{x})$, if a belonged to another cluster:

$$a(\vec{x}) = \frac{1}{\left|\mathcal{C}_{k(\vec{x})}\right| - 1} \sum_{\vec{u} \in \mathcal{C}_{k(\vec{x})}, \vec{u} \neq \vec{x}} d(\vec{u}, \vec{x}) \qquad b(\vec{x}) = \min_{l \neq k(\vec{x})} \frac{1}{|\mathcal{C}_l|} \sum_{\vec{u} \in \mathcal{C}_l} d(\vec{u}, \vec{x}) \tag{14.1.1799}$$

The silhouette coefficient of $\vec{x}$ is all the closer to 1 as its assignment to the cluster $\mathcal{C}_{k(\vec{x})}$ is satisfactory.

The "global silhouette coefficient" of the clustering is the average of all silhouette coefficients:

$$s = \frac{1}{n} \sum_{i=1}^{n} s\left(\vec{x}^i\right) \tag{14.1.1800}$$

14.1.20.5.5 Support Vector Machines (SVM) classifier

"Support vector machines" (SVM) is learning method used for binary classification[62] that searches for so-named "support vectors" which are observations that are found to lie at the edge of an area in space which presents a boundary between one of these classes of observations (e.g., the squares) and another class of observations (e.g., the circles). SVM seems to have been introduced by Vladimir Vapnik and colleagues. The earliest mention was in (Vapnik, 11979 according to holocene calendar), but the first main paper seems to be (Vapnik, 11995 according to holocene calendar). In the terminology of SVM we talk about the space between these two regions as the "margin" between the classes. Each region contains observations with the same value for the target variable (i.e., the class). The support vectors, and only the support vectors, are used to identify a hyperplane (a straight line in two dimensions) that separates the classes. The maximum margin between the separable classes is sought. This then represents the model.

---

[62] In its most simple type, SVM doesn't support multiclass classification natively. It supports binary classification and separating data points into two classes. For multiclass classification, the same principle is utilized after breaking down the multiclassification problem into multiple binary classification problems.

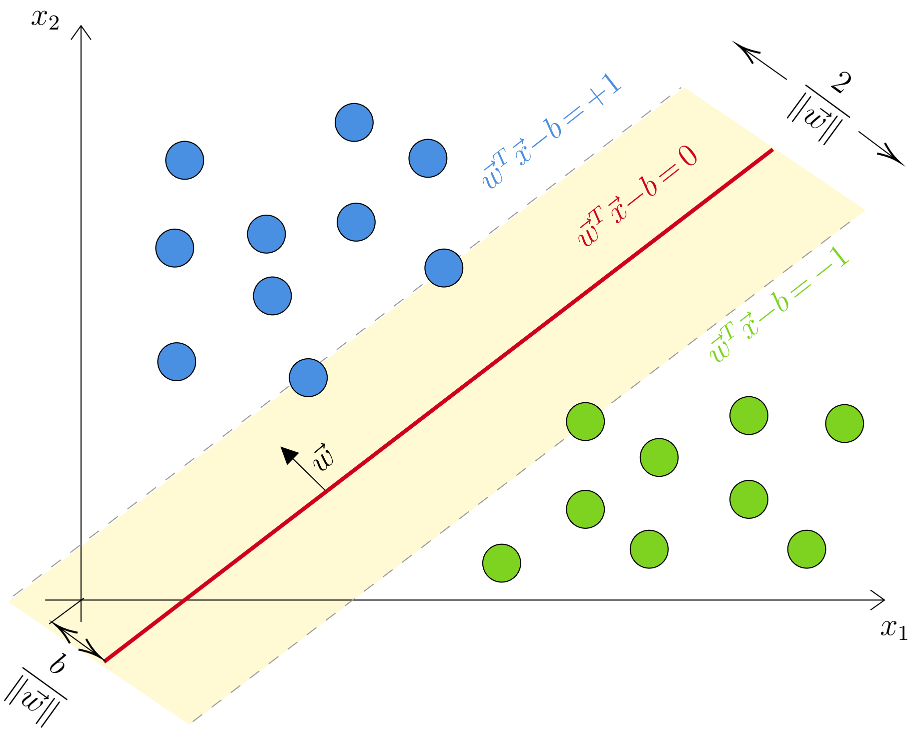


Figure 14.159: SVM idea (source: Wikipedia)

It is usually quite rare that we can separate the data with a straight line (or a hyperplane when we have more than two input variables). That is, the data is not usually distributed in such a way that it is "linearly separable". When this is the case, a technique is used to combine (or remap) the data in different ways, creating new variables so that the classes are then more likely to become linearly separable by a hyperplane (i.e., so that with the new dimensional data there is a gap between observations in the two classes). We can use the model we have built to score new observations by mapping the data in the same way as when the model was built, and then decide on which side of the hyperplane the observation lies and hence the decision associated with it.

Support vector machines have been found to perform well on problems that are non-linear, sparse, and high-dimensional. A disadvantage is that the algorithm is sensitive to the choice of tuning option (e.g., the type of transformations to perform), making it harder to use and time consuming to identify the best model. Another disadvantage is that the transformations performed can be computationally expensive and are performed both whilst building the model and when scoring new data.

An advantage of the method is that the modelling only deals with these support vectors rather than the whole training dataset, and so the size of the training set is not usually an issue. Also, as a consequence of only using the support vectors to build a model, the model is less affected by outliers.

Ok let us first introduce the idea in a gently way...:

Let $\mathcal{D}=\{(\vec{x}_i,y_i)\}_{i=1}^n$ be a classification dataset, with n points in a d-dimensional space. Further, let us assume that there are only two class labels, that is, $y_i\in\{+1,-1\}$ denoting the positive and negative classes.

A hyperplane in d dimensions is given as the set of all points $\vec{x}\in\mathbb{R}^d$ that satisfy the equation $h(\vec{x})=0$, where $h(\vec{x})$ is the hyperplane function, defined as follows (see section Analytical Geometry page 2800):

$$h(\vec{x})=\vec{w}^T\vec{x}+b=w_1x_1+w_2x_2+\ldots+w_dx_d+b \tag{14.1.1801}$$

Here, $\vec{w}$ is a dimensional weight vector and b is a scalar, named without surprise the "bias". For points that lie on the hyperplane, we have:

$$h(\vec{x})=\vec{w}^T\vec{x}+b=0 \tag{14.1.1802}$$

The hyperplane is thus defined as the set of all points such that $\vec{w}^T\vec{x}=-b$. To see the role played by b, assuming that $w_1\neq 0$, and setting $x_i=0$ for all $i>1$, we can obtain the offset where the hyperplane intersects the first axis. Therefore we have obviously:

$$w_1x_1=-b \quad \text{or} \quad x_1=\frac{-b}{w_1} \tag{14.1.1803}$$

In other words, the point:

$$\left(\frac{-b}{w_1},0,\ldots,0\right) \tag{14.1.1804}$$

lies on the hyperplane (and it's module is equal to the perpendicular distance from the hyperplane to the origin!). In a similar manner, we can obtain the offset where the hyperplane intersects each of the axes, which is given as $-b/w_i$ (provided $w_i\neq 0$).

A hyperplane splits the original d -dimensional space into two half-spaces (remember the first figure above depicting the idea!). A dataset is said to be "linearly separable" if each half-space has points only from a single class. If the input dataset is linearly separable, then we can find a separating hyperplane $h(\vec{x})=0$, such that for all points labelled $y_i=-1$, we have $h\left(\vec{x}_i\right)<0$, and for all points labelled $y_i=+1$, we have $h\left(\vec{x}_i\right)>0$. In fact, the hyperplane function $h(\vec{x})$ serves as a linear classifier or a linear discriminant, which predicts the class y for any given point x, according to the decision rule:

$$y=\begin{cases}+1 & \text{if } h(\vec{x})>0\\ -1 & \text{if } h(\vec{x})<0\end{cases} \tag{14.1.1805}$$

Let $\vec{a}_1$ and $\vec{a}_2$ be two arbitrary points that lie on the hyperplane. From the hyperplane equation we have:

$$\begin{aligned}h\left(\vec{a}_1\right)=\vec{w}^T\vec{a}_1+b=0\\ h\left(\vec{a}_2\right)=\vec{w}^T\vec{a}_2+b=0\end{aligned} \tag{14.1.1806}$$

Subtracting one from the other we obtain:

$$\vec{w}^T\left(\vec{a}_1-\vec{a}_2\right)=0 \tag{14.1.1807}$$

This means without surprise (as we also proved it in the section of Analytical Geometry) that the weight vector $\vec{w}$ is orthogonal to the hyperplane because it is orthogonal to any arbitrary vector $\left(\vec{a}_1-\vec{a}_2\right)$ on the hyperplane. In other words, the weight vector $\vec{w}$ specifies the direction that is normal to the hyperplane, which fixes the orientation of the hyperplane, whereas the bias b fixes the offset of the hyperplane in the d-dimensional space. Because both $\vec{w}$ and $-\vec{w}$ are normal to the hyperplane, we remove this ambiguity by requiring that $h(\vec{x}_i)>0$ when $y_i=1$, and $h(\vec{x}_i)<0$ when $y_i=-1$.

Ok now that we have finished with the gentle introduction let's go more in the maths with a text completely inspired from [185]!

We are given l training examples $\{\vec{x}_i,y_i\},\; i=1,\ldots,L$, where each example has d inputs ($\vec{x}_i\in\mathbb{R}^d$), and a class label with one of two values $y_i\in\{-1,1\}$.

Now, all hyperplanes in $\mathbb{R}^d$ are parametrized by a vector ($\vec{w}$), and a constant (b), expressed in the equation:

$$\vec{w}\circ\vec{x}+b=0 \tag{14.1.1808}$$

(recall again that $\vec{w}$ is in fact the vector orthogonal to the hyperplane). Given such a hyperplane ($\vec{w}$,b) that separates the data, this gives the function:

$$f(\vec{x})=\text{sgn}(\vec{w}\circ\vec{x}+b) \tag{14.1.1809}$$

which correctly classifies the training data (and hopefully other "testing" data it hasn't seen yet).

However, a given hyperplane represented by ($\vec{w}$,b) is equally expressed by all pairs $\{\lambda\vec{w},\lambda b\}$ for $\lambda\in\mathbb{R}^+$. So we define the "canonical hyperplane" to be that which separates the data from the hyperplane by a "distance" of at least[63] 1. That is, we consider those that satisfy:

$$\begin{aligned}\vec{x}_i\circ\vec{w}+b\geq+1 &\quad\text{when}\quad y_i=+1\\ \vec{x}_i\circ\vec{w}+b\leq-1 &\quad\text{when}\quad y_i=-1\end{aligned} \tag{14.1.1810}$$

or more compactly:

$$y_i(\vec{x}_i\circ\vec{w}+b)\geq 1 \qquad \forall i \tag{14.1.1811}$$

That we often write as:

$$y_i(\vec{x}_i\circ\vec{w}+b)-1\geq 0 \qquad \forall i \tag{14.1.1812}$$

All such hyperplanes have a "functional distance" ≥ 1 (quite literally, the function's value is ≥ 1). This shouldn't be confused with the "geometric" or "Euclidean distance" (also known as the "margin"). For a given hyperplane ($\vec{w}$,b), all pairs $\{\lambda\vec{w},\lambda b\}$ define the exact same hyperplane, but each has a different functional distance to a given data point.

To obtain the geometric distance from the hyperplane to a data point, we must normalize by the magnitude of $\vec{w}$. This distance is simply:

$$d\Big((\vec{w},b)\;,\;\vec{x}_i\Big)=\frac{y_i(\vec{x}_i\circ\vec{w}+b)}{\|\vec{w}\|}\geq\frac{1}{\|\vec{w}\|} \tag{14.1.1813}$$

Intuitively, we want the hyperplane that maximizes the geometric distance to the closest data points.

---

[63] In fact, we require that at least one example on both sides has a distance of *exactly* 1. Thus, for a given hyperplane, the scaling (the λ) is implicitly set.

As simple vector geometry shows that the margin is equal to $1/\|\vec{w}\|$ and maximizing it subject to the constraint in:

$$y_i(\vec{x}_i \circ \vec{w} + b) - 1 \geq 0 \quad \forall i \tag{14.1.1814}$$

is equivalent to find:

$$\min \|\vec{w}\| \quad \text{such that} \quad y_i\left(\vec{x}_i \circ \vec{w} + b\right) - 1 \geq 0 \quad \forall_i \tag{14.1.1815}$$

Minimize $\|\vec{w}\|$ is equivalent to minimize $\frac{1}{2}\|\vec{w}\|^2$ and the use of this term makes it possible to perform Nonlinear Programming (see page 6662) optimization later on. We therefore need to find:

$$\min \frac{1}{2}\|\vec{w}\|^2 \quad \text{s.t.} \quad y_i\left(\vec{x}_i \circ \vec{w} + b\right) - 1 \geq 0 \quad \forall_i \tag{14.1.1816}$$

In order to cater for the constraints in this minimization, we need to allocate them Lagrange multipliers (see page 6667) α, where[64] $\alpha_i \geq 0\,\forall_i$:

$$\begin{aligned} L_P &= \frac{1}{2}\|\vec{w}\|^2 - \alpha\left[y_i\left(\vec{x}_i \circ \vec{w} + b\right) - 1\right] \quad \forall_i \\ &= \frac{1}{2}\|\vec{w}\|^2 - \sum_{i=1}^{L} \alpha_i\left[y_i\left(\vec{x}_i \circ \vec{w} + b\right) - 1\right] \\ &= \frac{1}{2}\|\vec{w}\|^2 - \sum_{i=1}^{L} \alpha_i y_i\left(\vec{x}_i \circ \vec{w} + b\right) + \sum_{i=1}^{L} \alpha_i \end{aligned} \tag{14.1.1817}$$

We wish to find the $\vec{w}$ and b which minimizes, and the $\vec{\alpha}$ which maximizes the above relation (whilst keeping $\alpha_i \geq 0\,\forall_i$). We can do this by differentiating L_P with respect to $\vec{w}$ and b and setting the derivatives to zero:

$$\begin{aligned} \frac{\partial L_P}{\partial \vec{w}} = 0 \Rightarrow \vec{w} = \sum_{i=1}^{L} \alpha_i y_i \vec{x}_i \\ \frac{\partial L_P}{\partial b} = 0 \Rightarrow \sum_{i=1}^{L} \alpha_i y_i = 0 \end{aligned} \tag{14.1.1818}$$

Substituting these two relations into:

$$L_P = \frac{1}{2}\|\vec{w}\|^2 - \sum_{i=1}^{L} \alpha_i y_i\left(\vec{x}_i \circ \vec{w} + b\right) + \sum_{i=1}^{L} \alpha_i \tag{14.1.1819}$$

---

[64] These conditions are necessary for the primal optimization problem L_P to be strictly equal to the dual problem L_D, such that $L_P = L_D$ and not just equal or less such that $L_D \leq L_P$.

gives a new formulation which, being dependent on $\vec{\alpha}$, we need to maximize:

$$\begin{aligned}
L_D &= \frac{1}{2}\left(\sum_{i=1}^{L}\alpha_i y_i \vec{x}_i\right)\left(\sum_{j=1}^{L}\alpha_j y_j \vec{x}_j\right) - \sum_{i=1}^{L}\alpha_i y_i\left(\vec{x}_i \circ \sum_{j=1}^{L}\alpha_j y_j \vec{x}_j + b\right) + \sum_{i=1}^{L}\alpha_i \\
&= \frac{1}{2}\left(\sum_{i=1}^{L}\alpha_i y_i \vec{x}_i\right)\left(\sum_{j=1}^{L}\alpha_j y_j \vec{x}_j\right) - \sum_{i=1}^{L}\alpha_i y_i \vec{x}_i \circ \sum_{j=1}^{L}\alpha_j y_j \vec{x}_j - b\underbrace{\sum_{i=1}^{L}\alpha_i y_i}_{=0} + \sum_{i=1}^{L}\alpha_i \\
&= \sum_{i=1}^{L}\alpha_i - \frac{1}{2}\sum_{i,j}\alpha_i\alpha_j y_i y_j \vec{x}_i \circ \vec{x}_j \qquad \text{s.t. } \alpha_i \geq 0\,\forall_i, \sum_{i=1}^{L}\alpha_i y_i = 0 \\
&= \sum_{i=1}^{L}\alpha_i - \frac{1}{2}\sum_{i,j}\alpha_i H_{ij}\alpha_j \qquad \text{where: } H_{ij} = y_i y_j \vec{x}_i \circ \vec{x}_j \\
&= \sum_{i=1}^{L}\alpha_i - \frac{1}{2}\vec{\alpha}^T H \vec{\alpha} \qquad \text{s.t. } \alpha_i \geq 0\,\forall_i, \sum_{i=1}^{L}\alpha_i y_i = 0
\end{aligned} \tag{14.1.1820}$$

This new formulation L_D is referred to as we know to as the "Dual form" of the Primary L_P. And the corresponding constraint (conditions) are named the "Karush-Kuhn-Tucker conditions" (there exist other possible conditions but there are out of the scope of this textbook). It is worth noting that the Dual form requires only the dot product of each input vector $\vec{x}_i$ to be calculated, this is important for the Kernel Trick described further below.

Remark

The matrix H above is often written $H_{ij} \equiv y_i y_j k(\vec{x}_i, \vec{x}_j)$ where $k(\vec{x}_i, \vec{x}_j)$ is an example of a family of functions named "kernel functions". The special case $k(\vec{x}_i, \vec{x}_j) = \vec{x}_i \circ \vec{x}_j$ is known as a the "linear kernel".

The reason that this kernel trick is useful is that there are many classification/regression problems that are not linearly separable/regressable in the space of the inputs $\vec{x}$, which might be in a higher dimensionality feature space given a suitable mapping $\vec{x} \mapsto \Phi(\vec{x})$. For example the "radial kernel":

$$k\left(\vec{x}_i, \vec{x}_j\right) = e^{-\frac{\left\|\vec{x}_i - \vec{x}_j\right\|^2}{2\sigma^2}}$$

Other popular kernels (among many others) for classification and regression are the "polynomial kernel":

$$k\left(\vec{x}_i, \vec{x}_j\right) = \left(\vec{x}_i \circ \vec{x}_j + a\right)^b$$

and the "sigmoidal kernel":

$$k\left(\vec{x}_i, \vec{x}_j\right) = \tanh\left(a\vec{x}_i \circ \vec{x}_j - b\right)$$

where a and b are parameters defining the kernel's behaviour.

Having moved from minimizing L_P to maximizing L_D, we need to find:

$$\max_{\alpha}\left[\sum_{i=1}^{L}\alpha_i-\frac{1}{2}\vec{\alpha}^T H\vec{\alpha}\right] \quad \text{s.t.} \quad \alpha_i\geq 0 \quad \forall_i \quad \text{and} \quad \sum_{i=1}^{L}\alpha_i y_i=0 \tag{14.1.1821}$$

This is a convex quadratic optimization problem, and we run a solver which will return $\vec{\alpha}$ and from:

$$\vec{w}=\sum_{i=1}^{L}\alpha_i y_i\vec{x}_i \tag{14.1.1822}$$

will give us $\vec{w}$. What remains is to calculate b.

Any data point satisfying:

$$\sum_{i=1}^{L}\alpha_i y_i=0 \tag{14.1.1823}$$

which is a support vector denoted $\vec{x}_s$ (samples that are on the gutter) will have the form:

$$y_s\left(\vec{x}_s\circ\vec{w}+b\right)=1 \tag{14.1.1824}$$

If we inject into it the previous derived relation:

$$\vec{w}=\sum_{i=1}^{L}\alpha_i y_i\vec{x}_i \tag{14.1.1825}$$

we get:

$$y_s\left(\sum_{m\in S}\alpha_m y_m\vec{x}_m\circ\vec{x}_s+b\right)=1 \tag{14.1.1826}$$

Where S denotes the set of indices of the support vectors. S is determined by finding the indices i where $\alpha_i>0$. Multiplying through by y_s and then using $y_s^2=1$ we have :

$$y_s^2\left(\sum_{m\in S}\alpha_m y_m\vec{x}_m\circ\vec{x}_s+b\right)=y_s \tag{14.1.1827}$$

Therefore:

$$b=y_s-\sum_{m\in S}\alpha_m y_m\vec{x}_m\circ\vec{x}_s \tag{14.1.1828}$$

Instead of using an arbitrary support vector x_s, it is better to take an average over all of the support vectors in S :

$$b=\frac{1}{N_s}\sum_{s\in S}\left(y_s-\sum_{m\in S}\alpha_m y_m\vec{x}_m\circ\vec{x}_s\right) \tag{14.1.1829}$$

We now have the variables $\vec{w}$ and b that define our separating hyperplane's optimal orientation and hence our Support Vector Machines.

So to summarize... In order to use a SVM to solve a linearly separable, binary classification problem we need to:

- Create the matrix H, where $H_{ij}=y_iy_j\vec{x}_i\circ\vec{x}_j$
- Find $\vec{\alpha}$ so that:

  $$\sum_{i=1}^{L}\alpha_i-\frac{1}{2}\vec{\alpha}^TH\vec{\alpha} \tag{14.1.1830}$$

  is maximized, subject to the constraints:

  $$\alpha_i\geq 0\,\forall_i \quad \text{and} \quad \sum_{i=1}^{L}\alpha_iy_i=0 \tag{14.1.1831}$$

  This is done using a nonlinear programming solver.
- Calculate:

  $$\vec{w}=\sum_{i=1}^{L}\alpha_iy_i\vec{x}_i \tag{14.1.1832}$$

- Determine the set of support vectors S by finding the indices such that $\alpha_i>0$
- Calculate:

  $$b=\frac{1}{N_s}\sum_{s\in S}\left(y_s-\sum_{m\in S}\alpha_my_m\vec{x}_m\circ\vec{x}_s\right) \tag{14.1.1833}$$

- Each new point $\vec{x}'$ is classified by evaluating:

  $$y'=\text{sgn}\left(\vec{w}\circ\vec{x}'+b\right) \tag{14.1.1834}$$

Remark

We recommend the reader interested in delving deeper into the subject to read the article *Support Vector Machines Explained* from Tristan Fletcher [185] which was used to write the above presentation. You will then see how we can extend the SVM methodology to handle data that is not fully linearly separable or what are the maths behind regression SVM.

14.1.20.5.6 Gaussian Mixture Model (GMM) clustering

A more formal approach to clustering can be achieved if we assume underlying distributions of the observations. This is also known as "finite mixture model clustering". Observations arise from a distribution that is a mixture of two or more components, or clusters. Each cluster is described by a density and has an associated probability or weight in the mixture.

We can think of building a "Gaussian Mixture Model" as a type of clustering algorithm. Using again the expectation-maximization algorithm seen earlier above (see page 6697), the process and result is very similar to k-means clustering. The difference is that the clusters are assumed to each have an independent Gaussian distribution, each with their own mean and covariance matrix.

When performing k-means clustering, we assign points to clusters using the straight Euclidean distance. The Euclidean distance is a poor metric, however, when the cluster contains significant covariance! The Gaussian Mixture Models approach will take cluster covariance into account when forming the clusters.

Another important difference with k-means is that standard k-means performs a hard assignment of data points to clusters, i.e. each point is assigned to the closest cluster. With Gaussian Mixture Models, what we will end up is a collection of independent multivariate Gaussian distributions, and so for each data point, we will have a probability that it belongs to each of these distributions / clusters.

Suppose we are given a data set $D=\{\vec{x}_1,\ldots,\vec{x}_N\}$ where $\vec{x}_i$ is a d-dimensional vector measurement. Let us assume that the points are generated in an independent and identically distributed way from an underlying density $P(\vec{x})$.

We further assume that $P(\vec{x})$ is defined as a finite mixture model with K components:

$$P(\vec{x}|\Theta)=\sum_{k=1}^{K}\alpha_k P_k(\vec{x}|z_k,\theta_k) \tag{14.1.1835}$$

where:

- The $P_k(\vec{x}|z_k,\theta_k)$ are mixture components, $1\leq k\leq K$. Each is a density or distribution defined over $P(\vec{x})$, with parameters θ_k.
- $\vec{z}=(z_1,\ldots,z_K)$ is a vector of K binary indicator variables that are mutually exclusive and exhaustive (i.e., one and only one of the z_k's is equal to 1, and the others are 0). $\vec{z}$ is a K-ary random variable representing the identity of the mixture component that generated $\vec{x}$. It is convenient for mixture models to represent z as a vector of K indicator variables.
- The $\alpha_k=P(z_k)$ are the mixture weights, representing the probability that a randomly selected $\vec{x}$ was generated by component k, where $\sum_{k=1}^{K}\alpha_k=1$.

The complete set of parameters for a mixture model with K components is:

$$\Theta=\{\alpha_1,\ldots,\alpha_K,\theta_1,\ldots,\theta_K\} \tag{14.1.1836}$$

We can compute the "membership weight" (i.e. hidden posterior) of data point $\vec{x}_i$ in cluster k, given parameters Θ as:

$$w_{i,k}=P(z_{i,k}=1|\vec{x}_i,\Theta)\;=\;\frac{P_k(\vec{x}_i|z_k,\theta_k)\cdot\alpha_k}{\displaystyle\sum_{m=1}^{K}P_m(\vec{x}_i|z_m,\theta_m)\cdot\alpha_m},\qquad 1\leq k\leq K,\quad 1\leq i\leq N \tag{14.1.1837}$$

This follows from a direct application of Bayes rule often written as:

$$w_{i,k}=P(z_{i,k}=k|\vec{x}_i,\Theta)=\frac{P(z_{i,k}=k|\Theta)P(\vec{x}_i|z_{i,k}=k,\Theta)}{P(\vec{x}_N|\Theta)}=\frac{\mathcal{N}(\vec{x}_i|\mu_k,\Sigma_k)\alpha_k}{\displaystyle\sum_{m=1}^{K}\mathcal{N}(\vec{x}_i|\mu_m,\Sigma_m)\alpha_m} \tag{14.1.1838}$$

The membership weights above reflect our uncertainty, given $\vec{x}_i$ and Θ, about which of the K components generated vector $\vec{x}_i$. Note that we are assuming in our generative mixture model that each $\vec{x}_i$ was generated by a single component so these probabilities reflect our uncertainty about which component $\vec{x}_i$ came from, not any "mixing" in the generative process.

For $\vec{x}\in\mathbb{R}^d$ we can define a Gaussian mixture model by making each of the K components a Gaussian density with parameters $\vec{\mu}_k$ and Σ_k.

Each component (cluster) is a multivariate Gaussian density given for recall by:

$$P_k(\vec{x}|\theta_k)\;=\;\frac{1}{(2\pi)^{d/2}|\Sigma_k|^{1/2}}e^{-\frac{1}{2}(\vec{x}-\vec{\mu}_k)^T\Sigma_k^{-1}(\vec{x}-\vec{\mu}_k)} \tag{14.1.1839}$$

with its own parameters $\theta_k=\{\vec{\mu}_k,\Sigma_k\}$.

We use the Expectation-Maximization algorithm for Gaussian mixtures as follows: The algorithm is an iterative algorithm that starts from some initial estimate of Θ (e.g., random), and then proceeds to iteratively update Θ until convergence is detected. Each iteration consists of an E-step and a M-step.

To kickstart the EM algorithm, we randomly select data points to use as the initial means, and we set the covariance matrix for each cluster to be equal to the covariance of the full training set. Also, we give each cluster equal prior probability. A cluster's prior probability is just the fraction of the dataset that belongs to each cluster. We start by assuming the dataset is equally divided between the clusters.

In other words:

- In the "Expectation" step (E-step), we will calculate the (posterior) probability that each data point $\vec{x^i}$ belongs to each cluster k (using our current estimated mean vectors and covariance matrices) following:

  $$P_k(\vec{x}_i|\theta_k)=\frac{1}{(2\pi)^{d/2}|\Sigma_k|^{1/2}}e^{-\frac{1}{2}(\vec{x}_i-\vec{\mu}_k)^T\Sigma_k^{-1}(\vec{x}_i-\vec{\mu}_k)} \tag{14.1.1840}$$

  This seems analogous to the cluster assignment step in k-means. Technically this step denote the current parameter values as Θ. It computes the $w_{i,k}$ (using the equation above for membership weights) for all data points $\vec{x}_i, 1\leq i\leq N$ and all mixture components $1\leq k\leq K$. Note that for each data point $\vec{x}_i$ the membership weights are defined such that $\sum_{k=1}^{K}w_{i,k}=1$. This yields an $N\times K$ matrix of membership weights, where each of the rows sum to 1.

- In the "Maximization" step (M-step), we will re-calculate the cluster means and covariances based on the probabilities calculated in the expectation step (i.e. we use the membership weights and the data to calculate new parameter values). This seems analogous to the cluster movement step in k-means.

Let $N_k = \sum_{i=1}^{N} w_{i,k}$, i.e., the sum of the membership weights for the kth component—this is the effective number of data points assigned to component k.

Specifically:

$$\alpha_k^{\text{new}} = \frac{N_k}{N} \qquad 1 \leq k \leq K \tag{14.1.1841}$$

These are the new mixture weights:

$$\vec{\mu}_k^{\text{new}} = \left(\frac{1}{N_k}\right) \sum_{i=1}^{N} w_{i,k}\vec{x}_i \qquad 1 \leq k \leq K \tag{14.1.1842}$$

The updated mean is calculated in a manner similar to how we could compute a standard empirical average, except that the ith data vector $\vec{x}_i$ has a fractional weight $w_{i,k}$.

Note that this is a vector equation since $\vec{\mu}_k^{\text{new}}$ and $\vec{x}_i$ are both d-dimensional vectors:

$$\Sigma_k^{\text{new}} = \left(\frac{1}{N_k}\right) \sum_{i=1}^{N} w_{ik} \cdot (\vec{x}_i - \vec{\mu}_k^{\text{new}})(\vec{x}_i - \vec{\mu}_k^{\text{new}})^T \qquad 1 \leq k \leq K \tag{14.1.1843}$$

Again we get an equation that is similar in shape to how we would normally compute an empirical covariance matrix, except that the contribution of each data point is weighted by $w_{i,k}$. Note that this is a matrix equation of dimensionality $d \times d$ on each side.

The equations in the M-step need to be computed in this order, i.e., first compute the K new α's, then the K new $\vec{\mu}_k$'s, and finally the K new Σ_k's.

After we have computed all of the new parameters, the M-step is complete and we can now go back and recompute the membership weights in the E-step, then recompute the parameters again in the E-step, and continue updating the parameters in this manner. Each pair of E and M steps is considered to be one iteration.

The EM algorithm can be started by either initializing the algorithm with a set of initial parameters and then conducting an E-step, or by starting with a set of initial weights and then doing a first M-step. The initial parameters or weights can be chosen randomly (e.g. select K random data points as initial means and select the covariance matrix of the whole data set for each of the initial K covariance matrices) or could be chosen via some heuristic method (such as by using the k-means algorithm to cluster the data first and then defining weights based on k-means memberships).

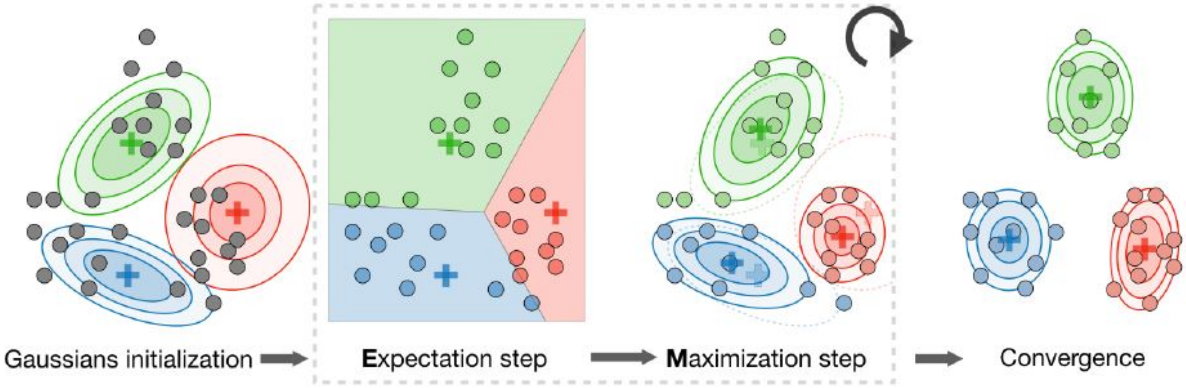

Figure 14.160: Expectation-Maximization iterative algorithm (authors: Afshine Amidi, Shervine Amidi)

Convergence is generally detected by computing the value of the log-likelihood after each iteration and halting when it appears not to be changing in a significant manner from one iteration to the next. Note that the log-likelihood (under the IID assumption) is defined as follows for this case:

$$\ln\left(L(\Theta)\right)=\ln\left(\prod_{i=1}^{N}P(\vec{x}_i|\Theta)\right)=\sum_{i=1}^{N}\ln\left(P(\vec{x}_i|\Theta)\right)=\sum_{i=1}^{N}\ln\left(\prod_{k=1}^{K}\alpha_k P_k(\vec{x}_i|z_k,\theta_k)\right) \tag{14.1.1844}$$

where $P_k(\vec{x}_i|z_k,\theta_k)$ is the Gaussian density for the kth mixture component.

Explicitly the complete data log-likelihood over all points $\{(\vec{x}_n,\vec{z}_n)\}_{n=1}^{N}$ is:

$$\begin{aligned}\ln\left(L(\Theta)\right)&=\sum_{i=1}^{N}\ln\left(\prod_{k=1}^{K}\alpha_k P_k(\vec{x}_i|z_k,\theta_k)\right)=\sum_{i=1}^{N}\ln\left(\prod_{k=1}^{K}\alpha_k\mathcal{N}(\vec{x}_n\,|\,\mu_k,\Sigma_k)^{\mathbb{I}(\vec{z}_n=k)}\right)\\&=\sum_{i=1}^{N}\sum_{k=1}^{K}\mathbb{I}(\vec{z}_n=k)\ln\left(\alpha_k\mathcal{N}(\vec{x}_n\,|\,\mu_k,\Sigma_k)\right)\end{aligned} \tag{14.1.1845}$$

We can now detail the Expectation-Maximization algorithm for Gaussian mixtures:

- **E-Step:**

  Before the E-step, we have an estimate θ_t of the parameters, and seek to compute a new lower bound on the observed log-likelihood. Earlier, we showed that the optimal lower bound is (see page 6704):

  $$L(q_{\theta_t},\theta)=\mathrm{E}_q[\ln\left(p(\vec{x},\vec{z}|\theta)\right)]+c^{te} \tag{14.1.1846}$$

  where $q_{\theta_t}(z)\equiv p(\vec{z}|\vec{x},\theta_t)$ and the second term is constant with respect to θ. The E-Step requires us to derive an expression for the first term. Using the relation above:

  $$\ln\left(L(\Theta)\right)=\sum_{i=1}^{N}\sum_{k=1}^{K}\mathbb{I}(\vec{z}_n=k)\ln\left(\alpha_k\mathcal{N}(\vec{x}_n\,|\,\mu_k,\Sigma_k)\right) \tag{14.1.1847}$$

the expected complete data log-likelihood is given by:

$$\begin{aligned}
Q(\theta_t,\theta)=\mathrm{E}_q[\ln p(\vec{x},\vec{z}|\theta)] &= \sum_{n=1}^{N}\sum_{k=1}^{K}\mathrm{E}_q\left[\mathbb{I}(z_n=k)\ln\left(\alpha_k\mathcal{N}(x_n\,|\,\mu_k,\Sigma_k)\right)\right]\\
&= \sum_{n=1}^{N}\sum_{k=1}^{K}\mathrm{E}_q\left[\mathbb{I}(z_n=k)\right]\ln\left(\alpha_k\mathcal{N}(x_n\,|\,\mu_k,\Sigma_k)\right)\\
&= \sum_{n=1}^{N}\sum_{k=1}^{K}P(z_n=k\,|\,x_n,\theta_t)\ln\left(\alpha_k\mathcal{N}(x_n\,|\,\mu_k,\Sigma_k)\right)\\
&= \sum_{n=1}^{N}\sum_{k=1}^{K}r_{nk}\ln(\alpha_k)+\sum_{n=1}^{N}\sum_{k=1}^{K}r_{nk}\ln\left(\mathcal{N}(x_n\,|\,\mu_k,\Sigma_k)\right)
\end{aligned} \tag{14.1.1848}$$

where $r_{nk}:=P(z_n=k\,|\,x_n,\theta_t)$ is named the "responsability" that cluster k takes for data point x_n after step t. During the E-Step, we compute these values explicitly with the relation seen earlier above:

$$w_{n,k}=P(z_{n,k}=k|\vec{x}_n,\Theta)=\frac{P(z_{n,k}=k|\Theta)P(\vec{x}_i|z_{i,k}=k,\Theta)}{P(\vec{x}_N|\Theta)}=\frac{\mathcal{N}(\vec{x}_n|\mu_k,\Sigma_k)\alpha_k}{\displaystyle\sum_{m=1}^{K}\mathcal{N}(\vec{x}_n|\mu_m,\Sigma_m)\alpha_m} \tag{14.1.1849}$$

- **M-Step:**

  During the M-Step, we optimize our lower bound with respect to the parameters $\theta=(\vec{\alpha},\vec{\mu},\vec{\Sigma})$. For the mixing weights $\vec{\pi}$, we use Lagrange multipliers to maximize the evidence lower bound (see page 6704) subject to the constraint $\sum_{k=1}^{K}\pi_k=1$. The Lagrangian (see page 6667) is:

$$L(\alpha,\lambda)=Q(\theta_t,\theta)+\lambda\left(\sum_{k=1}^{K}\alpha_k-1\right) \tag{14.1.1850}$$

  with for recall:

$$\begin{gathered}
Q(\theta_t,\theta)=\sum_{n=1}^{N}\sum_{k=1}^{K}r_{nk}\ln\left(\alpha_k\mathcal{N}(x_n\,|\,\mu_k,\Sigma_k)\right)\\
r_{nk}:=P(z_n=k\,|\,x_n,\theta_t)
\end{gathered} \tag{14.1.1851}$$

  So let us derive the four corresponding results... In order to resolve this problem, we have to find the parameters for which the partial derivatives are null:

$$\max_{\Theta,\lambda}L(\theta,r_{nk},\lambda)\Leftrightarrow\nabla_{\theta,\lambda}L(\theta_t,r_{nk},\lambda)=0\Leftrightarrow\begin{cases}\dfrac{\partial L(\theta_t,r_{nk},\lambda)}{\partial\alpha_k}=0\\ \dfrac{\partial L(\theta_t,r_{nk},\lambda)}{\partial\mu_k}=0\\ \dfrac{\partial L(\theta_t,r_{nk},\lambda)}{\partial\Sigma_k}=0\\ \dfrac{\partial L(\theta_t,r_{nk},\lambda)}{\partial\lambda}=0\end{cases} \tag{14.1.1852}$$

First, let's start with the equation with respect to λ:

$$\begin{aligned}\frac{\partial \mathcal{L}(\theta, r_{nk}, \lambda)}{\partial \lambda} = 0 \Leftrightarrow & \frac{\partial}{\partial \lambda}\left[\left(\sum_{n=1}^{N}\sum_{k=1}^{K} r_{nk}\ln\left(\alpha_k \mathcal{N}\left(x_n \,|\, \mu_k, \Sigma_k\right)\right)\right) - \lambda\left(\sum_{k=1}^{K}\alpha_k - 1\right)\right] = 0\\ & \frac{\partial}{\partial \lambda}\left[-\lambda\sum_{k=1}^{K}\alpha_k + \lambda\right] = 0\\ & -\sum_{k=1}^{K}\alpha_k + 1 = 0\\ & \sum_{k=1}^{K}\alpha_k = 1\end{aligned} \tag{14.1.1853}$$

Ok, so we are back to the definition of the constraint. No surprise here but not very useful.

Now let's move on with the equation with respect to α_k. Note that in the following derivations, we use the fact that deriving an α_j with j different than j results in a constant (this basically means that the summation over the K clusters can be ignored):

$$\begin{aligned}\frac{\partial L(\theta_t, r_{nk}, \lambda)}{\partial \alpha_k} = 0 \quad \Leftrightarrow & \frac{\partial}{\partial \alpha_k}\left[\left(\sum_{n=1}^{N}\sum_{k=1}^{K} r_{nk}\ln\left(\alpha_k \mathcal{N}\left(x_n \,|\, \mu_k, \Sigma_k\right)\right)\right) - \lambda\left(\sum_{k=1}^{K}\alpha_k - 1\right)\right] = 0\\ & \frac{\partial}{\partial \alpha_k}\left[\left(\sum_{n=1}^{K} r_{nk}\ln\left(\alpha_k \mathcal{N}\left(x_n \,|\, \mu_k, \Sigma_k\right)\right)\right) - \lambda\alpha_k\right] = 0\\ & \frac{\partial}{\partial \alpha_k}\left[\left(\sum_{n=1}^{N} r_{nk}\ln\left(\alpha_k\right) + \sum_{n=1}^{N} r_{nk}\ln\left(\mathcal{N}\left(x_n \,|\, \mu_k, \Sigma_k\right)\right)\right] - \lambda\alpha_k\right] = 0\\ & \frac{\partial}{\partial \alpha_k}\left[\sum_{n=1}^{N} r_{nk}\ln\left(\alpha_k\right) - \lambda\alpha_k\right] = 0\\ & \frac{\sum_{n=1}^{N} r_{nk}}{\alpha_k} - \lambda = 0\\ & \alpha_k = \frac{\sum_{n=1}^{N} r_{nk}}{\lambda}\end{aligned} \tag{14.1.1854}$$

Now in order to get rid of the λ, we use the definition of the constraint regarding the mixtures weights:

$$\begin{aligned}\sum_{k=1}^{K}\alpha_k = 1 \Leftrightarrow & \sum_{k=1}^{K}\frac{\sum_{n=1}^{N} r_{nk}}{\lambda} = 1\\ & \frac{\sum_{k=1}^{K}\sum_{n=1}^{N} r_{nk}}{\lambda} = 1\\ & \lambda = \sum_{k=1}^{K}\sum_{n=1}^{N} r_{nk}\end{aligned} \tag{14.1.1855}$$

And this gives us the final closed-form expressions for the mixture weights:

$$\alpha_k = \frac{\sum_{n=1}^{N} r_{nk}}{\sum_{k=1}^{K}\sum_{n=1}^{N} r_{nk}} = \frac{\sum_{n=1}^{N} r_{nk}}{N} \tag{14.1.1856}$$

This tells us that for each class, after the M-Step, the mixture weight will be the sum of all the individual weights for that class normalized by the sum of all the individual weights for all the classes. And this makes perfect sense, if all the observations put a little weight on a specific class compared to the other classes than this class will have a small overall weight, and vice-versa.

Now let's move on the derivation of the mean vector μ. This one is a little trickier because, this time, we are computing the partial derivative for vectors and matrices:

$$\begin{aligned}\frac{\partial L(\theta_t,r_{nk},\lambda)}{\partial\mu_k}=0\Leftrightarrow&\frac{\partial}{\partial\mu_k}\left[\left(\sum_{n=1}^{N}\sum_{k=1}^{K}r_{nk}\ln\left(\alpha_k\mathcal{N}\left(x_n\,|\,\mu_k,\Sigma_k\right)\right)\right)-\lambda\left(\sum_{k=1}^{K}\alpha_k-1\right)\right]=0\\&\frac{\partial}{\partial\mu_k}\left[\sum_{n=1}^{N}r_{nk}\ln\left(\alpha_k\right)+\sum_{n=1}^{N}r_{nk}\ln\left(\mathcal{N}\left(x_n\,|\,\mu_k,\Sigma_k\right)\right)\right]=0\\&\frac{\partial}{\partial\mu_k}\Bigg[\sum_{n=1}^{N}r_{nk}\ln\left(\frac{1}{(2\pi)^{(N/2)}\left|\Sigma_k\right|^{1/2}}\exp\left(-\frac{1}{2}\left(x_n-\mu_k\right)^T\Sigma_k^{-1}\left(x_n-\mu_k\right)\right)\right)\Bigg]\Bigg]=0\\&\frac{\partial}{\partial\mu_k}\sum_{n=1}^{N}r_{nk}\ln\left(\frac{1}{(2\pi)^{(N/2)}\left|\Sigma_k\right|^{1/2}}\right)+\sum_{n=1}^{N}r_{nk}\ln\left(\exp\left(-\frac{1}{2}\left(x_n-\mu_k\right)^T\Sigma_k^{-1}\left(x_n-\mu_k\right)\right)\right)]=0\\&\frac{\partial}{\partial\mu_k}\left[\sum_{n=1}^{N}r_{nk}\left(-\frac{1}{2}\left(x_n-\mu_k\right)^T\Sigma_k^{-1}\left(x_n-\mu_k\right)\right)\right]=0\end{aligned}\tag{14.1.1857}$$

Hence:

$$\begin{aligned}&\sum_{n=1}^{N}r_{nk}\left(-\frac{1}{2}\left(-2\Sigma_k^{-1}\left(x_n-\mu_k\right)\right)\right)=0\\&\sum_{n=1}^{N}r_{nk}\Sigma_k^{-1}\left(x_n-\mu_k\right)=0\\&\sum_{n=1}^{N}r_{nk}\Sigma_k^{-1}x_n-\sum_{n=1}^{N}r_{nk}\Sigma_k^{-1}\mu_k=0\end{aligned}\tag{14.1.1858}$$

So finally:

$$\mu_k=\frac{\sum_{n=1}^{N}r_{nk}\Sigma_k^{-1}x_n}{\sum_i r_{nk}\Sigma_{jk}^{-1}}=\frac{\sum_{n=1}^{N}r_{nk}x_n}{\sum_{n=1}^{N}r_{nk}}\tag{14.1.1859}$$

This looks perfectly right. Out of the M-Step, the mean value for a specific Gaussian distribution will be the expected value of the data points with respect to the variational distribution r_{nk} normalized by the sum of all the weights.

Finally, let's derive the analytical update expression for the covariance matrix Σ (we use in this development derivatives of matrices as seen in the section of Linear Algebra page

1976):

$$\begin{aligned}\frac{\partial L(\theta_t, r_{nk}, \lambda)}{\partial \Sigma_k} = 0 \quad \Leftrightarrow & \frac{\partial}{\partial \Sigma_k}\left[\left(\sum_{n=1}^{N}\sum_{k=1}^{K} r_{nk} \ln\left(\alpha_k \mathcal{N}\left(x_n \,|\, \mu_k, \Sigma_k\right)\right)\right) - \lambda\left(\sum_{k=1}^{K}\alpha_k - 1\right)\right] = \mathbb{O}\\ & \frac{\partial}{\partial \Sigma_k}\left[\sum_{n=1}^{N} r_{nk} \ln\left(\mathcal{N}\left(x_n \,|\, \mu_k, \Sigma_k\right)\right)\right] = \mathbb{O}\\ & \frac{\partial}{\partial \Sigma_k}\left[\sum_{n=1}^{N} r_{nk} \ln\left(\frac{1}{(2\pi)^{(N/2)}\left|\Sigma_k\right|^{1/2}}\exp\left(-\frac{1}{2}\left(x_n - \mu_k\right)^T \Sigma_k^{-1}\left(x_n - \mu_k\right)\right)\right]\right] = \mathbb{O}\\ & \frac{\partial}{\partial \Sigma_k}\left[\sum_{n=1}^{N} r_{nk}\left(\ln\left(\frac{1}{(2\pi)^{(N/2)}}\right) + \frac{1}{2}\ln\left(\frac{1}{\left|\Sigma_k\right|}\right) + \ln\left(\exp\left(-\frac{1}{2}\left(x_n - \mu_k\right)^T \Sigma_k^{-1}\left(x_n - \mu_k\right)\right)\right)\right)\right] = \mathbb{O}\\ & \frac{\partial}{\partial \Sigma_k}\left[\sum_{n=1}^{N} r_{nk}\left(-\frac{1}{2}\ln\left(\left|\Sigma_k\right|\right) - \frac{1}{2}\left(x_n - \mu_k\right)^T \Sigma_k^{-1}\left(x_n - \mu_k\right)\right)\right] = \mathbb{O}\\ & \frac{\partial}{\partial \Sigma_k}\left[\sum_{n=1}^{N} r_{nk}\left(\ln\left(\left|\Sigma_k\right|\right) + \left(x_n - \mu_k\right)^T \Sigma_k^{-1}\left(x_n - \mu_k\right)\right)\right] = \mathbb{O}\end{aligned} \tag{14.1.1860}$$

Therefore:

$$\frac{\partial}{\partial \Sigma_k^{-1}}\left[\sum_{n=1}^{N} r_{nk}\left(\ln\left(\left|\Sigma_k\right|\right) + \left(x_n - \mu_k\right)^T \Sigma_k^{-1}\left(x_n - \mu_k\right)\right)\right] = \mathbb{O} \tag{14.1.1861}$$

Hence:

$$\sum_{n=1}^{N} r_{nk}\left(-\Sigma_k^T + \left(x_n - \mu_k\right)\left(x_n - \mu_k\right)^T\right) = \mathbb{O} \tag{14.1.1862}$$

Finally:

$$\Sigma_k^T = \frac{\sum_{n=1}^{N} r_{nk}\left(x_n - \mu_k\right)\left(x_n - \mu_k\right)^T}{\sum_{n=1}^{N} r_{nk}} \tag{14.1.1863}$$

And this looks pretty dam right! The covariance matrix after the M-Step is a re-weighted version of the previous covariance matrix.

Most algorithms searches over a range of different types of Gaussians and n (named sometimes the "number of components") to find the best model by the Bayesian information criterion (BIC). The model is often referred to a three letter code nomenclature from the variance-covariance matrix describing the "shape" (relative magnitude of eigenvalues categorized into 2 different possibilities), "volume" (absolute magnitude of eigenvalues categorized into 3 different possibilities) and "orientation" (orientation of the eigenvectors categorized into 4 different possibilities) of the clusters. So there is a total of $2 \cdot 3 \cdot 4 = 24$ possibilities, here is a non-exhaustive list:

- `EII`: equal volume, round shape (spherical covariance)
- `VII`: varying volume, round shape (spherical covariance)
- `EEI`: equal volume, equal shape, axis parallel orientation (diagonal covariance)
- `VEI`: varying volume, equal shape, axis parallel orientation (diagonal covariance)

- `EVI`: equal volume, varying shape, axis parallel orientation (diagonal covariance)
- `VVI`: varying volume, varying shape, equal orientation (diagonal covariance)
- `EEE`: equal volume, equal shape, equal orientation (ellipsoidal covariance)
- `EEV`: equal volume, equal shape, varying orientation (ellipsoidal covariance)
- `VEV`: varying volume, equal shape, varying orientation (ellipsoidal covariance)
- `VVV`: varying volume, varying shape, varying orientation (ellipsoidal covariance)

Some of the above combinations are illustrated below:

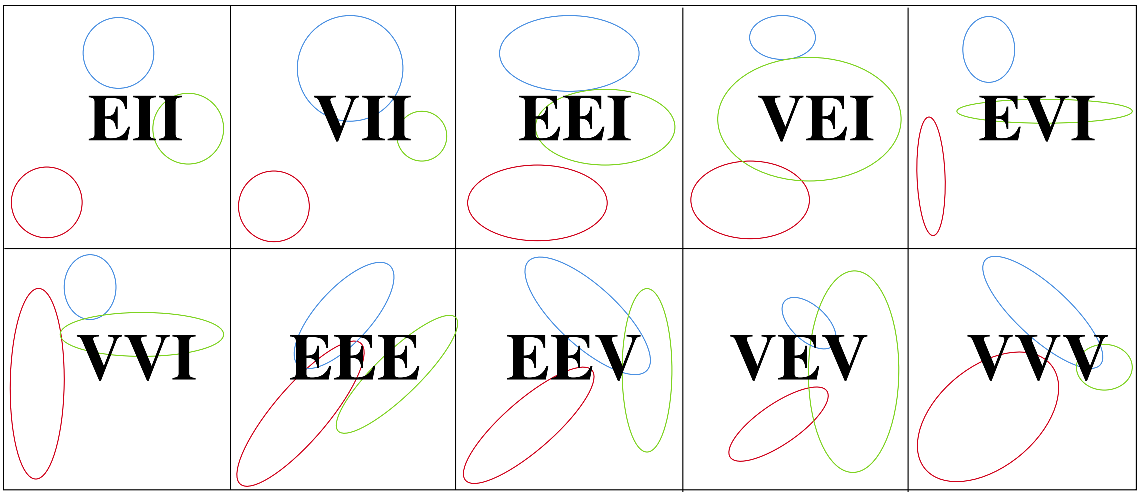

Figure 14.161: **Variance-Covariance matrix typical structures**

14.1.20.5.7 Density-Based Spatial Clustering of Applications with Noise (DBSCAN)

"Density-based spatial clustering of applications with noise" (DBSCAN) is a data clustering algorithm proposed by Martin Ester, Hans-Peter Kriegel, Jörg Sander and Xiaowei Xu in 11996 (holocene calendar). It is a density-based clustering non-parametric (unsupervised) algorithm: given a set of points in some space, it groups together points that are closely packed together (points with many nearby neighbors), marking as outliers points that lie alone in low-density regions (whose nearest neighbors are too far away). DBSCAN is one of the most common, and most commonly cited, clustering algorithms iN the early 121st century (holocene calendar).

Consider a set of points in some space to be clustered. Let ε be a parameter specifying the radius of a neighborhood with respect to some point. For the purpose of DBSCAN clustering, the points are classified as:

- core points
- (directly-) reachable points
- outliers

as follows:

Definitions (#14.1.571):

D1. A point p is a "core point" if at least minPts[65] points are within distance ε of it (including p)

D2. A point q is "directly reachable" from p if point q is within distance ε from core point p. Points are only said to be directly reachable from core points.

An object is said to be in a "ε-neighbourhood" if the object is within a radius of ε from an object as:

$$N_\varepsilon(p):\{q\,|\,d(p,q)\leq\varepsilon\}$$

D3. A point q is "reachable" from p if there is a path $p_1,\ldots,p_n$ with $p_1=p$ and $p_n=q$, where each p_{i+1} is directly reachable from p_i. Note that this implies that the initial point and all points on the path must be core points, with the possible exception of q.

D4. All points not reachable from any other point are "outliers" or "noise".

Now if p is a core point, then it forms a cluster together with all points (core or non-core) that are reachable from it. Each cluster contains at least one core point; non-core points can be part of a cluster, but they form its "edge", since they cannot be used to reach more points.

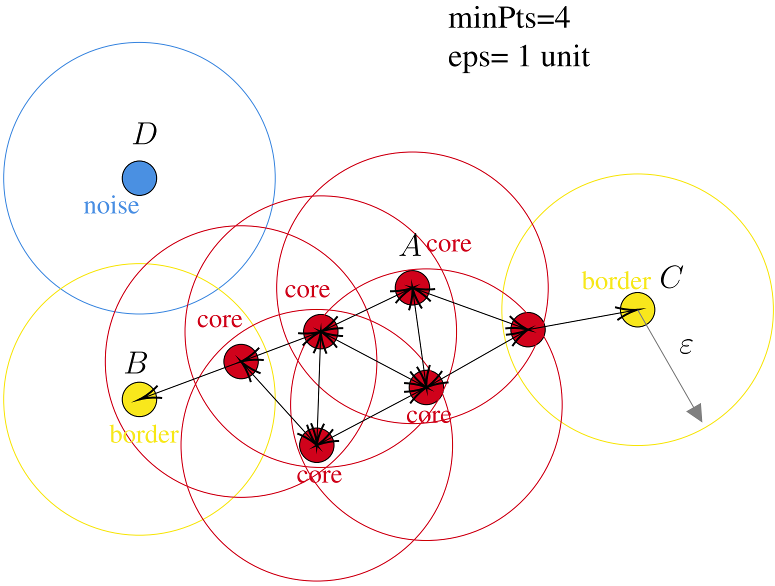
Remark

Reachability is not a symmetric relation: by definition, only core points can reach non-core points. The opposite is not true, so a non-core point may be reachable, but nothing can be reached from it.

In the figure below $\text{minPts}=4$ the point A and the other red points are "core points", because the area surrounding these points in an ε radius contain at least 4 points (including the point itself). Because they are all reachable from one another, they form a single cluster. Points B and C are not core points, but are reachable from A (via other core points) and thus belong to the cluster as well. Point N is a noise point that is neither a core point nor directly-reachable:

---

[65] While minPts intuitively is the minimum cluster size, in some cases DBSCAN can produce smaller clusters. A DBSCAN cluster consists of at least one core point. As other points may be border points to more than one cluster, there is no guarantee that at least minPts points are included in every cluster.



DBSCAN requires two parameters: ε (eps) and the minimum number of points required to form a dense region (minPts). It starts with an arbitrary starting point that has not been visited. This point's ε-neighborhood is retrieved, and if it contains sufficiently many points, a cluster is started. Otherwise, the point is labeled as noise. Note that this point might later be found in a sufficiently sized ε-environment of a different point and hence be made part of a cluster.

If the number of points is more than minPts, the current point and its nearby points from a cluster, and the starting point is marked as visited. Then, all the points in the cluster are not marked as visited that are processed in the same way recursively, to expand the cluster. Otherwise, the point is temporarily marked as a noise point. If the cluster is fully expanded, that is, all points in the cluster are marked as visited, and then the same algorithm is used to process the non-visited points. Until all objects are marked as a certain cluster or noise, the clustering process ends.

DBSCAN can be used with any distance function (as well as similarity functions or other predicates). The distance function (dist) can therefore be seen as an additional parameter.

Here is a general idea of the DBSCAN algorithm:

```
Input: DB (database), distFunc, $\varepsilon$, minPts
foreach $\text{point}\ (P) \in \text{database DB}$ do
    if $\text{point}\ (P)$ is not yet classified then
        $\text{collect all objects density} - \text{reachable from}\ (P)$ and assign them to a new cluster;
    else
        $\text{assign}\ (P)\ \text{to noise}$;
return cluster, label
```

Or with more details:

Algorithm 16: DBSCAN Algorithm

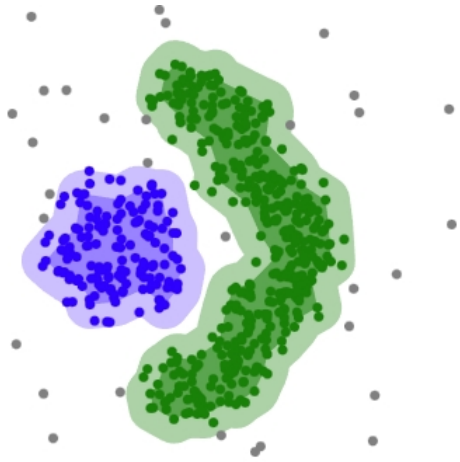
```
  Input: DB (database), distFunc, $\varepsilon$, minPts
Function DBSCAN(DB,distFunc,$\varepsilon$,minPts):
    $C := 0$ ;                          ▷ we initialize the number of clusters
    foreach point $p \in$ database DB do
        if label$(P) \neq$ undefined then
            Next ;                      ▷ we jump to the next iteration
        Neighbors $N :=$ RangeQuery(DB, distFunc, P, $\varepsilon$);
        if Card$(N) <$ minPts then
            label$(P) =$ noise;
            Next ;                      ▷ we jump to the next iteration
        $C := C + 1$;
        label$(P) := C$;
        SeedSet $S := N \setminus \{P\}$;   ▷ random point of $C$ excepted the core one
        foreach point $Q \in S$ do
            if label$(Q) =$ noise then
                label$(Q) := C$;
            if label$(Q) \neq$ undefined then
                Next ;                  ▷ we jump to the next iteration
            label$(Q) := C$;
            Neighbors $N :=$ RangeQuery(DB, distFunc, Q, $\varepsilon$);
            if Card$(N) \geq$ minPts then
                $S := S \cup N$
    return cluster, label
Function RangeQuery(DB,distFunc,Q,$\varepsilon$):
    Neighbors $N :=$ empty list;
    foreach point $P \in$ database DB do
        if distFun$(Q, P) \leq \varepsilon$ then
            $N := N \cup \{P\}$;
    return $N$
```

As we can see from the above pseudocode DBSCAN has a worst-case of $\mathcal{O}(n^2)$.

DBSCAN has the following advantages:

- DBSCAN does not require one to specify the number of clusters in the data a priori, as opposed to k-means.
- DBSCAN can find arbitrarily-shaped clusters. It can even find a cluster completely surrounded by (but not connected to) a different cluster. Due to the MinPts parameter, the so-called single-link effect (different clusters being connected by a thin line of points) is reduced.

  DBSCAN can find non-linearly separable clusters. The dataset below cannot be adequately clustered with k-means or Gaussian Mixture EM clustering:



- DBSCAN has a notion of noise, and is robust to outliers.
- DBSCAN requires just two parameters and is mostly insensitive to the ordering of the points in the database.

and the following disadvantages:

- DBSCAN is not entirely deterministic: border points that are reachable from more than one cluster can be part of either cluster, depending on the order the data are processed.
- The quality of DBSCAN depends on the distance measure used in the function $\text{regionQuery}(P, \varepsilon)$. The most common distance metric used is Euclidean distance.
- DBSCAN cannot cluster data sets well with large differences in densities, since the $\text{minPts} - \varepsilon$ combination cannot then be chosen appropriately for all clusters.
- If the data and scale are not well understood, choosing a meaningful distance threshold ε can be difficult.

Remark

Generalized DBSCAN (GDBSCAN) is a generalization by the same authors to arbitrary "neighborhood" and "dense" predicates. HDBSCAN is a hierarchical version of DBSCAN.

14.1.20.5.8 Mean shift clustering

"Mean shift" is a powerful and versatile non parametric iterative algorithm that can be used for lot of purposes like finding modes, clustering, tracking images etc. Mean Shift was introduced by Keinosuke Fukunaga and Larry D. Hostetler in 11975 (holocene calendar) and has been extended to be applicable in other fields like Computer Vision. The text that follows will provide a discussion of Mean Shift , prove its convergence and slightly discuss its important applications.

This text provides an intuitive idea of Mean shift and the later sections will expand the idea. Mean shift considers feature space as a empirical probability density function. If the input is a set of points then Mean shift considers them as sampled from the underlying probability density function. If dense regions (or clusters) are present in the feature space , then they correspond to the mode (or local maxima) of the probability density function. We can also identify clusters associated with the given mode using Mean Shift.

For each data point, Mean shift associates it with the nearby peak of the dataset's probability density function. For each data point, Mean shift defines a window around it and computes the mean of the data point. Then it shifts the center of the window to the mean and repeats the algorithm till it converges. After each iteration, we can consider that the window shifts to a more denser region of the dataset.

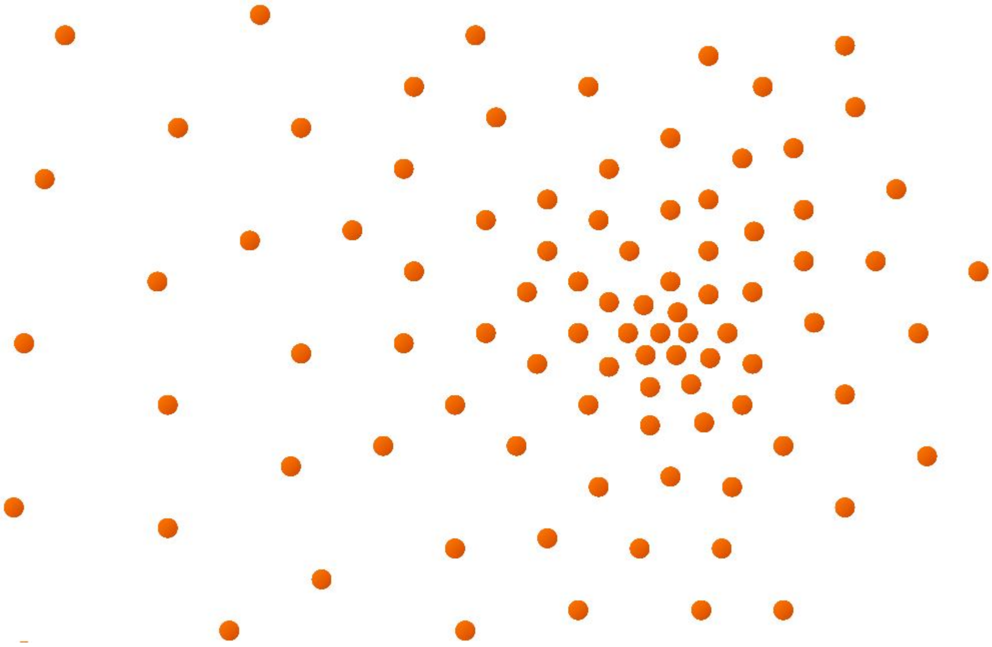
At the high level, we can specify Mean Shift as follows :

1. Choose a kernel K
2. Fix a window size h[66]
3. Randomly segment the domain with the kernel K (of size h)
4. Compute the mean of data (barycenter) weighted within the window h of each kernel
5. Shift the window h of each kernel K to the mean (barycenter) and repeat till convergence
6. Calculate the probability each point has to belong to one of the kernel K
7. Cluster each point to the kernel K have the highest probability

Before dealing with the mathematical aspect, let us consider the graphic and playful aspect! The purpose of the Mean Shift algorithm is to find the maximum density region(s) per iteration. So consider for example the following bi-varied case with some points:

---

[66] Some algorithms have a dynamic window



where we place randomly one or many circles (in d-dimensional case it will be d-dimensions sphere instead of simple circles) of a given radius:

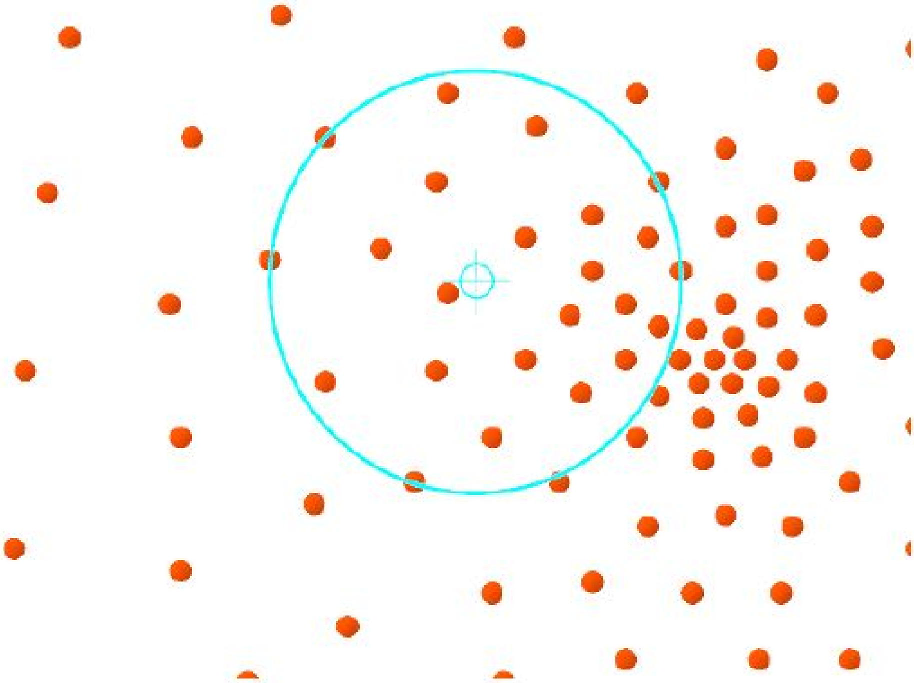


Figure 14.162: **Initial configuration of a bi-dimensional mean shift application**

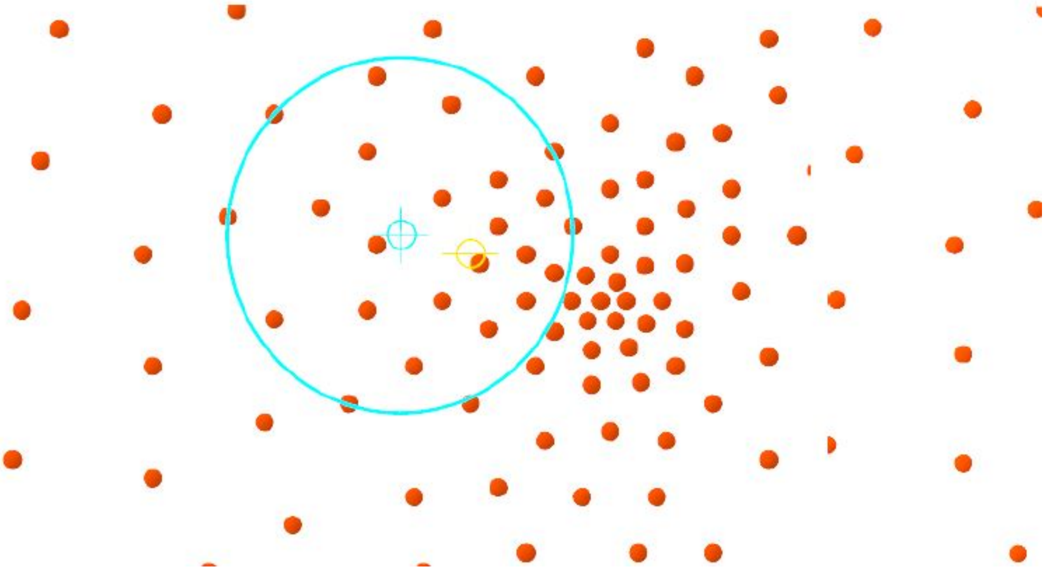
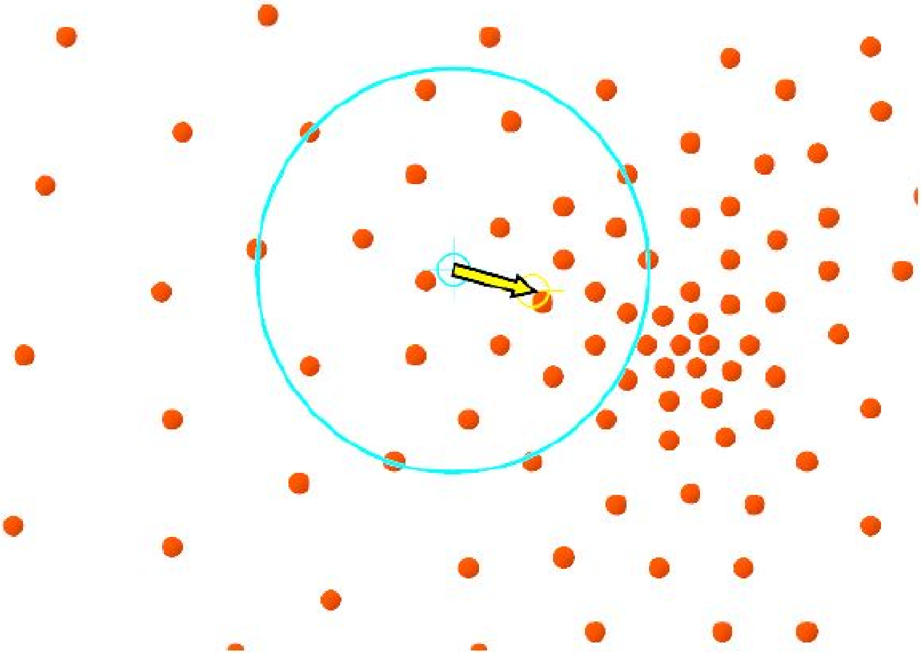
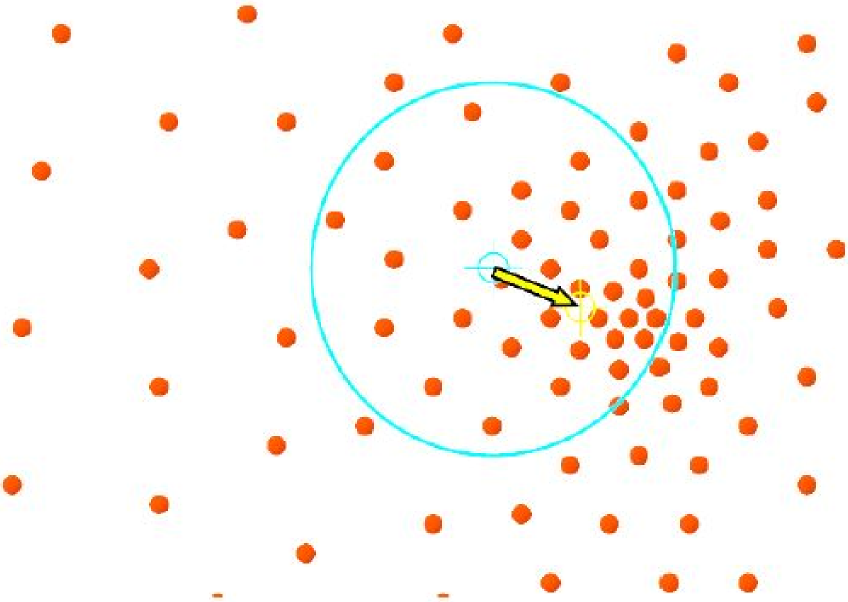
Then more or less empirically (there are different techniques!) we calculate the center of mass inside this circle:



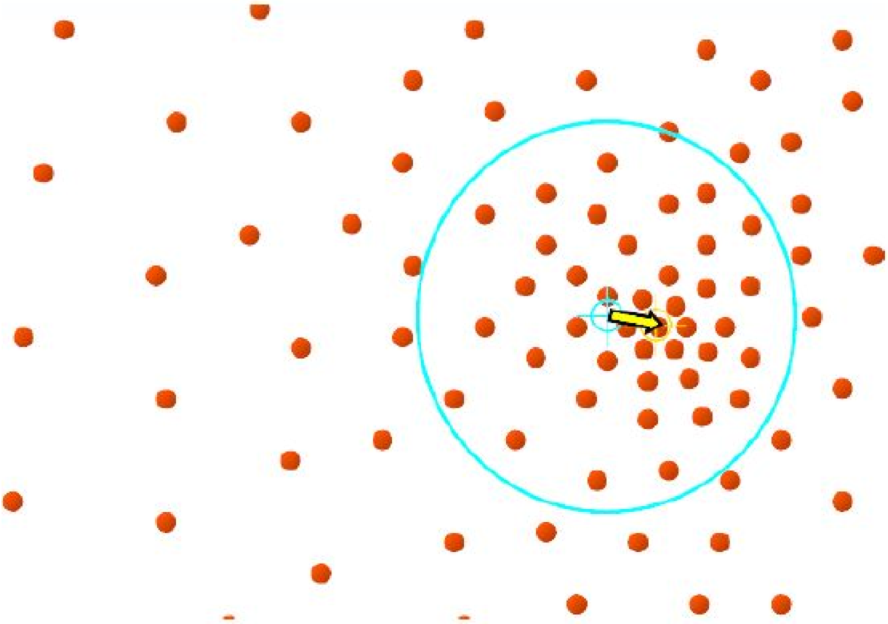
Then we move the circle on the center of gravity (barycenter) to get:



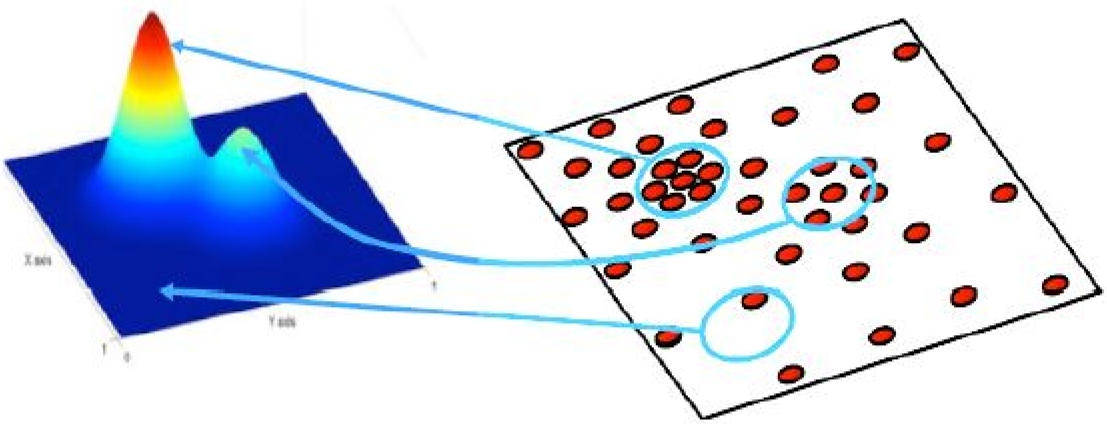
and we repeat the procedure:



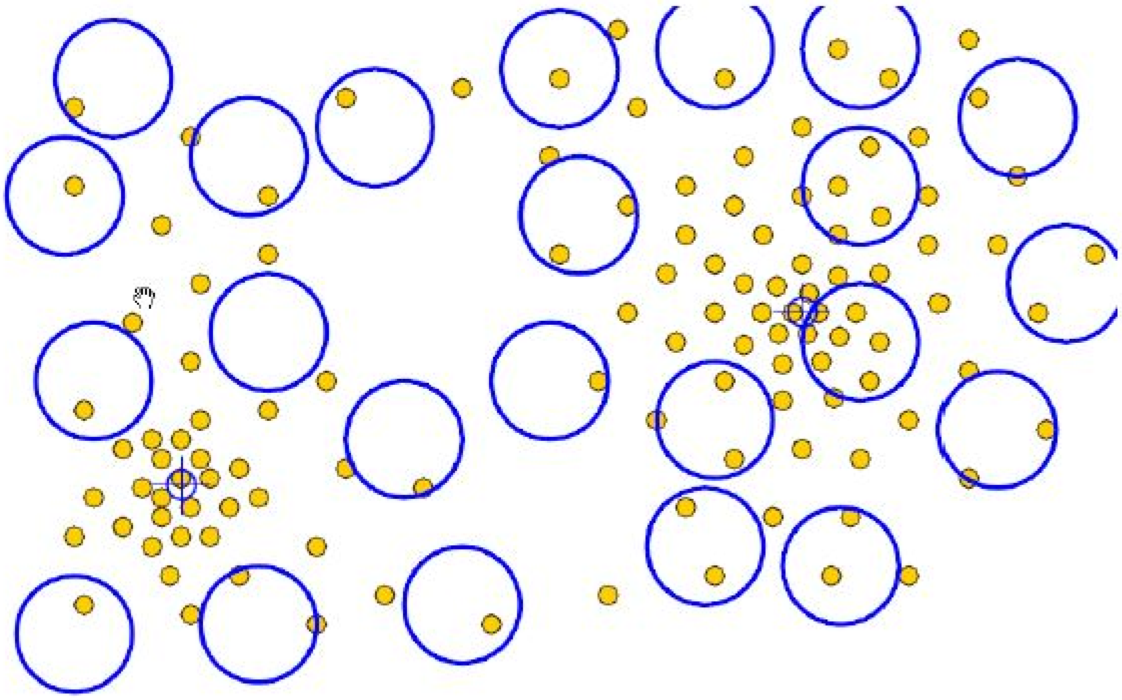
And so on:



That is to say that if we have for example a distribution of points such as below:



In reality we will randomly segment the domain and run the algorithm iteratively in parallel for each sphere (circle in the case of dimension 2):



Remark

The reader will be able to find a practical example in our `R` companion book!

As the reader can guess intuitively, this method converges securely (it can be proved algebraically but it's quite boring!), on the other hand it converges infinitely so we must set a convergence terminal for the algorithm to stop its iterations.

Let's move on to the computational aspect! We will introduce two different and very common approaches.

For the both approach, the first idea of the Mean Shift algorithm is to consider the workspace as a probability density (or multiple one!). Then each point of the workspace is identified by a coordinate vector $\vec{p}_i$ with a "mass" (corresponding mathematically to it's probability density function: the kernel!) given by the kernel:

$$K(\vec{p}_0-\vec{p}_i) \tag{14.1.1864}$$

centered on $\vec{p}_0$. We have already meet such Kernels[67] and we know what should be their properties. We won't come back here on these aspects! If the workspace contains a set of points, the latter are considered as a sample of an underlying probability density function and the dense regions (local maximum) as the modal value of the function of density of interest!

Obvious a very common Kernel is the multivariate Gaussian one given for recall by (where the lowercase k means that at each iteration k the variance-covariance matrix is recomputed):

$$K(\vec{p}_0-\vec{p}_i)=\sum_{i=1}^{N}\frac{1}{(2\pi)^{N/2}|\Sigma_k|^{1/2}}e^{-\frac{1}{2}(\vec{p}_0-\vec{p}_i)^T\Sigma_k^{-1}(\vec{p}_0-\vec{p}_i)} \tag{14.1.1865}$$

In practice some algorithms introduce a constant h such that the latter is written for a d-dimensional case:

$$K(\vec{p}_0-\vec{p}_i)=\frac{1}{h^d}\sum_{i=1}^{N}e^{-\frac{\|\vec{p}_0-\vec{p}_i\|^2}{h^2}}=\frac{1}{h^d}\sum_{i=1}^{N}e^{-\left\|\frac{\vec{p}_0-\vec{p}_i}{h}\right\|^2}=\frac{1}{h^d}\sum_{i=1}^{N}K\left(\left\|\frac{\vec{p}_0-\vec{p}_i}{h}\right\|^2\right) \tag{14.1.1866}$$

The first typical implementation of the Mean Shift clustering algorithm is based on the barycenter in Geometry (or center of gravity in physics). For this let us recall that we have proved in the section of Euclidean Geometry (page 2635), that the barycenter was given by:

$$\overrightarrow{\mathrm{O}G}=\frac{\displaystyle\sum_{i=1}^{N}\alpha_i\overrightarrow{\mathrm{O}A_i}}{\displaystyle\sum_{i=1}^{N}\alpha_i} \tag{14.1.1867}$$

This will be written in the context of Mean Shift with Gaussian kernel:

$$\boxed{\vec{p}_0^{[k+1]}=\frac{\displaystyle\sum_{i=1}^{N}K\left(\left\|\frac{\vec{p}_0^{[k]}-\vec{p}_i}{h}\right\|^2\right)\vec{p}_i}{\displaystyle\sum_{i=1}^{N}K\left(\left\|\frac{\vec{p}_0^{[k]}-\vec{p}_i}{h}\right\|^2\right)}} \tag{14.1.1868}$$

The difference:

$$m(\vec{p}_0^{[k+1]})=\vec{p}_0^{[k+1]}-\vec{p}_0^{[k]} \tag{14.1.1869}$$

is named the "mean shift vector" in the paper of Fukunaga and Hostetler. The mean-shift algorithm sets afterwards $\vec{p}_0^{[k]}\leftarrow m(\vec{p}_0)$, and repeats the estimation k time $m(\vec{p}_0)^{[k]}$ converges.

---

[67] Several types of kernel functions are commonly used: uniform, triangle, Epanechnikov, quartic (biweight), tricube, triweight, Gaussian, quadratic and cosine.

For the second typical possible implementation, consider again that $\{\vec{p}_i\}_{i=1\ldots N}$ is the position of the points and K is a given kernel function (that weights the points) for a given iteration, then for each of the N measurement points we have, we calculate the mean relatively to a reference point $\vec{p}_0$ (the center point of the kernel):

$$f(\vec{p}_0)=\frac{1}{N}\sum_{i=1}^{N}K\left(\left\|\frac{\vec{p}_0-\vec{p}_i}{h}\right\|^2\right) \tag{14.1.1870}$$

The first step in this second method with this underlying density $f(\vec{p}_0,h)$ is to find the mode of this density! The mode is located at the zero of the gradient $\vec{\nabla}f(\vec{p}_0,h)=\vec{0}$ and this second method is an elegant way to locate this zero!

Indeed, let us compute the gradient:

$$\begin{aligned}\vec{\nabla}f(\vec{p}_0,h)=\vec{\nabla}\left(\frac{1}{Nh^d}\sum_{i=1}^{N}K\left(\left\|\frac{\vec{p}_0-\vec{p}_i}{h}\right\|^2\right)\right)&=\frac{1}{Nh^d}\sum_{i=1}^{N}K'\left(\left\|\frac{\vec{p}_0-\vec{p}_i}{h}\right\|^2\right)\frac{2}{h^2}(\vec{p}_0-\vec{p}_i)\\&=\frac{2}{Nh^{2+d}}\sum_{i=1}^{N}K'\left(\left\|\frac{\vec{p}_0-\vec{p}_i}{h}\right\|^2\right)(\vec{p}_0-\vec{p}_i)=\vec{0}\end{aligned} \tag{14.1.1871}$$

Now a traditional idea is to replace $\vec{p}_0$ in the last parenthesis thanks to gradient itself. Indeed, that latter leads us to:

$$\frac{2}{Nh^{2+d}}\sum_{i=1}^{N}K'\left(\left\|\frac{\vec{p}_0-\vec{p}_i}{h}\right\|^2\right)\vec{p}_0-\frac{2}{Nh^{2+d}}\sum_{n=1}^{N}K'\left(\left\|\frac{\vec{p}_0-\vec{p}_i}{h}\right\|^2\right)\vec{p}_i=\vec{0} \tag{14.1.1872}$$

Hence after rearranging:

$$\vec{p}_0=\frac{\displaystyle\sum_{i=1}^{N}K'\left(\left\|\frac{\vec{p}_0-\vec{p}_i}{h}\right\|^2\right)\vec{p}_i}{\displaystyle\sum_{n'=1}^{N}K'\left(\left\|\frac{\vec{p}_0-\vec{p}_i}{h}\right\|^2\right)} \tag{14.1.1873}$$

So we get a fixed-point iteration, that brings us to write:

$$\boxed{\vec{p}_0^{[k+1]}=\frac{\displaystyle\sum_{i=1}^{N}K'\left(\left\|\frac{\vec{p}_0^{[k]}-\vec{p}_i}{h}\right\|^2\right)\vec{p}_i}{\displaystyle\sum_{n'=1}^{N}K'\left(\left\|\frac{\vec{p}_0^{[k]}-\vec{p}_i}{h}\right\|^2\right)}} \tag{14.1.1874}$$

Remark

As in the case of Gaussian Kernel we have $K'=K$ we then fall back on the result of the first method:

$$\vec{p}_0^{[k+1]}=\frac{\sum_{i=1}^{N}K\left(\left\|\frac{\vec{p}_0^{[k]}-\vec{p}_i}{h}\right\|^2\right)\vec{p}_i}{\sum_{n'=1}^{N}K\left(\left\|\frac{\vec{p}_0^{[k]}-\vec{p}_i}{h}\right\|^2\right)} \tag{14.1.1875}$$

What interest us is again the "mean shift vector" defined this time by:

$$m(\vec{p}_0^{[k+1]})=\vec{p}_0^{[k+1]}-\vec{p}_0^{[k]}=\frac{\sum_{i=1}^{N}\vec{p}_iK'\left(\left\|\frac{\vec{p}_0^{[k]}-\vec{p}_i}{h}\right\|^2\right)}{\sum_{n'=1}^{N}K'\left(\left\|\frac{\vec{p}_0^{[k]}-\vec{p}_i}{h}\right\|^2\right)}-\vec{p}_0^{[k]} \tag{14.1.1876}$$

Whatever the method, the choice of bandwidth parameter h or Kernel are critical. A large h might result in incorrect clustering and might merge distinct clusters. A very small h might result in too many clusters.

Mean-shift looks very similar to k-means, they both move the point closer to the cluster centroids. One may wonder: How is this different from k-means? The key difference is that Mean shift does not require the user to specify the number of clusters. In some cases, it is not straightforward to guess the right number of clusters to use. In k-means, the output may end up having too few clusters or too many clusters to be useful. At the cost of larger time complexity, Mean shift determines the number of clusters suitable to the dataset provided.

Another commonly cited difference is that k-means can only learn circle or ellipsoidal clusters. However, this is not true. The reason that Mean shift can learn arbitrary shapes is because the features are mapped to another higher dimensional feature space through the kernel. The arbitrary shapes are due to the algorithm finding circle or ellipsoidal clusters in higher dimensional feature space. When the features are mapped back to 1D/2D/3D, the resulting clusters look like strange shapes. This is also the trick as used in Support Vector Machines.

A traditional k-means does not use kernels, but Kernel k-means is available. Kernel k-means is useful if:

1. The number of clusters is known or can be reasonably estimated
2. Dataset needs learning non-ellipsoidal cluster shapes

So, you can enjoy the better runtime complexity of k-means and learn arbitrary clusters if you can determine the number of clusters to use.

14.1.20.5.9 Hierarchical Ascendant Clustering (HAC)

In data mining and statistics, "hierarchical clustering", also named "hierarchical cluster analysis" (HCA) or "hierarchical agglomerative clustering" is an unsupervised method of cluster analysis which seeks to build a hierarchy of clusters in a predefined order. Let us remind that strategies for hierarchical clustering generally fall into two types:

- **Agglomerative/Ascendant:** This is a "bottom-up" approach! each observation starts in its own cluster, and pairs of clusters are merged as one moves up the hierarchy. We speak then of "hierarchical ascendant clustering" (HAC), also known as "Hierarchical Agglomerative Clustering" (HAC) or "AGNES" (acronym for "AGglomerative NESting")
- **Divisive/Descendant:** This is a "top-down" approach! all observations start in one cluster, and splits are performed recursively as one moves down the hierarchy. We speak then of "hierarchical descendant clustering" (HDC), also known as "DIANA" (acronym for "DivisiveANAly").

In order to decide which clusters should be combined (for agglomerative), or where a cluster should be split (for divisive), a measure of dissimilarity between sets of observations is required. In most methods of hierarchical clustering, this is achieved by use of an appropriate metric (a measure of distance between pairs of observations), and a linkage criterion which specifies the dissimilarity of sets as a function of the pairwise distances of observations in the sets.

Remark

"Non hierarchical clustering" involves formation of new clusters by merging or splitting the clusters. It does not follow a tree like structure like hierarchical clustering. This technique groups the data in order to maximize or minimize some evaluation criteria. k-means clustering is an effective way of non hierarchical clustering (see page 6854). In this method the partitions are made such that non-overlapping groups having no hierarchical relationships between themselves.

To introduce this clustering technique let us consider the following companion example based on the following list of data in Microsoft® Excel®:

	A	B	C	D
1	Observation	Wedge	Area	Owner
2	1	60	18.4	1
3	2	85.5	16.8	1
4	3	64.8	21.6	1
5	4	61.5	20.8	1
6	5	87	23.6	1
7	6	110.1	19.2	1
8	7	108	17.6	1
9	8	82.8	22.4	1
10	9	69	20	1
11	10	93	20.8	1
12	11	51	22	1
13	12	81	20	1
14	13	75	19.6	2
15	14	52.8	20.8	2
16	15	64.8	17.2	2
17	16	43.2	20.4	2
18	17	84	17.6	2
19	18	49.2	17.6	2
20	19	59.4	16	2
21	20	66	18.4	2
22	21	47.4	16.4	2
23	22	33	18.8	2
24	23	51	14	2
25	24	63	14.8	2

Figure 14.163: List of data for our study of HAC in Microsoft® Excel® 14.0.6123

We wish to have a hierarchical organization of likeness of individuals based on their income (*Wage*) and their living space (*Area*).

One possible technique is to define for this measurement a distance of similarity. For example, the Euclidean distance:

$$d_{ij}(x,y)=\sqrt{(x_i-x_j)^2+(y_i-y_j)^2} \tag{14.1.1877}$$

is a special choice that will associate two individuals whose distance is minimal. We speak then in the area of clustering "single linkage".

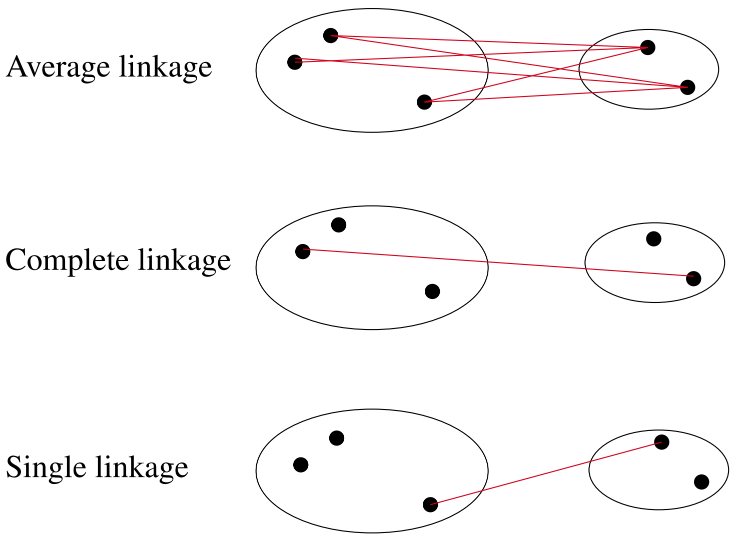


Figure 14.164: **Type of links in Hierarchical Clustering**

Formally:

- Maximum or complete linkage clustering:

$$\max\{d(a,b):a\in A,b\in B\}\tag{14.1.1878}$$

- Minimum or single linkage clustering:

$$\min\{d(a,b):a\in A,b\in B\}\tag{14.1.1879}$$

- Average linkage:

$$\frac{1}{\text{Card}(A\cdot B)}\sum_{a\in A}\sum_{b\in B}d(a,b)\tag{14.1.1880}$$

✍**Example:**

How to measure the distance between two individuals considering:

Id	Firstname	Age	Children	Shoe size	Height
1	Alain	45	3	45	182
2	Martine	28	1	36	165
3	Pierre	22	0	43	172

Who is Martine closest to? We will use the Euclidean distance!

- Distance between Alain and Martine:

$$d_{1*2}=\sqrt{(45-28)^2+(3-1)^2+(45-36)^2+(182-165)^2}$$

- Distance between Martine and Pierre:

$$d_{2*3}=\sqrt{(28-22)^2+(1-0)^2+(36-43)^2+(165-172)^2}$$

- Distance between Alain and Pierre :

$$d_{1*3}=\sqrt{(45-22)^2+(3-0)^2+(45-43)^2+(182-172)^2}$$

Table of distances:

	Alain	Martine	Pierre
Alain	0		
Martine	25.74	0	
Pierre	25.33	11.61	0

We notice that the two variables *Size* and *Children* have little weight in the distance calculation. To remedy this, we must center and reduce the data normally before computing distances!

So we can easily, using a spreadsheet software like Microsoft® Excel® 14.0.6123, create a "distance matrix" or "proximity matrix" which is a symmetric matrix with zero in diagonal and that relatively to the list above will give us:

	A	B	C	D	E	F	G	H	I	J	K	L	M	N	O	P	Q	R	S	T	U	V	W	X	Y	Z	AA

Figure 14.165: **Distance matrix in Microsoft® Excel® 14.0.6123**

where we put in the cell `D4` the following Euclidean distance formula:

```
=SQRT((B4-D2)^2+(C4-D3)^2)
```

we then drag this formula for the rest of the matrix to the cell `AA27`.

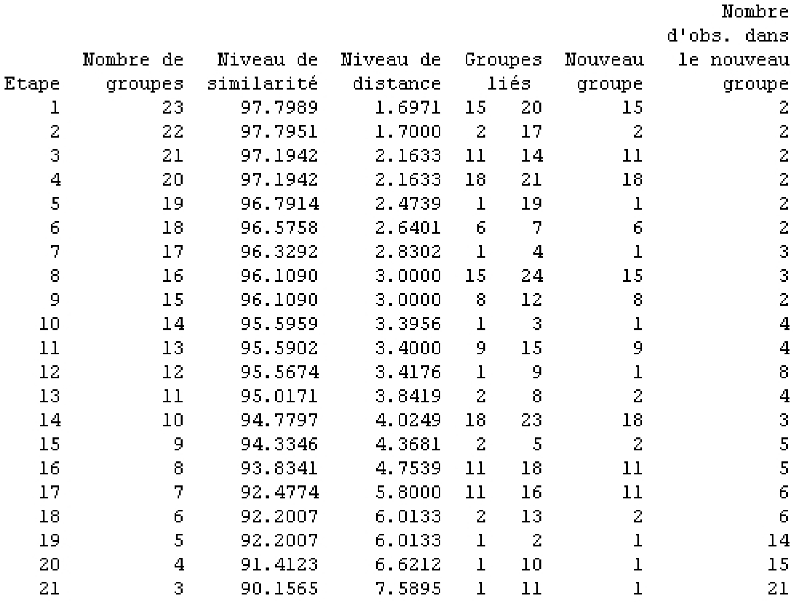
Then we use the bottom-up method (ascendant agglomeration) where we combine the groups until there is only one group remaining (containing all data) and this is a very boring work to describe and to do manually in spreadsheet software with a table of the size given above. We will give a step by step small example later below (see page 6904).

Remark

Let us remind that in their implementation, hierarchical clustering algorithms can adopt one of two following methods:

- The "top-down" ("descending") or "dividing method" consists in starting with a large cluster consisting of the whole data set and then in each step, the successive splitting of the generated clusters is carried out until each cluster consists of only one individual.
- The "bottom-up" ("ascending") or "agglomerative method" reverses the previous logic, it starts with clusters each composed of an individual and then at each step, the clusters are associated in pairs to form other clusters which are in turn joined two to two until a cluster is obtained.

This work will give us in a tabular form following the detailed steps given in our Minitab 15.1.1.0 companion book (values are not rounded to hundredths unlike the small matrix given in the figure above):



```
                                                                   Nombre
                                                                d'obs. dans

   21           3     90.1565      7.5895    1   11         1           21
```

Figure 14.166: HAC distance summary list in Minitab 15.1.1.0

where the level of similarity of the linked group i,j is defined empirically by:

$$S_{i,j}=1-\frac{d_{i,j}(x,y)}{\max(d_{i,j}(x,y))} \qquad (14.1.1881)$$

Thus, for the first row we have for example:

$$S_{15,20}=1-\frac{d_{15,20}(x,y)}{\max(d_{15,20}(x,y))}=1-\frac{1.6971}{77.1010}=97.7989\% \qquad (14.1.1882)$$

The preceding list is more pleasant to analyse if, as it is customary, we represent it is a "dendrogram" (from Greek dendro "tree" and gramma "drawing"), i.e. a tree diagram frequently used to illustrate the arrangement of the clusters produced by hierarchical clustering, as given by Minitab 15.1.1.0 below:

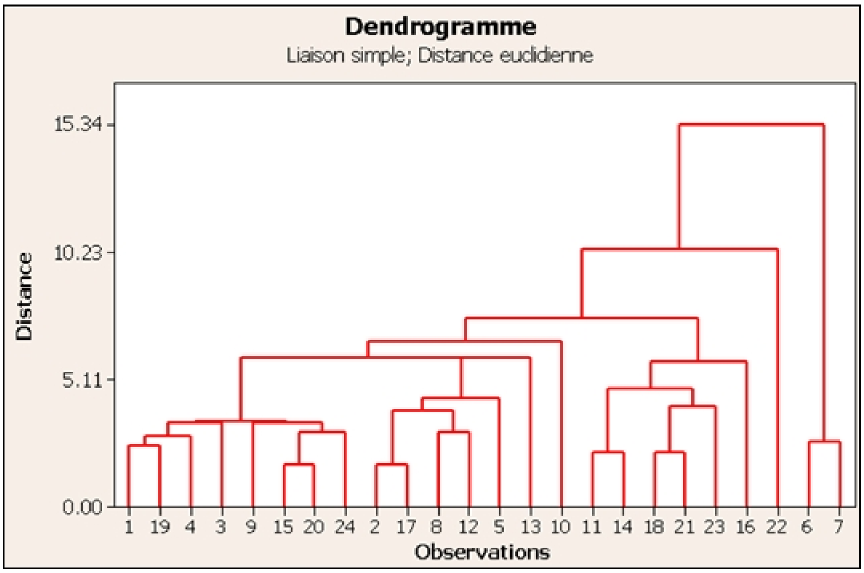

Figure 14.167: **Dendrograms plot in Minitab 15.1.1.0**

If you follow the detailed steps given in our MATLAB® 2013a companion book you will get:

Dendrograms and HAC are also used in biostatistics as shown below (still with R but not described in the companion book yet):

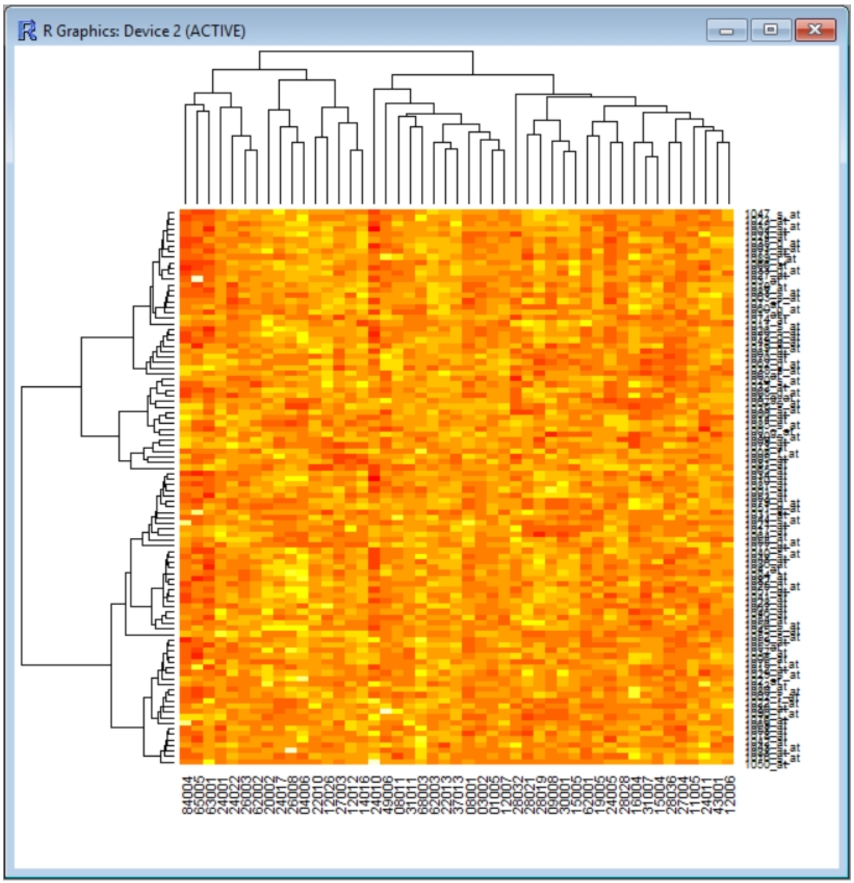

Figure 14.171: Dendrograms heatmap microarray plot in `R` 3.0.2

Or in financial engineering to group similar times series (still with `R` and detailed steps given in the companion book):

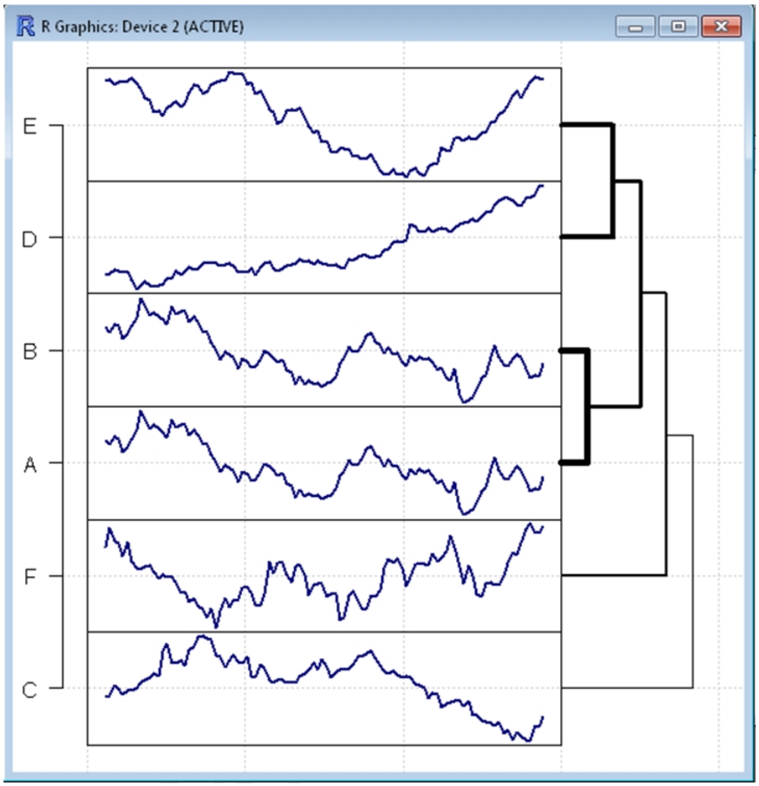

Figure 14.172: **Dendrograms TSA microarray plot in R 3.0.2**

Let's go now for a detailed step by step example! For this consider the following table:

Object	**Weight**	**Length**
a	12	10
b	15	25
c	30	55
d	50	100
e	35	70
f	45	70
g	35	60

All that remains is to determine the matrix of Euclidean distances. The following distance matrix is then obtained with the data set presented above:

	a	b	c	d	e	f	g
a	-	15.30	48.47	97.69	64.26	68.48	55.04
b	15.30	-	33.54	82.76	49.24	54.08	40.31
c	48.47	33.54	-	49.24	15.81	21.21	7.07
d	97.69	82.76	49.24	-	33.54	30.41	42.72
e	64.26	49.24	15.81	33.54	-	10.00	10.00
f	68.48	54.08	21.21	30.41	10.00	-	14.14
g	55.04	40.31	7.07	42.72	10.00	14.14	-

Obviously, the distance between a point and itself is 0 for example $d(a,a)=0$ and the distance:

$$d(a,c)=d(c,a)=\sqrt{(12-30)^2+(10-55)^2}=48.47 \tag{14.1.1883}$$

For the next step, the closest individuals are detected and aggregated into a new cluster and the distance matrix is again calculated. This last one is based on the old one except that the distance between this new cluster formed and the other objects or individuals (or clusters since after 2 iterations, it is possible that clusters already aggregate between them) are recalculated according to the defined method (Single linkage or Complete linkage, ... etc).

On the basis of the previous distance matrix, it can be seen that c and g are the closest (7.07), then they are aggregated. The distance between the cluster $\{\mathrm{c},\mathrm{g}\}$ and the other objects is updated according to the Complete Linkage method (another method could have been used as we have already mention it):

	a	b	{c, g}	d	e	f
a	-	15.30	55.04	97.69	64.26	68.48
b	15.30	-	40.31	82.76	49.24	54.08
{c, g}	55.04	40.31	-	49.24	15.81	21.21
d	97.69	82.76	49.24	-	33.54	30.41
e	64.26	49.24	15.81	33.54	-	10.00
f	68.48	54.08	21.21	30.41	10.00	-

As the method of the complete linkage or the maximum linkage defines the distance between cluster based on the most distant points, then one can calculate:

$$\begin{aligned} d(\mathrm{a},\{\mathrm{c},\mathrm{g}\})&=\max(d(\mathrm{a},\mathrm{c}),d(\mathrm{a},\mathrm{g}))=\max(48.47,55.04)=55.04\\ d(\mathrm{f},\{\mathrm{c},\mathrm{g}\})&=\max(d(\mathrm{f},\mathrm{c}),d(\mathrm{f},\mathrm{g}))=\max(21.21,14.14)=21.21 \end{aligned} \tag{14.1.1884}$$

On the basis of the updated matrix above, a close distance between f and e is detected since their distance is the smallest and equal to 10. Again, a cluster $\{\mathrm{e},\mathrm{f}\}$ is constructed and their distance from the others will also be readjusted according to maximum linkage:

	a	b	{c, g}	d	{e, f}
a	-	15.30	55.04	97.69	68.48
b	15.30	-	40.31	82.76	54.08
{c, g}	55.04	40.31	-	49.24	21.21
d	97.69	82.76	49.24	-	33.54
{e, f}	68.48	54.08	21.21	33.54	-

As the method of the Complete linkage or the maximum linkage defines the distance between cluster based on the most distant points, then one can calculate:

$$\begin{aligned} d(\mathrm{a},\{\mathrm{e},\mathrm{f}\})&=\max(d(\mathrm{a},\mathrm{e}),d(\mathrm{a},\mathrm{f}))=\max(64.26,68.48)=68.48\\ d(\{\mathrm{c},\mathrm{g}\},\{\mathrm{e},\mathrm{f}\})&=\max(d(\{\mathrm{c},\mathrm{g}\},\mathrm{c}),d(\{\mathrm{c},\mathrm{g}\},\mathrm{f}))=\max(15.81,21.21)=21.21 \end{aligned} \tag{14.1.1885}$$

This time it is a and b that will be clustered at a distance of 15.3 and the matrix after updating the distances becomes this:

	$\{a,b\}$	$\{c,g\}$	d	$\{e,f\}$
$\{a,b\}$	-	55.04	97.69	68.48
$\{c,g\}$	55.04	-	49.24	21.21
d	97.69	49.24	-	33.54
$\{e,f\}$	68.48	21.21	33.54	-

The following matrix will give what we have for distances after that $\{\mathrm{c},\mathrm{g}\}$ and $\{\mathrm{e},\mathrm{f}\}$ are grouped to another cluster at a distance of 21.21:

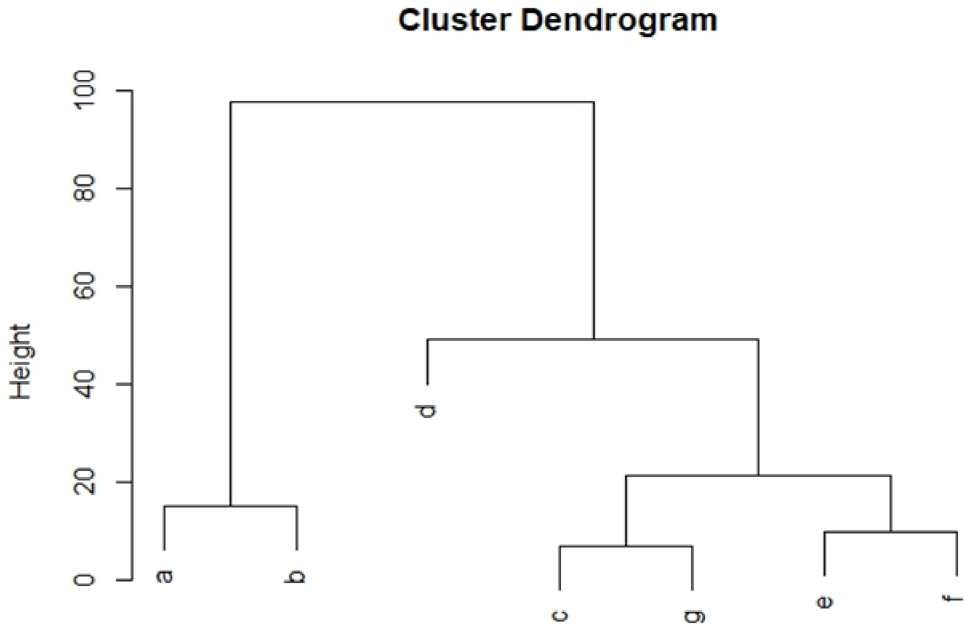
	$\{a,b\}$	$\{\{c,g\},\{e,f\}\}$	d
$\{a,b\}$	-	55.04	97.69
$\{\{c,g\},\{e,f\}\}$	55.04	-	49.24
d	97.69	49.24	-

And then it is the cluster group $\{\{\mathrm{c},\mathrm{g}\},\{\mathrm{e},\mathrm{f}\}\}$ and d that will be grouped at a distance of 49.24, updating the new distances gives:

	$\{a,b\}$	$\{\{c,g\},\{e,f\},d\}$
$\{a,b\}$	-	97.69
$\{\{c,g\},\{e,f\},d\}$	97.69	-

The algorithm ends at the next iteration when $\{\mathrm{a},\mathrm{b}\}$ and the cluster group $\{\{\mathrm{c},\mathrm{g}\},\{\mathrm{e},\mathrm{f}\},\mathrm{d}\}$ will form the root cluster at a distance of 97.69.

This gives us finally the following hierarchical agglomerative ascendant clustering:



The vertical axis *Height* above corresponds to the following calculations we did above:

- $\{\mathrm{c},\mathrm{g}\}$: 7.07
- $\{\mathrm{e},\mathrm{f}\}$: 10.00
- $\{\mathrm{a},\mathrm{b}\}$: 15.3
- $\{\{\mathrm{c},\mathrm{g}\},\{\mathrm{e},\mathrm{f}\}\}$: 21.1
- $\{\{\mathrm{c},\mathrm{g}\},\{\mathrm{e},\mathrm{f}\},d\}$: 97.69

Hierarchical clustering offers the advantage of presenting hierarchical groups so that the resulting ramifications are easy to read. In contrast to the k-means, it does not require the definition of the number of clusters in advance and it is reproducible in the sense that the choice of the initial cluster centers is not random. But in return it is more expensive in time when it comes to implementing it for a large database.

This is why in practice, when dealing with huge databases we use mixed (or hybrid) methods, i.e. before doing a HAC, we first run a k-means and after we do a HAC on the resulting k-means (therefore the bottom of the dendrogram tree will be obtain with a k-means and the upper part with the HAC). This process is named "hybrid hierarchical k-means clustering" (hkmeans) and the reader can see a practical example in our `R` companion book.

Obviously as for the k-nn and the k-means, we may run the HAC on the factorial space obtained after having run a PCA (Principal Component Analysis as seen on page 1213) on our data (see our `R` companion book for an application example). We can also even reduce the dimensions using that latter if necessary!

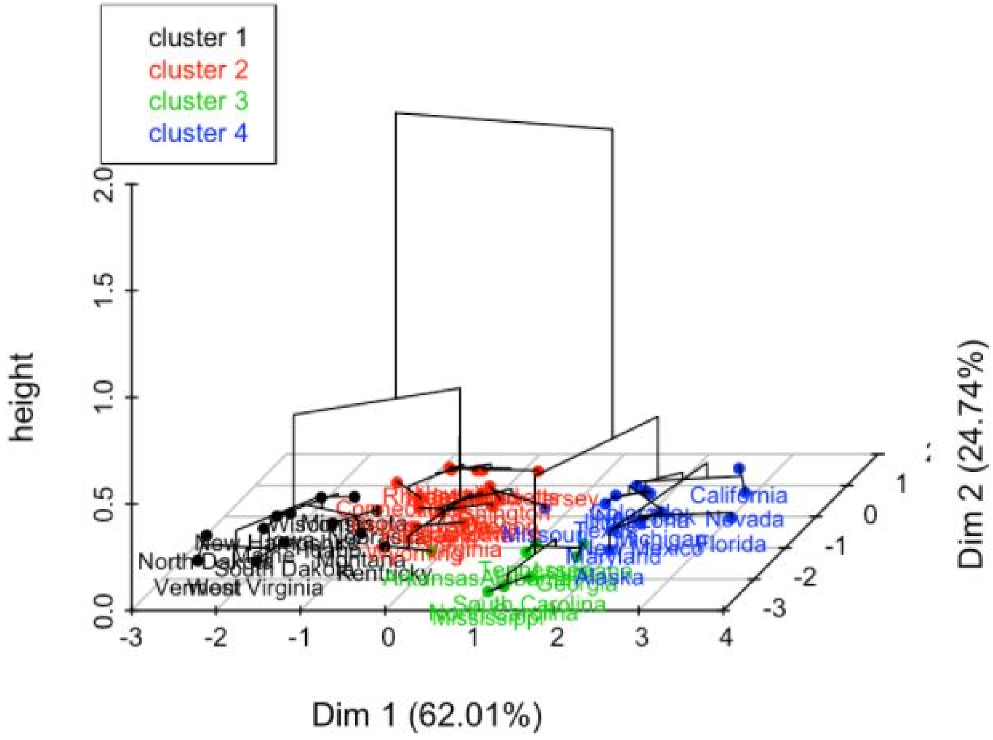


Figure 14.173: HAC on a factor map with R

Remark

To do a classification on qualitative data we will use typically a Multiple Correspondence Analysis (MCA).

14.1.20.5.10 Linear Discriminant Analysis

"Fisher Linear Discriminant Analysis" is a method used in statistics, pattern recognition and machine learning to find a linear combination of features which characterizes or separates two or more classes of objects or events. The resulting combination may be used as a linear classifier, or, more commonly, for dimensionality reduction before later classification.

There are commonly three linear discriminant methods for this technique:

- Maximum likelihood: Assigns $\vec{x}$ to the group that maximizes population (group) density.
- Bayes Discriminant Rule: Assigns $\vec{x}$ to the group that maximizes $\pi_i f_i(\vec{x})$ where π_i represents the prior probability of that classification, and $f_i(x)$ represents the population density.
- Fisher's linear discriminant rule. We will focus here on that method which is the easiest (so see details below!)

LDA is closely related to PCA, for both of them are based on linear, i.e. matrix multiplication, transformations. For the case of PCA, the transformation is based on minimizing mean square error between original data vectors and data vectors that can be estimated fro the reduced dimensionality data vectors. And the PCA does not take into account any difference in class. But for the case of LDA, the transformation is based on maximizing a ratio of “between-class variance" to "within-class variance" with the goal of reducing data variation in the same class and increasing the separation between classes. Let's see an example of LDA.

The idea is seeking to obtain a scalar y (in the special two classes case it's a scalar otherwise it's a vector!) by projecting the samples X onto a line:

$$y = \vec{\theta}^T X \qquad (14.1.1886)$$

Then we try to find the $\vec{\theta}^*$ to maximize the ratio of "between-class variance" to "within-class variance". Next, we will introduce how to use mathematics way to present this problem.

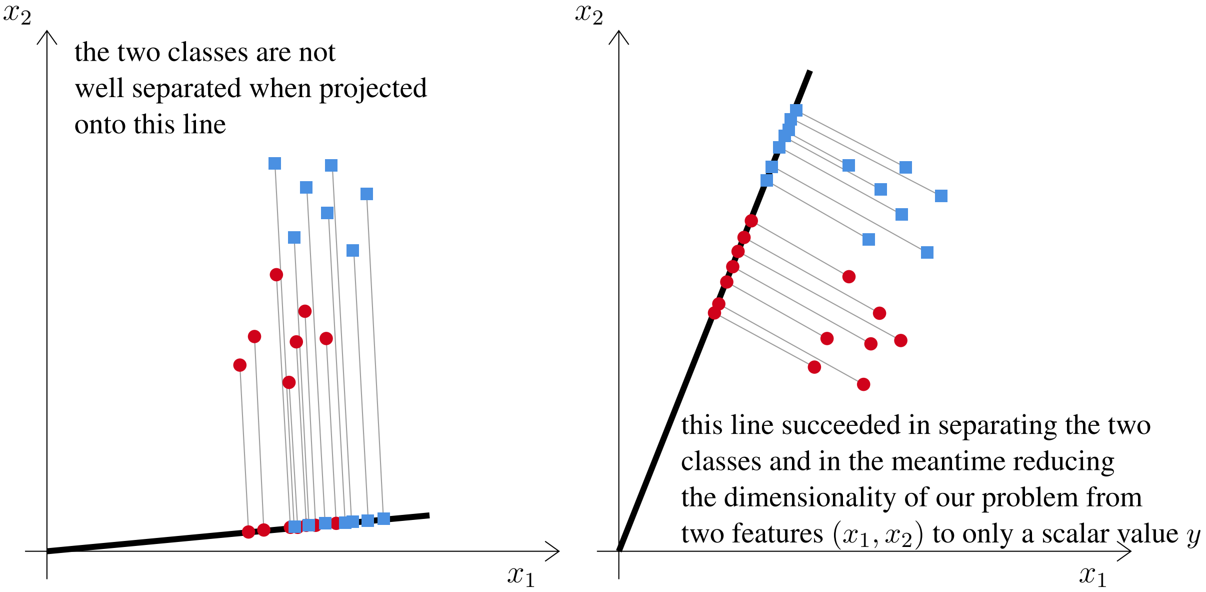

Figure 14.174: Underlying idea of linear discriminant analysis

To figure out the LDA, first we need know how to translate "between-class variance" and "within-class variance" to mathematics language. Then we try to maximize the ratio between these two. To simplify the problem, we start with two classes problem.

14.1.20.5.10.1 Two classes problem

Assume we have a set of D-dimensional samples $X = \{\vec{x}^{(1)}, \vec{x}^{(2)}, \ldots, \vec{x}^{(m)}\}$, n_1 of which belong to class $\mathcal{C}_1$, and n_2 of which belong to class $\mathcal{C}_2$.

We also assume the mean vector of two classes in X-space (if needed, there is a practical detailed numerical example just a little bit further below that can help the reader to understand what follows!):

$$\vec{u}_k = \frac{1}{n_k} \sum_{i \in \mathcal{C}_k} \vec{x}^{(i)} \quad \text{where} \quad k = 1, 2 \tag{14.1.1887}$$

and in y-space:

$$\hat{u}_k = \frac{1}{n_k} \sum_{i \in \mathcal{C}_k} y^{(i)} = \frac{1}{n_k} \sum_{i \in \mathcal{C}_k} \vec{\theta}^T \vec{x}^{(i)} = \vec{\theta}^T \vec{u}_k \quad \text{where} \quad k = 1, 2 \tag{14.1.1888}$$

One way to define a measure of separation between two classes is to choose the distance between the projected means, which is in y-space, so the "between-class variance" is:

$$\hat{u}_2 - \hat{u}_1 = \vec{\theta}^T (\vec{u}_2 - \vec{u}_1) \tag{14.1.1889}$$

Also, we can define the "within-class variance" for each class $\mathcal{C}_k$ is:

$$\hat{s}_k^2 = \sum_{i \in C_k} (\vec{y}^{(i)} - \hat{u}_k)^2 \quad \text{where} \quad k = 1, 2 \tag{14.1.1890}$$

Then, we get the between-class variance and within-class variance, we can define our objective function $J(\theta)$ as:

$$J(\theta)=\frac{(\hat{u}_2-\hat{u}_1)^2}{\hat{s}_1^2+\hat{s}_2^2} \tag{14.1.1891}$$

In fact, if maximizing the objective function J, we are looking for a projection where examples from the class are projected very close to each other and at the same time, the projected means are as farther apart as possible.

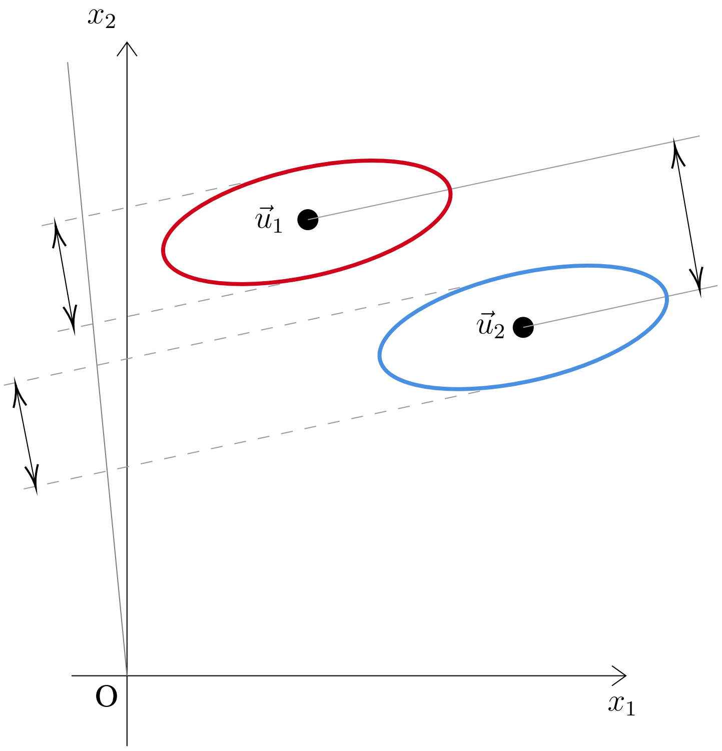

Figure 14.175: **Expected configuration for linear Discriminant analysis**

To find the optimum θ^*, we must express $J(\theta)$ as a function of θ. Before the optimum,we need introduce the "scatter" matrix instead of variance.

We define some measures of the scatter as following:

- The scatter matrix in feature space-x:

$$\vec{S}_k=\sum_{i\in\mathcal{C}_k}(\vec{x}^{(i)}-\vec{u}_k)(\vec{x}^{(i)}-\vec{u}_k)^T \tag{14.1.1892}$$

- The within-class scatter matrix:

$$S_W=S_1+S_2 \tag{14.1.1893}$$

- The between-class scatter matrix:

$$S_B=(\vec{u}_2-\vec{u}_1)(\vec{u}_2-\vec{u}_1)^T \tag{14.1.1894}$$

Let's see $J(\theta)$ again:

$$J(\theta)=\frac{(\hat{u}_2-\hat{u}_1)^2}{\hat{s}_1^2+\hat{s}_2^2} \tag{14.1.1895}$$

The scatter of the projection y can then be expressed as a function of the scatter matrix in feature space X:

$$\begin{aligned}\hat{s}_k^2 &=\sum_{i\in\mathcal{C}_k}(\vec{y}^{(i)}-\hat{u}_k)^2=\sum_{i\in\mathcal{C}_k}(\vec{\theta}^T\vec{x}^{(i)}-\vec{\theta}^T\vec{u}_k)^2=\sum_{i\in\mathcal{C}_k}\vec{\theta}^T(\vec{x}^{(i)}-\vec{u}_k)(\vec{x}^{(i)}-\vec{u}_k)^T\vec{\theta}\\ &=\vec{\theta}^T S_k\vec{\theta}\end{aligned} \tag{14.1.1896}$$

So we can get:

$$\hat{s}_1^2+\hat{s}_2^2=\vec{\theta}^T S_1\theta+\vec{\theta}^T S_2\vec{\theta}=\vec{\theta}^T S_W\vec{\theta} \tag{14.1.1897}$$

Similarly, the difference between the projected means can be expressed in terms of the means in the original feature space:

$$(\hat{u}_2-\hat{u}_1)^2=(\vec{\theta}^T\vec{u}_2-\vec{\theta}^T\vec{u}_1)^2=\vec{\theta}^T(\vec{u}_2-\vec{u}_1)(\vec{u}_2-\vec{u}_1)^T\vec{\theta}=\vec{\theta}^T S_B\vec{\theta} \tag{14.1.1898}$$

We can finally express the "Fisher criterion" in terms of S_W and S_B as:

$$\boxed{J(\vec{\theta})=\frac{\vec{\theta}^T S_B\vec{\theta}}{\vec{\theta}^T S_W\vec{\theta}}} \tag{14.1.1899}$$

Next, we will maximize this objective function.

The easiest way to maximize the object function J is to derive it and set it to zero:

$$\begin{aligned}\frac{\partial J(\vec{\theta})}{\partial\vec{\theta}} &=\frac{\partial}{\partial\vec{\theta}}\left(\frac{\vec{\theta}^T S_B\vec{\theta}}{\vec{\theta}^T S_W\vec{\theta}}\right)\\ &=(\vec{\theta}^T S_W\vec{\theta})\frac{\partial(\vec{\theta}^T S_B\vec{\theta})}{\partial\vec{\theta}}-(\theta^T S_B\vec{\theta})\frac{\partial(\vec{\theta}^T S_W\vec{\theta})}{\partial\vec{\theta}}=\vec{0}\\ \Longrightarrow &=(\vec{\theta}^T S_W\vec{\theta})2S_B\vec{\theta}-(\vec{\theta}^T S_B\vec{\theta})2S_W\vec{\theta}=\vec{0}\end{aligned} \tag{14.1.1900}$$

Divided by $\vec{\theta}^T S_W\vec{\theta}$:

$$\begin{aligned}&\Longrightarrow\left(\frac{\vec{\theta}^T S_W\vec{\theta}}{\vec{\theta}^T S_W\vec{\theta}}\right)S_B\vec{\theta}-\left(\frac{\vec{\theta}^T S_B\vec{\theta}}{\vec{\theta}^T S_W\vec{\theta}}\right)S_W\vec{\theta}=\vec{0}\\ &\Longrightarrow S_B\vec{\theta}-JS_W\vec{\theta}=\vec{0}\\ &\Longrightarrow S_W^{-1}S_B\vec{\theta}-J\vec{\theta}=\vec{0}\\ &\Longrightarrow J\vec{\theta}=S_W^{-1}S_B\vec{\theta}\\ &\Longrightarrow J\vec{\theta}=S_W^{-1}(\vec{u}_2-\vec{u}_1)(\vec{u}_2-\vec{u}_1)^T\vec{\theta}\\ &\Longrightarrow J\vec{\theta}=S_W^{-1}(\vec{u}_2-\vec{u}_1)(\underbrace{(\vec{u}_2-\vec{u}_1)^T\vec{\theta}}_{c^{te}\in\mathbb{R}})\\ &\Longrightarrow J\vec{\theta}=c^{te}S_W^{-1}(\vec{u}_2-\vec{u}_1)\\ &\Longrightarrow\vec{\theta}=\frac{c^{te}}{J}S_W^{-1}(\vec{u}_2-\vec{u}_1)\end{aligned} \tag{14.1.1901}$$

Notice that using the third row above, we have a classical generalized eigenvalue problem:

$$\left(S_W^{-1}S_B - J\right)\vec{\theta} = \vec{0} \qquad (14.1.1902)$$

Often denoted as ((see section Linear Algebra page 1998):

$$\det\left(S_W^{-1}S_B - \lambda I\right) = 0 \qquad (14.1.1903)$$

For now, the problem has been solved and we just want to get the direction of the $\vec{\theta}$, which is the optimum $\vec{\theta}^*$:

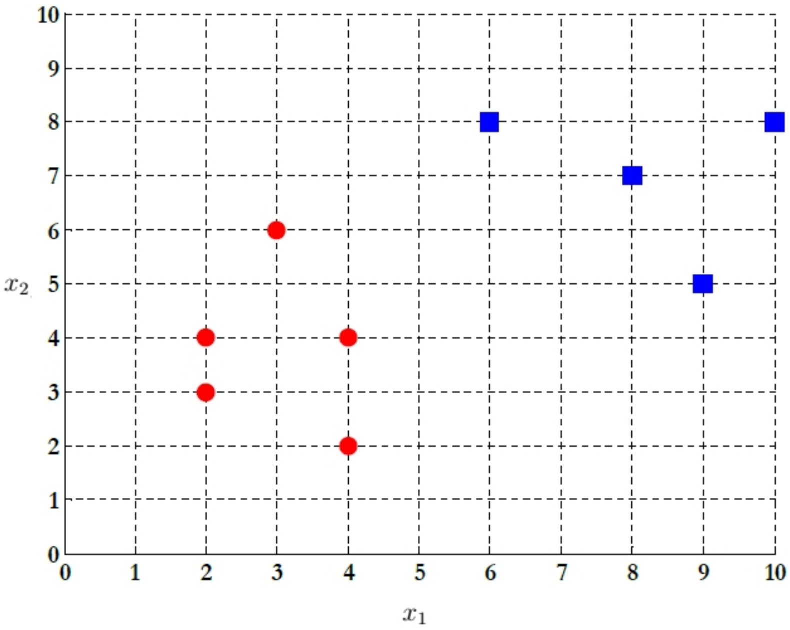
$$\vec{\theta}^* \propto S_W^{-1}(\vec{u}_2 - \vec{u}_1) \qquad (14.1.1904)$$

This is known as "Fisher's linear discriminant" (11936 according to holocene calendar), although it is not a discriminant but rather a specific choice of direction for the projection of the data down to one dimension, which is $y = \vec{\theta}^{*T}X$.

✍**Example:**

We want to compute the Linear Discriminant projection for the following two-dimensional dataset:

- Samples for class $\mathcal{C}_1 : X_1 = (x_1, x_2) = \{(4,2),(2,4),(2,3),(3,6),(4,4)\}$
- Sample for class $\mathcal{C}_2 : X_2 = (x_1, x_2) = \{(9,10),(6,8),(9,5),(8,7),(10,8)\}$



The classes means are :

$$\vec{u}_1 = \frac{1}{n_1}\sum_{\vec{x}\in\mathcal{C}_1}\vec{x}^{(i)} = \frac{1}{5}\left[\begin{pmatrix}4\\2\end{pmatrix}+\begin{pmatrix}2\\4\end{pmatrix}+\begin{pmatrix}2\\3\end{pmatrix}+\begin{pmatrix}3\\6\end{pmatrix}+\begin{pmatrix}4\\4\end{pmatrix}\right] = \begin{pmatrix}3\\3.8\end{pmatrix}$$

$$\vec{u}_2 = \frac{1}{n_2}\sum_{\vec{x}\in\mathcal{C}_2}\vec{x}^{(i)} = \frac{1}{5}\left[\begin{pmatrix}9\\10\end{pmatrix}+\begin{pmatrix}6\\8\end{pmatrix}+\begin{pmatrix}9\\5\end{pmatrix}+\begin{pmatrix}8\\7\end{pmatrix}+\begin{pmatrix}10\\8\end{pmatrix}\right] = \begin{pmatrix}8.4\\7.6\end{pmatrix}$$

The covariance matrix of the first class is:

$$\begin{aligned}
S_1 = \sum_{\vec{x}\in\mathcal{C}_1} (\vec{x}^{(i)} - \vec{u}_1)\,(\vec{x}^{(i)} - \vec{u}_1)^T &= \left[\begin{pmatrix} 4 \\ 2 \end{pmatrix} - \begin{pmatrix} 3 \\ 3.8 \end{pmatrix}\right]^2 + \left[\begin{pmatrix} 2 \\ 4 \end{pmatrix} - \begin{pmatrix} 3 \\ 3.8 \end{pmatrix}\right]^2 \\
&+ \left[\begin{pmatrix} 2 \\ 3 \end{pmatrix} - \begin{pmatrix} 3 \\ 3.8 \end{pmatrix}\right]^2 + \left[\begin{pmatrix} 3 \\ 6 \end{pmatrix} - \begin{pmatrix} 3 \\ 3.8 \end{pmatrix}\right]^2 + \left[\begin{pmatrix} 4 \\ 4 \end{pmatrix} - \begin{pmatrix} 3 \\ 3.8 \end{pmatrix}\right]^2 \\
&= \begin{pmatrix} 1 & -0.25 \\ -0.25 & 2.2 \end{pmatrix}
\end{aligned}$$

Covariance matrix of the second class:

$$\begin{aligned}
S_2 = \sum_{\vec{x}\in\mathcal{C}_2} (\vec{x}^{(i)} - \vec{u}_2)\,(\vec{x}^{(i)} - \vec{u}_2)^T &= \left[\begin{pmatrix} 9 \\ 10 \end{pmatrix} - \begin{pmatrix} 8.4 \\ 7.6 \end{pmatrix}\right]^2 + \left[\begin{pmatrix} 6 \\ 8 \end{pmatrix} - \begin{pmatrix} 8.4 \\ 7.6 \end{pmatrix}\right]^2 \\
&+ \left[\begin{pmatrix} 9 \\ 5 \end{pmatrix} - \begin{pmatrix} 8.4 \\ 7.6 \end{pmatrix}\right]^2 + \left[\begin{pmatrix} 8 \\ 7 \end{pmatrix} - \begin{pmatrix} 8.4 \\ 7.6 \end{pmatrix}\right]^2 + \left[\begin{pmatrix} 10 \\ 8 \end{pmatrix} - \begin{pmatrix} 8.4 \\ 7.6 \end{pmatrix}\right]^2 \\
&= \begin{pmatrix} 2.3 & -0.05 \\ -0.05 & 3.3 \end{pmatrix}
\end{aligned}$$

Therefore we have the within-class scatter matrix:

$$S_W = S_1 + S_2 = \begin{pmatrix} 1 & -0.25 \\ -0.25 & 2.2 \end{pmatrix} + \begin{pmatrix} 2.3 & -0.05 \\ -0.05 & 3.3 \end{pmatrix} = \begin{pmatrix} 3.3 & -0.3 \\ -0.3 & 5.5 \end{pmatrix}$$

Between-class scatter matrix:

$$\begin{aligned}
S_B = (\vec{u}_1 - \vec{u}_2)\,(\vec{u}_1 - \vec{u}_2)^T &= \left[\begin{pmatrix} 3 \\ 3.8 \end{pmatrix} - \begin{pmatrix} 8.4 \\ 7.6 \end{pmatrix}\right]\left[\begin{pmatrix} 3 \\ 3.8 \end{pmatrix} - \begin{pmatrix} 8.4 \\ 7.6 \end{pmatrix}\right]^T \\
&= \begin{pmatrix} -5.4 \\ -3.8 \end{pmatrix} \begin{pmatrix} -5.4 & -3.8 \end{pmatrix} = \begin{pmatrix} 29.16 & 20.52 \\ 20.52 & 14.44 \end{pmatrix}
\end{aligned}$$

The LDA projection is then obtained as the solution of the generalized eigen value problem:

$$\begin{aligned}
&S_W^{-1} S_B \vec{\theta} = \lambda \vec{\theta} \\
&\qquad \det\left(S_W^{-1} S_B - \lambda I\right) = 0 \\
&\qquad \Rightarrow \left| \begin{pmatrix} 3.3 & -0.3 \\ -0.3 & 5.5 \end{pmatrix}^{-1} \begin{pmatrix} 29.16 & 20.52 \\ 20.52 & 14.44 \end{pmatrix} - \lambda \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \right| = 0 \\
&\qquad \Rightarrow \left| \begin{pmatrix} 0.3045 & 0.0166 \\ 0.0166 & 0.1827 \end{pmatrix} \begin{pmatrix} 29.16 & 20.52 \\ 20.52 & 14.44 \end{pmatrix} - \lambda \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \right| = 0 \\
&\qquad \Rightarrow \left| \begin{pmatrix} 9.2213 - \lambda & 6.489 \\ 4.2339 & 2.9794 - \lambda \end{pmatrix} \right| \\
&\qquad = \left(9.2213 - \lambda \right)(2.9794 - \lambda) - 6.489 \times 4.2339 = 0 \\
&\qquad \Rightarrow \lambda^2 - 12.2007\lambda = 0 \Rightarrow \lambda(\lambda - 12.2007) = 0 \\
&\qquad \Rightarrow \lambda_1 = 0, \lambda_2 = 12.2007
\end{aligned}$$

We have therefore also two eigenvectors. One is the zero vector so it has no interest. It remains only the second that takes us to write:

$$S_W^{-1}S_B\vec{\theta}_2=\lambda_2\vec{\theta}_2 \Leftrightarrow \begin{pmatrix}9.2213 & 6.489\\ 4.2339 & 2.9794\end{pmatrix}\begin{pmatrix}\theta_1^{(2)}\\ \theta_2^{(2)}\end{pmatrix}=\underbrace{12.2007}_{\lambda_2}\begin{pmatrix}\theta_1^{(2)}\\ \theta_2^{(2)}\end{pmatrix}$$

Therefore we just have to solve the following system:

$$\begin{aligned}9.2213\theta_1^{(2)}+6.489\theta_2^{(2)}&=12.2007\theta_1^{(2)}\\ 4.2339\theta_1^{(2)}+2.979\theta_2^{(2)}&=12.2007\theta_2^{(2)}\end{aligned}$$

Hence:

$$\vec{\theta}^*=\vec{\theta}_2=\begin{pmatrix}\theta_1^{(2)}\\ \theta_2^{(2)}\end{pmatrix}=\begin{pmatrix}0.9088\\ 0.4173\end{pmatrix}$$

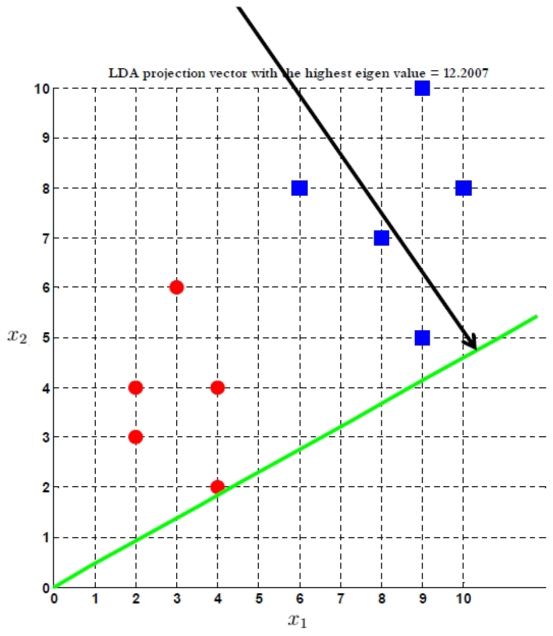
We can get the same result more directly using the relation derived also earlier above:

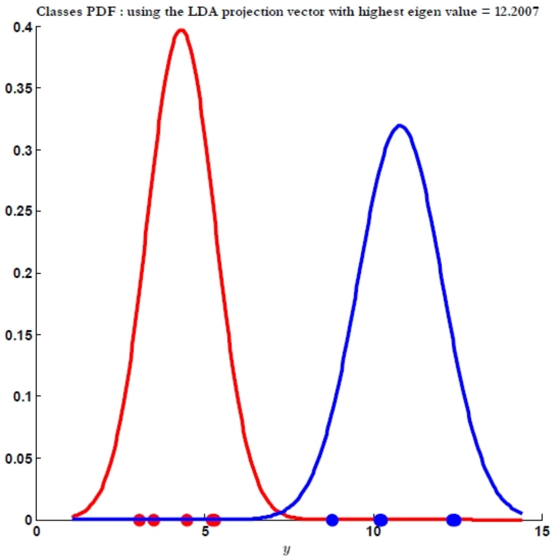
$$\vec{\theta}^*\propto S_W^{-1}(\vec{u}_2-\vec{u}_1)$$

Hence:

$$\begin{aligned}\vec{\theta}^*=S_W^{-1}(\mu_1-\mu_2)&=\begin{pmatrix}3.3 & -0.3\\ -0.3 & 5.5\end{pmatrix}^{-1}\left[\begin{pmatrix}3\\ 3.8\end{pmatrix}-\begin{pmatrix}8.4\\ 7.6\end{pmatrix}\right]\\ &=\begin{pmatrix}0.3045 & 0.0166\\ 0.0166 & 0.1827\end{pmatrix}\begin{pmatrix}-5.4\\ -3.8\end{pmatrix}=\begin{pmatrix}0.9088\\ 0.4173\end{pmatrix}\end{aligned}$$

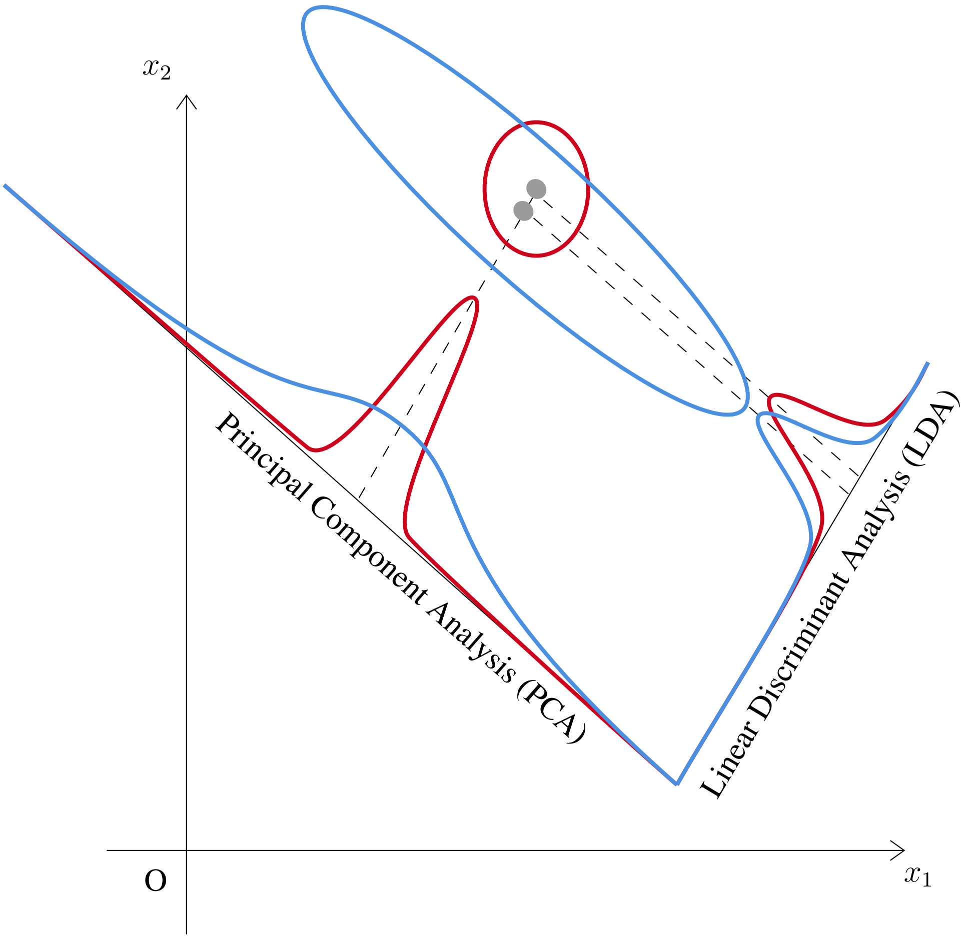
The projection vector corresponding to the **highest** eigen value





Using this vector leads to **good separability** between the two classes

Notice that LDF will fail when the discriminatory information is not in the mean but rather in the variance of the data as illustrated below:



x_2
x_1
O
Principal Component Analysis (PCA)
Linear Discriminant Analysis (LDA)

Figure 14.176: Typical case where LDA fail and PCA don't

Through this example with see better why LDA is not only a classification technique. It is a composite, two-stage technique: first it reduce dimensionality, then it classifies.

Classification of new data that weren't in the training set is essentially done with the class that belongs the closest class mean[68].

Remark

The reader can refer to our R or MATLAB® free companion books to see examples with the respective script language of these two softwares for the same set of numerical data.

---

[68] And in the case of the Bayesian approach of LDA a prior term is added to shift the mean closer or further from the new point.

14.1.20.5.10.2 Multiclass problem

Based on two classes problem, we can see that the Fisher's LDA generalizes gracefully for multiple classes problem (we speak then of "Multiple Discriminant Analysis"). Assume we still have a set of D-dimensional samples $X=\{\vec{x}^{(1)},\vec{x}^{(2)},\ldots,\vec{x}^{(m)}\}$, and there are totally C classes. Instead of one projection y, mentioned above, we now will seek $(\mathcal{C}-1)$ projections $[y_1,y_2,\ldots y_{\mathcal{C}-1}]$ by means of $(\mathcal{C}-1)$ projection vectors $\vec{\theta}_i$ arranged by columns into a projection matrix $\Theta=[\vec{\theta}_1|\vec{\theta}_2|\ldots|\vec{\theta}_{C-1}]$, where:

$$y_i=\vec{\theta}_i^T X \Longrightarrow \vec{y}=\Theta^T X \tag{14.1.1905}$$

First we will use the scatters in space-x as following:

- Within-class scatter matrix:

$$S_W=\sum_{i=1}^{\mathcal{C}} S_i \quad \text{where} \quad S_i=\sum_{i\in\mathcal{C}_i}(\vec{x}^{(i)}-\vec{u}_i)(\vec{x}^{(i)}-\vec{u}_i)^T \text{ and } \vec{u}_i=\frac{1}{n_i}\sum_{i\in\mathcal{C}_i}\vec{x}^{(i)} \tag{14.1.1906}$$

- Between-class scatter matrix:

$$S_B=\sum_{i=1}^{\mathcal{C}} n_i(\vec{u}_i-\vec{u})(\vec{u}_i-\vec{u})^T \quad \text{where} \quad \vec{u}=\frac{1}{m}\sum_{i=1}^{m}\vec{x}^{(i)}=\frac{1}{m}\sum_{i=1}^{\mathcal{C}} n_i\vec{u}_i \tag{14.1.1907}$$

- Total scatter matrix:

$$S_T=S_B+S_W \tag{14.1.1908}$$

Similarly, we define the mean vector and scatter matrices for the projected samples as:

- $\vec{\hat{u}}_i=\frac{1}{n_i}\sum_{i\in\mathcal{C}_i}\vec{y}^{(i)}$
- $\vec{\hat{u}}=\frac{1}{N}\sum_{i=1}^{m}\vec{y}^{(i)}$
- $\hat{S}_W=\sum_{i=1}^{\mathcal{C}}\sum_{\vec{y}\in\mathcal{C}_i}(\vec{y}-\vec{\hat{u}}_i)(\vec{y}-\vec{\hat{u}}_i)^T$
- $\hat{S}_B=\sum_{i=1}^{\mathcal{C}} n_i(\vec{\hat{u}}_i-\vec{\hat{u}})(\vec{\hat{u}}_i-\vec{\hat{u}})^T$

From our derivation for the two-class problem, we can get:

$$\begin{gathered}\hat{S}_W=\Theta^T S_W\Theta\\ \hat{S}_B=\Theta^T S_B\Theta\end{gathered} \tag{14.1.1909}$$

Recall that we are looking for a projection that maximizes the ratio of between-class to within-class scatter. Since the projection is no longer a scalar (it has $\mathcal{C}-1$ dimensions), we use the determinant of the scatter matrices to obtain a scalar objective function:

$$J(\Theta)=\frac{|\hat{S}_B|}{|\hat{S}_W|}=\frac{|\Theta^T S_B\Theta|}{|\Theta^T S_W\Theta|} \tag{14.1.1910}$$

And now, our job is to seek the projection matrix Θ^* that maximize this ratio. We will not give the derivation process. But we know that the optimal projection matrix Θ^* is the one whose columns are the eigenvectors corresponding to the largest eigenvalues of the following generalized eigenvalue problem:

$$\Theta^* = [\theta_1^*|\theta_2^*|\ldots|\theta_{C-1}^*] = \text{argmax}\frac{|\Theta^T S_B \Theta|}{|\Theta^T S_W \Theta|} \tag{14.1.1911}$$

Hence:

$$(S_B - \lambda_i S_W)\Theta_i^* = 0 \tag{14.1.1912}$$

Thus, if S_W is a non-singular matrix, and can be inverted, then the Fisher's criterion is maximized when the projection matrix Θ^* is composed of the eigenvectors of:

$$S_W^{-1} S_B \tag{14.1.1913}$$

Noticed that, there will be at most $\mathcal{C}-1$ eigenvectors with non-zero real corresponding eigenvalues λ_i. This is because S_B is of rank $(\mathcal{C}-1)$ or less. So we can see that LDA can represent a massive reduction in the dimensionality of the problem. In face recognition for example there may be several thousand variables, but only a few hundred classes.

Remark

The reader must keep in mind that what we have seen here is a naive approach of LDA. Investigating further and using Bayesian analysis, we can prove that the above results are just a special case of that latter. Maybe (or maybe not) we will provide the detailed bayesian derivation in the 5th edition of the present book.

14.1.20.6 Dimensionality Reduction

"Dimensionality reduction" or "dimension reduction" is the process of reducing the number of random variables under consideration.

More technically, dimensionality reduction is typically choosing a basis or mathematical representation within which you can describe most but not all of the variance within your data, thereby retaining the relevant information, while reducing the amount of information necessary to represent it.

Approaches can be divided into "feature selection" and "feature extraction".

Definitions (#14.1.572):

D1. "Feature selection" approaches try to find a subset of the known input variables (also naed "features" or "attributes"). The three strategies are: the filter strategy (e.g. information gain), the wrapper strategy (e.g. search guided by accuracy), and the embedded strategy (selected features are added or are removed while building the model based on prediction errors).

Typical feature selection methods are:

- Missing Value Ratio
- Low Variance Filter
- High Correlation Filter
- Random Forests
- Backward Feature Selection
- Forward Feature Selection
- ...

D2. "Feature extraction" approaches transform the data from a well known interpretable high-dimensional space to a space of smaller abstract dimensional space. The data transformation may be linear, as in Principal Component Analysis (we have already study quite in detail the naive version of Principal Component Analysis in the section Statistics page 1213), but many non-linear dimensionality reduction techniques also exist.

Typical feature extraction methods are:

- Components/Factor based:
  - Factor Analysis
  - Principal Component Analysis
  - Independent Component Analysis
  - ...
- Projection based:
  - ISOMAP
  - T-SNE
  - UMAP

- ∗ Linear discriminant analysis (LDA)
- ∗ ...

For a more exhaustive list of techniques the reader can refer as always to the Data Science Mind Map at page 6770.

14.1.20.6.1 Principal Component Analysis

As already mentioned earlier, PCA unsupervised feature selection dimensionality reduction is already treated quite with details in its naive version in the section of Statistics at page 1213.

14.1.20.6.2 Linear Discriminant Analysis (LDA)

The LDA supervised projection dimensionality reduction method has also been treated earlier quite in details in it's naive version at page 6908 because it is also a classification technique as we saw it!

So let us focus on the second most common component/factor based dimensionality reduction technique that is MDS:

14.1.20.6.3 MultiDimensional Scaling (MDS)

The goal of "multidimensional scaling" (MDS) is to visualize a set of N objects based on their similarities measured in n different aspects, and the "classical MDS" (cMDS), also known as "principal coordinates analysis" (PCoA), is one of the methods for MDS but that adds the possibility to reduce the space dimension of the original set.

Let us introduce the first aspect of MDS. Being known the level of similarity of individual cases of a dataset (without knowing their intrinsic characteristics!), the purpose of MDS is to find a way of visualizing the original intrinsic unknown characteristics. In other words, MDS is used to translate information about the pairwise distances among a set of N objects or individuals into a configuration of N points mapped into an abstract Cartesian space.

Formally, given a pairwise similarity matrix $D_x = [d_{ij}^x]_{N\times N}$ (see section Linear Algebra page 1959) of a set of N objects (N data points in an n-dimensional space) $X = [\vec{x}_1,\ldots,\vec{x}_N]$ but of unknown components, where the ij-th component d_{ij}^x is some measurement of the similarity between $\vec{x}_i$ and $\vec{x}_j$ such as the Euclidean distance $d_{ij}^x = ||\vec{x}_i - \vec{x}_j||_2$ between $\vec{x}_i$ and $\vec{x}_j$, we want to be able to construct a map $Y = [\vec{y}_1,\ldots,\vec{y}_N]$ in an n dimensional space that explains well enough the original D_x by reversing the original unknown components of the $X = [\vec{x}_1,\ldots,\vec{x}_N]$. When $n = 2$ or 3, the resulting dataset Y can be visualized and the corresponding chart is then name a "perceptual plot".

So the idea is given the only known dissimilarity matrix $D_x = [d_{ij}^x]_{N\times N}$ to find a best estimate of the original unknown $X = [\vec{x}_1,\ldots,\vec{x}_N]$, that we will denote $Y = [\vec{y}_1,\ldots,\vec{y}_N]$. These estimates will obviously lead to a dissimilarity matrix that we will denote $D_y = [d_{ij}^y]_{N\times N}$.

Our goal again is then to find $Y = [\vec{y}_1,\ldots,\vec{y}_N]$ so that its pairwise similarity matrix D_y matches D_x optimally, in the sense that the following objective function, named sometimes "strain" in the MDS study field, is minimized:

$$o(Y) = \left\|D_y^2 - D_x^2\right\| \tag{14.1.1914}$$

with obviously all d_{ij}^x who are given, but where the given estimated pairwise similarity of Euclidean distance:

$$d_{ij}^y = \|\vec{y}_i - \vec{y}_j\| = \sqrt{(\vec{y}_i - \vec{y}_j)^T(\vec{y}_i - \vec{y}_j)} \tag{14.1.1915}$$

have to be determined.

Remark

This optimization problem is also often denoted:

$$o(\hat{X}) = \left\|D_{\hat{x}}^2 - D_x^2\right\| \tag{14.1.1916}$$

with D_x^2 given and $D_{\hat{x}}$ to be found when calculated as:

$$d_{ij}^{\hat{x}} = \left\|\vec{\hat{x}}_i - \vec{\hat{x}}_j\right\| = \sqrt{\left(\vec{\hat{x}}_i - \vec{\hat{x}}_j\right)^T\left(\vec{\hat{x}}_i - \vec{\hat{x}}_j\right)} \tag{14.1.1917}$$

The optimisation problem above is often written explicitly as (but there are other empirical choices as we already know that leads to different final results):

$$\arg\min_{Y} \sum_{i,j} \left(d_{ij}^{y} - d_{ij}^{x}\right)^2 \tag{14.1.1918}$$

otherwise it doesn't make really sense.

This relation is often normalized (to have values that have non physical units) and root squared (it's more convenient to deal with distance)and a special name is given to it, the "Kruskal's Stress coefficient" and denoted:

$$\arg\min_{Y} \text{Stress}_D \sqrt{\frac{\sum_{i,j} \left(d_{ij}^{y} - d_{ij}^{x}\right)^2}{\sum_{i,j} d_{ij}^{x}}} \tag{14.1.1919}$$

Remark

Some computer softwares don't normalize, nor take the square root, that's why the objective final value function may differ between softwares.

14.1.20.6.3.1 Classical MDS (cMDS)

Given again a pairwise similarity matrix $D_x = [d_{ij}^x]_{N\times N}$ of a set of N objects (N data points in an n dimensional space) $X = [\vec{x}_1, \ldots, \vec{x}_N]$, where the ij-th component d_{ij}^x is some measurement of the similarity between $\vec{x}_i$ and $\vec{x}_j$ such as the Euclidean distance $d_{ij}^x = ||\vec{x}_i - \vec{x}_j||_2$ between $\vec{x}_i$ and $\vec{x}_j$, we can construct a map $Y = [\vec{y}_1, \ldots, \vec{y}_N]$ in an m dimensional space ($m < n$) so that its pairwise distance matrix $D_y = [d_{ij}^y]_{N\times N} = ||\vec{y}_i - \vec{y}_j||_2$ explains well enough the original D_x. As $m < n$, cMDS can be considered as a method for dimension reduction.

In some cases only the similarities d_{ij}^x $(i, j = 1, \ldots, N)$ are given, while the N objects in X are not explicitly given, and the dimensionality n may not even be known!

We first assume the given pairwise similarity is the Euclidean distance $d_{ij} = ||\vec{x}_i - \vec{x}_j||_2$:

$$d_{ij}^2 = \|\vec{x}_i - \vec{x}_j\|^2 = (\vec{x}_i - \vec{x}_j)^T(\vec{x}_i - \vec{x}_j) = \|\vec{x}_i\|^2 - 2\vec{x}_i^T\vec{x}_j + \|\vec{x}_j\|^2 \tag{14.1.1920}$$

and we build the following similarity matrix:

$$D_x^2 = \left[d_{ij}^2\right]_{N\times N} = \left[\|\vec{x}_i\|^2 - 2\vec{x}_i^T\vec{x}_j + \|\vec{x}_j\|^2\right]_{N\times N} = X_r - 2X^TX + X_c \tag{14.1.1921}$$

where we have defined the following three matrices to simplify the notations:

$$\begin{gathered}
X_r = \begin{bmatrix} \|\vec{x}_1\|^2 & \cdots & \|\vec{x}_1\|^2 \\ \vdots & \ddots & \vdots \\ \|\vec{x}_N\|^2 & \cdots & \|\vec{x}_N\|^2 \end{bmatrix} \\
X_c = X_r^T = \begin{bmatrix} \|\vec{x}_1\|^2 & \cdots & \|\vec{x}_N\|^2 \\ \vdots & \ddots & \vdots \\ \|\vec{x}_1\|^2 & \cdots & \|\vec{x}_N\|^2 \end{bmatrix} \\
X^TX = \begin{bmatrix} \vec{x}_1^T \\ \vdots \\ \vec{x}_N^T \end{bmatrix} [\vec{x}_1, \cdots, \vec{x}_N] = \begin{bmatrix} \vec{x}_1^T\vec{x}_1 & \cdots & \vec{x}_1^T\vec{x}_N \\ \vdots & \ddots & \vdots \\ \vec{x}_N^T\vec{x}_1 & \ldots & \vec{x}_N^T\vec{x}_N \end{bmatrix}
\end{gathered} \tag{14.1.1922}$$

We then introduce a centering matrix (for recall $\mathbb{J}$ is a matrix of ones as already defined in the section of Linear Algebra):

$$C_N = \mathbb{1}_N - \frac{1}{N}\mathbb{J}_N \tag{14.1.1923}$$

which is an $N \times N$ and symmetric $\text{C}_N^T = \text{C}_N$.

Pre-multiplying C_N by a column vector $\vec{a} = [a_1, \ldots, a_N]^T$ removes the mean $\bar{a} = \sum_{i=1}^N a_i/N$ of from each component of $\vec{a}$:

$$\begin{aligned} C_N\vec{a} = \mathbb{1}\vec{a} - \frac{1}{N}\mathbb{J}_N\vec{a} &= \begin{bmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & 1 \end{bmatrix}\begin{bmatrix} a_1 \\ \vdots \\ a_N \end{bmatrix} - \frac{1}{N}\begin{bmatrix} 1 & \cdots & 1 \\ \vdots & \ddots & \vdots \\ 1 & \cdots & 1 \end{bmatrix}\begin{bmatrix} a_1 \\ \vdots \\ a_N \end{bmatrix} \\ &= \begin{bmatrix} a_1 \\ \vdots \\ a_N \end{bmatrix} - \begin{bmatrix} \bar{a} \\ \vdots \\ \bar{a} \end{bmatrix} = \begin{bmatrix} a_1 - \bar{a} \\ \vdots \\ a_N - \bar{a} \end{bmatrix} \end{aligned} \tag{14.1.1924}$$

Taking transpose on both sides, we see that post-multiplying C_N by a row vector $\vec{a}^T$ removes the mean of $\vec{a}^T$ from each component:

$$\vec{a}^T C_N = \vec{a}^T\mathbb{1} - \frac{1}{N}\vec{a}^T\mathbb{J} = [a_1 - \bar{a}, \ldots, a_N - \bar{a}] \tag{14.1.1925}$$

We now apply double centering to D_x^2 by pre and post multiplying C_N to D_x^2:

$$\begin{aligned} C_N D_x^2 C_N &= C_N\left(X_r - 2X^TX + X_c\right)C_N = C_N X_r C_N - 2C_N\left(X^TX\right)C_N + C_N X_c C_N \\ &= -2C_N\left(X^TX\right)C_N = -2\left(XC_N\right)^T\left(XC_N\right) = -2\overline{X}^T\overline{X} \end{aligned} \tag{14.1.1926}$$

where $X_rC_N = \mathbb{0}$ as all components of each row of X_r are the same as their mean, and removing the mean results in a zero row vector. Similarly, $C_NX_c = \mathbb{0}$, and we have also defined just above:

$$\overline{X} = XC_N = \left[\overline{\vec{x}}_1, \ldots, \overline{\vec{x}}_N\right] \tag{14.1.1927}$$

with the mean of each row of X removed, i.e., the ith column is:

$$\overline{\vec{x}}_i = \vec{x}_i - \overline{\vec{x}}, \quad \text{where} \quad \overline{\vec{x}} = \frac{1}{N}\sum_{i=1}^N \vec{x}_i \tag{14.1.1928}$$

We therefore see that $\sum_{i=1}^N \bar{x}_i = 0$, i.e.., all vectors in $\bar{X} = [\bar{x}_1, \ldots, \bar{x}_N]$ are those in $X = [\vec{x}_1, \ldots, \vec{x}_N]$ shifted by the mean vector $\bar{X}$. Now the points in $\bar{X}$ are centralized, but their pairwise similarities remain the same as the given d_{ij}^x.

The relation:

$$C_N D_x^2 C_N = -2\overline{X}^T\overline{X} \tag{14.1.1929}$$

that we have just proved earlier can be rearranged to get:

$$B_x=\overline{X}^T\overline{X}=-\frac{1}{2}C_ND_x^2C_N \tag{14.1.1930}$$

that is Gram matrix (see section Linear Algebra page 2014) of $\overline{X}$.

Our goal is to find $Y=[y_1,\cdots,y_N]$ so that its pairwise similarity matrix D_y matches D_x optimally, in the sense that the following objective function is minimized:

$$o(Y)=\left\|D_y^2-D_x^2\right\| \tag{14.1.1931}$$

Assuming Y is also a double centered matrix as well as X, we get its Gram matrix:

$$B_y=\overline{Y}^T\overline{Y}=-\frac{1}{2}C_ND_y^2C_N \tag{14.1.1932}$$

and the objective function above can be redefined as:

$$o(Y)=\|B_y-B_x\|=\left\|\overline{Y}^T\overline{Y}-\overline{X}^TX\right\| \tag{14.1.1933}$$

We now carry out eigenvalue decomposition (see section Linear Algebra page 2023) of the $N\times N$ symmetric matrix B_x to find its real eigenvalue matrix Λ and the orthogonal eigenvector matrix V satisfying $B_xV=\Lambda V$, i.e.:

$$\begin{aligned}B_x&=V\Lambda V^{-1}=V\Lambda V^T=[\vec{v}_1,\ldots,\vec{v}_N]\begin{bmatrix}\lambda_1&\cdots&0\\\vdots&\ddots&\vdots\\0&\cdots&\lambda_N\end{bmatrix}\begin{bmatrix}\vec{v}_1^T\\\vdots\\\vec{v}_N^T\end{bmatrix}\\&=\left(V\Lambda^{1/2}\right)\left(\Lambda^{1/2}V^T\right)=\left(\Lambda^{1/2}V^T\right)^T\left(\Lambda^{1/2}V^T\right)\end{aligned} \tag{14.1.1934}$$

To minimize the objective function $o(Y)=\|B_y-B_x\|$, we let:

$$Y=\Lambda^{1/2}V^T=\begin{bmatrix}\sqrt{\lambda_1}&\cdots&0\\\vdots&\ddots&\vdots\\0&\cdots&\sqrt{\lambda_N}\end{bmatrix}\begin{bmatrix}\vec{v}_1^T\\\vdots\\\vec{v}_N^T\end{bmatrix}=\begin{bmatrix}\sqrt{\lambda_1}\vec{v}_1^T\\\vdots\\\sqrt{\lambda_N}\vec{v}_N^T\end{bmatrix} \tag{14.1.1935}$$

Each column $\vec{y}_i$ in $Y=[\vec{y}_1,\ldots,\vec{y}_N]$ is an n dimension vector. To reduce the dimensionality from n to a given chosen m, we take the first m rows of Y corresponding to the m greatest eigenvalues of $\lambda_1\geq\ldots\geq\lambda_m\geq\ldots\geq\lambda_N$ and their corresponding eigenvectors $\vec{v}_1,\ldots,\vec{v}_m$ as we do in Principal Component Analysis (see section Statistics page 1213).

Remark

In practice it happens sometimes that only D_x^2 is given without the original coordinates of the N data points $X=[\vec{x}_1,\ldots,\vec{x}_N]$. Also the objective function may have different empirical expression and the distance may be another one than the classic Euclidean.

In summary, here are the different steps:

- Given the pairwise similarity, an $N\times N$ matrix $D_x=[d_{ij}]$, construct the squared proximity matrix $D_x^2=[d_{ij}^2]$

- Apply double centering to get $B_x = -C_N D_x^2 C_N$;
- Find the m greatest eigenvalues $\lambda_1, \ldots, \lambda_m$ of B_x, and the corresponding eigenvectors $\vec{v}_1, \ldots, \vec{v}_m$;
- Get the map:

$$Y_{m\times N} = \Lambda_m^{1/2} V_m = \begin{bmatrix} \sqrt{\lambda_1 \vec{v}_1^T} \\ \vdots \\ \sqrt{\lambda_m \vec{v}_m^T} \end{bmatrix} \tag{14.1.1936}$$

Remark

For a practical application the reader can take a look to our `R` or MATLAB® companion books.

So let us focus on the third most common component/factor based dimensionality reduction technique:

14.1.20.6.4 Factor Analysis (Exploratory Factor Analysis (EFA))

The method of "Factor Analysis" (FA), also named "Exploratory Factor Analysis" (EFA), not to be confuse with the method of Chi-square Correspondence Factor Analysis (see section Statistics page 1233), models a set of D observed manifest variables in $\vec{x}=[x_1,\ldots,x_D]^T$ as a linear combination of a set of $d<D$ unobserved hidden "latent variables" or "common factors" in $\vec{z}=[z_1,\ldots,z_d]^T$, to explain and reveal the variability and dependency among the D observed variables, typically correlated, in terms of the latent variables, assumed to be independent and therefore uncorrelated. The method of FA is therefore considered as a means for dimensionality reduction[69]!

Specifically, we assume each of the observed variables in $\vec{x}$ is a linear combination of the d factors in $\vec{z}$:

$$x_i=\sum_{j=1}^d w_{ij}z_j+\varepsilon_i=[w_{i1},\ldots,w_{id}]\begin{bmatrix} z_1\\ \vdots\\ z_d\end{bmatrix} \tag{14.1.1937}$$

with $i=1,\ldots,D$ or in matrix form:

$$\begin{aligned}\vec{x}=\begin{pmatrix} x_1\\ \vdots\\ \vdots\\ x_D\end{pmatrix}&=\begin{bmatrix} w_{11} & \ldots & w_{1d}\\ \vdots & \ddots & \vdots\\ \vdots & \ddots & \vdots\\ w_{D1} & \ldots & w_{Dd}\end{bmatrix}\begin{pmatrix} z_1\\ \vdots\\ z_d\end{pmatrix}+\begin{pmatrix} \varepsilon_1\\ \vdots\\ \vdots\\ \varepsilon_D\end{pmatrix}\\ &=[\vec{w}_1,\ldots,\vec{w}_d]\begin{bmatrix} z_1\\ \vdots\\ z_d\end{bmatrix}+\vec{\varepsilon}=\sum_{i=1}^d z_i\vec{w}_i+\vec{\varepsilon}=W\vec{z}+\vec{\varepsilon}\end{aligned} \tag{14.1.1938}$$

where:

$$W=[\vec{w}_1,\ldots,\vec{w}_d]=\begin{bmatrix} w_{11} & \ldots & w_{1d}\\ \vdots & \ddots & \vdots\\ w_{D1} & \ldots & w_{Dd}\end{bmatrix} \tag{14.1.1939}$$

is a $D\times d$ factor loading matrix, and ε_i is the noise associated with x_i.

Remark

In many textbooks the reader can find the following notation:

$$x_i-\mu_i=\sum_{j=1}^d l_{ij}F_j+\varepsilon_i=L\vec{F}+\vec{\varepsilon} \tag{14.1.1940}$$

where the l_{ij} are named the "loadings" and the F_j the "latent factors".

---

[69] The text that follows is completely inspired from the lecture notes of the professor Ruye Wang (`http://fourier.eng.hmc.edu/e176/lectures/index_e176.html`)

✍**Example:**

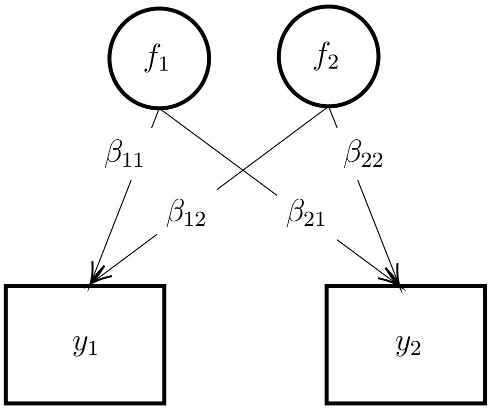
Let's approach this technique by going directly with an example. For this, consider that 5 candidates have passed 3 exams in the field of Finance, Statistics and Standards (Norms) to validate their entry into a MBA course. Each of the corrected exams is marked on a scale ranging from 0 to 10 points corresponding to the variables to be explained. The data is summarized in the table below:

Candidate n°	Finance y_1	Statistics y_2	Norms y_3
1	3	6	5
2	7	3	3
3	10	9	8
4	3	9	7
5	10	6	5

It was suggested by an expert committee that the results obtained are dependent on two explanatory variables not directly observable, f_1 and f_2, which are respectively judged as being the *Analytical Capacity* and the *Memorization Capacity* of the candidates. It is accepted that each of the explained variables depends linearly on these two factors such as (this is a notation common in french textbooks for EFA):

$$\begin{aligned}y_1&=\beta_{10}+\beta_{11}f_1+\beta_{12}f_2+\varepsilon_1\\y_2&=\beta_{20}+\beta_{21}f_1+\beta_{22}f_2+\varepsilon_2\\y_3&=\beta_{30}+\beta_{31}f_1+\beta_{32}f_2+\varepsilon_3\end{aligned}$$

For information, this type of model is represented in the framework of the Structural Equation Modelling (we will introduce this type of model later) in the following way (disregarding the constant and the error terms):



With the following assumptions:

$$\mathrm{E}(\varepsilon_i)=0,\mathrm{V}(\varepsilon_i)=\sigma^2_{\varepsilon_i},\mathrm{cov}(\varepsilon_i,\varepsilon_j)=0\,\forall i\neq j$$

and:

$$\mathrm{E}(f_i)=0,\mathrm{V}(f_i)=1,\mathrm{cov}(f_i,f_j)=0\,\forall i\neq j$$

The model is generally written in french textbooks in the following matrix form, using our particular example:

$$\bar{Y}=\bar{\beta}_0+L\bar{f}+\bar{\varepsilon}=\begin{pmatrix}\beta_{10}\\ \beta_{20}\\ \beta_{30}\end{pmatrix}+\begin{bmatrix}\beta_{11} & \beta_{12} & \beta_{13}\\ \beta_{21} & \beta_{22} & \beta_{23}\\ \beta_{31} & \beta_{32} & \beta_{33}\end{bmatrix}\begin{pmatrix}f_1\\ f_2\\ f_3=0\end{pmatrix}+\begin{pmatrix}\varepsilon_1\\ \varepsilon_2\\ \varepsilon_3\end{pmatrix}$$

Also, for simplicity and without loss of generality, we assume the dataset has a zero mean. If W were available, the d factors in $\vec{z}$ can be found by solving this over-determined linear equation system of D equations but $d<D$ unknowns by the least-square method as seen at page 6381 (with minimum squared error $||\vec{\varepsilon}||^2$):

$$\hat{\vec{z}}=W^{-}\vec{x}=(W^TW)^{-1}W^T\vec{x} \tag{14.1.1941}$$

where for recall $W^{-}=(W^TW)^{-1}W^T$ is the left pseudo-inverse of W.

However, as neither W nor $\vec{z}$ is available, we need to estimate both of them at the same time, based on a set of N observed data points $X=[\vec{x}_1,\ldots,\vec{x}_N]$, typically $N\gg d$, by the method of expectation-maximization (EM), which in general is an iterative algorithm to find the maximum likelihood (ML) or maximum a posteriori (MAP) estimates of some model parameters.

We treat both $\vec{z}$ and $\vec{\varepsilon}$ as random vectors, and make the following assumptions:

- The latent variables in $\vec{z}$ are of zero mean, independent of each other, and with unity variance:

  $$\vec{\mu}_z=\mathrm{E}(\vec{z})=\vec{0},\qquad \Sigma_z=\mathbb{1} \tag{14.1.1942}$$

  and they are Normally distributed:

  $$P(\vec{z})=\mathcal{N}(\vec{0},\mathbb{1}) \tag{14.1.1943}$$

- The noise components in $\vec{\varepsilon}$ are of zero mean, independent of each other, and with a diagonal covariance matrix:

  $$\vec{\mu}_\varepsilon=\mathrm{E}(\vec{\varepsilon})=\vec{0}\qquad \mathbf{\Sigma}_\varepsilon=\Psi=\begin{bmatrix}\psi_1 & \cdots & 0\\ \vdots & \ddots & \vdots\\ 0 & \cdots & \psi_D\end{bmatrix} \tag{14.1.1944}$$

  and they are also normally distributed:

  $$P(\vec{\varepsilon})=\mathcal{N}(\vec{0},\Psi) \tag{14.1.1945}$$

- The latent variables and the noise are independent of each other:

  $$\Sigma_{z\varepsilon}=\mathrm{cov}(\vec{z},\vec{\varepsilon})=\mathrm{E}\left[(\vec{z}-\vec{\mu}_z)(\vec{\varepsilon}-\vec{\mu}_\varepsilon)^T\right]=\mathrm{E}(\vec{z}\vec{\varepsilon}^T)=\mathbb{0} \tag{14.1.1946}$$

The two matrices W and Ψ defined above are the parameters of the FA model, generally denoted by $\theta=\{W,\Psi\}$.

As a linear combination of the two Gaussian vectors $\vec{z}$ and $\vec{\varepsilon}$ then:

$$\vec{x}=W\vec{z}+\vec{\varepsilon} \tag{14.1.1947}$$

also has a Gaussian distribution. We first find its mean $\mathrm{E}(\vec{x})$:

$$\Sigma_x=\vec{\mu}_x=\mathrm{E}(\vec{x})=\mathrm{E}(W\vec{z}+\vec{\varepsilon})=W\mathrm{E}(\vec{z})+\mathrm{E}(\vec{\varepsilon})=\vec{0} \tag{14.1.1948}$$

and variance-covariance matrix Σ_x (see page 720):

$$\begin{aligned}\Sigma_x&=\mathrm{cov}(\vec{x})=\mathrm{E}\left[(\vec{x}-\vec{\mu}_x)(\vec{x}-\vec{\mu}_x)^T\right]=\mathrm{E}(\vec{x}\vec{x}^T)=\mathrm{E}\left[(W\vec{z}+\vec{\varepsilon})(W\vec{z}+\vec{\varepsilon})^T\right]\\&=W\mathrm{E}(\vec{z}\vec{z}^T)W^T-\mathrm{E}(\vec{\varepsilon}\vec{z}^T)W^T-W\mathrm{E}(\vec{z}\vec{\varepsilon}^T)+\mathrm{E}(\vec{\varepsilon}\vec{\varepsilon}^T)\\&=WW^T+\Psi\end{aligned} \tag{14.1.1949}$$

Remark

That last relation is often denoted in textbooks as:

$$\mathrm{cov}(\vec{x})=LL^T+\Psi \tag{14.1.1950}$$

with therefore:

$$\begin{aligned}\mathrm{V}(x_i)&=l_{i1}^2+\ldots+l_{id}^2+\psi_i\\\mathrm{cov}(x_i,x_k)&=l_{i1}l_{k1}+\ldots+l_{id}l_{kd}\end{aligned} \tag{14.1.1951}$$

The portion of the variance of the ith variable contributed by the m common factors is named the "ith communality". That portion of $\mathrm{V}(x_i)=\sigma_{ii}$ due to the specific factor is often named the "uniqueness", or "specific variance". Denoting the ith communality by h_i^2, we see that:

$$\mathrm{V}(x_i)=\sigma_{ii}=h_i^2+\psi_i \tag{14.1.1952}$$

where:

$$h_i^2=l_{i1}^2+l_{i2}^2+\ldots+l_{id}^2 \tag{14.1.1953}$$

✍**Example:**

Let us observe what are the implications of the aforementioned assumptions. To do this, let's write the general form of each of the linear relations from our previous example:

$$y_i=\beta_{i0}+\beta_{i1}f_1+\beta_{i2}f_2+\varepsilon_i \tag{14.1.1954}$$

If we calculate the variance, then we have using its properties:

$$\begin{aligned}&\mathrm{V}(y_i)=\mathrm{V}(\beta_{i0})+\mathrm{V}(\beta_{11}f_1)+\mathrm{V}(\beta_{i2}f_2)+\mathrm{V}(\varepsilon_i)\\&=\mathrm{V}(\beta_{i1}f_1)+\mathrm{V}(\beta_{i2}f_2)+\sigma_i^2=\beta_{i1}^2\mathrm{V}(f_1)+\beta_{i2}^2V(f_2)+\sigma_{\varepsilon_i}^2\\&=\underbrace{\beta_{i1}^2+\beta_{i2}^2}_{\text{communality}}+\sigma_{\varepsilon_i}^2\end{aligned} \tag{14.1.1955}$$

Hence in the general case:

$$\mathrm{V}\left(y_i\right)=\underbrace{\sum_{j=1}\beta_{i1}^2}_{\text{communality}}+\sigma_{\varepsilon_i}^2 \tag{14.1.1956}$$

The "communality" is then the part of the variance of the variable which is explained purely by the factors of the explanatory variables of the model. The greater the communality, the better the predictive power of the factors !!

Obviously, if the factors are perfect predictors, we have the specific variance $\sigma_{\varepsilon_i}^2$ which would then be zero.

And then get the Normal distribution of $\vec{x}$ given $\vec{\theta}$:

$$P(\vec{x}|\vec{\theta})=\mathcal{N}(\vec{\mu}_x,\Sigma_x)=\mathcal{N}(\vec{0},WW^T+\Psi) \tag{14.1.1957}$$

We can further find the joint distribution $P(\vec{z},\vec{x})$, also a Gaussian, which has a zero mean:

$$\vec{\mu}=\mathrm{E}\left(\begin{bmatrix}\vec{z}\\\vec{x}\end{bmatrix}\right)=\begin{bmatrix}\vec{\mu}_z\\\vec{\mu}_x\end{bmatrix}=\begin{bmatrix}\vec{0}\\\vec{0}\end{bmatrix} \tag{14.1.1958}$$

and a covariance matrix Σ composed of four submatrices:

$$\Sigma=\begin{bmatrix}\Sigma_{zz} & \Sigma_{zx}\\ \Sigma_{xz} & \Sigma_{xx}\end{bmatrix} \tag{14.1.1959}$$

where he have immediately:

$$\begin{aligned}
\Sigma_{zz}&=\mathbb{1}\\
\Sigma_{xx}&=WW^T+\Psi\\
\Sigma_{zx}&=\Sigma_{zx}^T=\mathrm{E}(\vec{z}-\vec{\mu}_z)(\vec{x}-\vec{\mu}_x)^T=\mathrm{E}(\vec{z}\vec{x}^T)=E[\vec{z}(W\vec{z}+\vec{\varepsilon})^T]\\
&=\mathrm{E}(\vec{z}\vec{z}^T)W^T+\mathrm{E}(\vec{z}\vec{\varepsilon}^T)=\mathbb{1}W^T+\mathbb{O}=W^T
\end{aligned} \tag{14.1.1960}$$

Now the Normal distribution $P(\vec{z},\vec{x}|\vec{\theta})$ given model parameter $\vec{\theta}=\{W,\Psi\}$ can be expressed as:

$$\begin{aligned}
P(\vec{x},\vec{z}|\vec{\theta})=P\left(\begin{bmatrix}\vec{z}\\\vec{x}\end{bmatrix}\right)&=\mathcal{N}(\vec{\mu},\Sigma)=\mathcal{N}\left(\begin{bmatrix}\vec{0}\\\vec{0}\end{bmatrix},\begin{bmatrix}\Sigma_{zz} & \Sigma_{zx}\\ \Sigma_{xz} & \Sigma_{xx}\end{bmatrix}\right)\\
&=\mathcal{N}\left(\begin{bmatrix}\vec{0}\\\vec{0}\end{bmatrix},\begin{bmatrix}\mathbb{1} & W^T\\ W & WW^T+\Psi\end{bmatrix}\right)
\end{aligned} \tag{14.1.1961}$$

✍**Example:**

Let us now calculate the covariance of a couple of variables y_i,y_j from our previous example by first writing:

$$\begin{aligned}
y_i&=\beta_{i0}+\beta_{i1}f_1+\beta_{i2}f_2+\varepsilon_i\\
y_j&=\beta_{j0}+\beta_{j1}f_1+\beta_{j2}f_2+\varepsilon_j
\end{aligned} \tag{14.1.1962}$$

We then have:

$$\text{cov}\left(y_i,y_j\right)=\text{cov}\left(\beta_{i0}+\beta_{i1}f_1+\beta_{i2}f_2+\varepsilon_i,\beta_{j0}+\beta_{j1}f_1+\beta_{j2}f_2+\varepsilon_j\right) \quad (14.1.1963)$$

From the definition of covariance we know that the constants will vanish. So we can focus on:

$$\text{cov}\left(y_i,y_j\right)=\text{cov}\left(\beta_{i1}f_1+\beta_{i2}f_2+\varepsilon_i,\beta_{j1}f_1+\beta_{j2}f_2+\varepsilon_j\right) \quad (14.1.1964)$$

We saw just previously that in the simple case where $i=j$, we have in our particular case:

$$\text{cov}\left(y_i,y_j\right)_{i=j}=V\left(y_i\right)=\beta_{i1}^2+\beta_{i2}^2+\sigma_{\varepsilon_i}^2 \quad (14.1.1965)$$

Now let's deal with the case where $i\neq j$. We then have:

$$\begin{aligned}
&\text{cov}\left(y_i,y_j\right)=\text{cov}\left(\beta_{i1}f_1+\beta_{i2}f_2+\varepsilon_i,\beta_{j1}f_1+\beta_{j2}f_2+\varepsilon_j\right)\\
&=\beta_{j1}\,\text{cov}\left(\beta_{i1}f_1+\beta_{i2}f_2+\varepsilon_i,f_1\right)+\beta_{j2}\,\text{cov}\left(\beta_{i1}f_1+\beta_{i2}f_2+\varepsilon_i,f_2\right)\\
&+\text{cov}\left(\beta_{i1}f_1+\beta_{i2}f_2+\varepsilon_i,\varepsilon_j\right)\\
&=\beta_{j1}\left(\beta_{i1}\,\text{cov}\left(f_1,f_1\right)+\beta_{i2}\,\text{cov}\left(f_2,f_1\right)+\text{cov}\left(\varepsilon_i,f_1\right)\right)\\
&+\beta_{j2}\left(\beta_{i1}\,\text{cov}\left(f_1,f_2\right)+\beta_{i2}\,\text{cov}\left(f_2,f_2\right)+\text{cov}\left(\varepsilon_i,f_2\right)\right)\\
&+1\cdot\left(\left(\beta_{i1}\,\text{cov}\left(f_1,\varepsilon_j\right)+\beta_{i2}\,\text{cov}\left(f_2,\varepsilon_j\right)+\text{cov}\left(\varepsilon_i,\varepsilon_j\right)\right)\right)\\
&=\beta_{j1}\left(\beta_{i1}\text{V}\left(f_1\right)+\beta_{i2}\,\text{cov}\left(f_2,f_1\right)+\text{cov}\left(\varepsilon_i,f_1\right)\right)\\
&+\beta_{j2}\left(\beta_{i1}\,\text{cov}\left(f_1,f_2\right)+\beta_{i2}\text{V}\left(f_2\right)+\text{cov}\left(\varepsilon_i,f_2\right)\right)\\
&+1\cdot\left(\left(\beta_{i1}\,\text{cov}\left(f_1,\varepsilon_j\right)+\beta_{i2}\,\text{cov}\left(f_2,\varepsilon_j\right)+\text{cov}\left(\varepsilon_i,\varepsilon_j\right)\right)\right)\\
&=\beta_{j1}\left(\beta_{i1}+\beta_{i2}\,\text{cov}\left(f_2,f_1\right)+\text{cov}\left(\varepsilon_i,f_1\right)\right)\\
&+\beta_{j2}\left(\beta_{i1}\,\text{cov}\left(f_1,f_2\right)+\beta_{i2}+\text{cov}\left(\varepsilon_i,f_2\right)\right)\\
&+1\cdot\left(\left(\beta_{i1}\,\text{cov}\left(f_1,\varepsilon_j\right)+\beta_{i2}\,\text{cov}\left(f_2,\varepsilon_j\right)+\text{cov}\left(\varepsilon_i,\varepsilon_j\right)\right)\right)
\end{aligned} \quad (14.1.1966)$$

Since the factors are assumed to be independent random variables by assumption in the model, their covariance is zero. It is the same for the terms of errors. It remains then:

$$\begin{aligned}
&\text{cov}\left(y_i,y_j\right)=\beta_{j1}\left(\beta_{11}+\text{cov}\left(\varepsilon_i,f_1\right)\right)+\beta_{j2}\left(\beta_{i2}+\text{cov}\left(\varepsilon_i,f_2\right)\right)\\
&+1\cdot\left(\left(\beta_{i1}\,\text{cov}\left(f_1,\varepsilon_j\right)+\beta_{i2}\,\text{cov}\left(f_2,\varepsilon_j\right)\right)\right)
\end{aligned} \quad (14.1.1967)$$

We will make the assumption that the errors are random variables independent of the factors. So at the level of the covariances for the moment all the assumptions are then:

$$\begin{aligned}
\text{cov}\left(f_i,f_j\right)_{i\neq j}&=0\\
\text{cov}\left(\varepsilon_i,f_j\right)_{i=j}&=0\\
\text{cov}\left(\varepsilon_i,\varepsilon_j\right)_{i\neq j}&=0
\end{aligned} \quad (14.1.1968)$$

So their covariance also becomes zero and it remains:

$$\text{cov}\left(y_i,y_j\right)_{i\neq j}=\beta_{j1}\beta_{i1}+\beta_{j2}\beta_{i2} \quad (14.1.1969)$$

So in the general case where $i\neq j$ we finally have:

$$\text{cov}\left(y_i,y_j\right)_{i\neq j}=\sum_{k=1}^{m}\beta_{jk}\beta_{ik} \quad (14.1.1970)$$

We can then build the "theoretical matrix of the variances-covariances of the factorial model" in the particular case which serves as an example, we have:

$$\begin{aligned}C&=\begin{bmatrix}\beta_{11}^2+\beta_{12}^2+\sigma_{\varepsilon_1}^2 & \beta_{21}\beta_{11}+\beta_{22}\beta_{12} & \beta_{31}\beta_{11}+\beta_{32}\beta_{21}\\ \beta_{11}\beta_{21}+\beta_{12}\beta_{22} & \beta_{11}^2+\beta_{22}^2+\sigma_{\varepsilon_2}^2 & \beta_{21}\beta_{31}+\beta_{22}\beta_{32}\\ \beta_{11}\beta_{31}+\beta_{12}\beta_{32} & \beta_{21}\beta_{31}+\beta_{22}\beta_{32} & \beta_{31}^2+\beta_{32}^2+\sigma_{\varepsilon_3}^2\end{bmatrix}\\ &=L\cdot L^T+\begin{bmatrix}\sigma_{\varepsilon_1}^2 & 0 & 0\\ 0 & \sigma_{\varepsilon_2}^2 & 0\\ 0 & 0 & \sigma_{\varepsilon_3}^2\end{bmatrix}=L\cdot L^T+\Psi\end{aligned}\tag{14.1.1971}$$

Notice that if we disregard the error term, it comes in our particular case:

$$\begin{aligned}C&=\begin{bmatrix}\beta_{11}^2+\beta_{12}^2 & \beta_{21}\beta_{11}+\beta_{22}\beta_{12} & \beta_{31}\beta_{11}+\beta_{32}\beta_{21}\\ \beta_{11}\beta_{21}+\beta_{12}\beta_{22} & \beta_{11}^2+\beta_{22}^2 & \beta_{21}\beta_{31}+\beta_{22}\beta_{32}\\ \beta_{11}\beta_{31}+\beta_{12}\beta_{32} & \beta_{21}\beta_{31}+\beta_{22}\beta_{32} & \beta_{31}^2+\beta_{32}^2\end{bmatrix}\\ &=\begin{bmatrix}\beta_{11} & \beta_{12} & \beta_{13}\\ \beta_{21} & \beta_{22} & 0\\ \beta_{31} & \beta_{32} & 0\end{bmatrix}\begin{bmatrix}\beta_{11} & \beta_{12} & \beta_{13}\\ \beta_{21} & \beta_{22} & 0\\ \beta_{31} & \beta_{32} & 0\end{bmatrix}^T\\ &=\begin{bmatrix}\beta_{11} & \beta_{12} & \beta_{13}\\ \beta_{21} & \beta_{22} & 0\\ \beta_{31} & \beta_{32} & 0\end{bmatrix}\begin{bmatrix}\beta_{11} & \beta_{21} & \beta_{31}\\ \beta_{12} & \beta_{22} & \beta_{32}\\ \beta_{13} & 0 & 0\end{bmatrix}\end{aligned}\tag{14.1.1972}$$

In practice, we can easily calculate the "experimental variance-covariance matrix" of the measured data. We usually note it in the case of three variables to be explained:

$$\hat{C}=\begin{bmatrix}S_1^2 & S_{12} & S_{13}\\ S_{21} & S_2^2 & S_{23}\\ S_{31} & S_{32} & S_3^2\end{bmatrix}=L\cdot L^T+\Psi\tag{14.1.1973}$$

Then we just have to put the two matrices in correspondence (well normally it is customary to denote by b_{ij} the estimated values of the β_{ij} but we will suppose that the reader will be able to easily differentiate the moment when we work with the estimators or the actual theoretical values):

$$\begin{bmatrix}S_1^2 & S_{12} & S_{13}\\ S_{21} & S_2^2 & S_{23}\\ S_{31} & S_{32} & S_3^2\end{bmatrix}=\begin{bmatrix}\beta_{11}^2+\beta_{12}^2+\sigma_{\varepsilon_1}^2 & \beta_{21}\beta_{11}+\beta_{22}\beta_{12} & \beta_{31}\beta_{11}+\beta_{32}\beta_{21}\\ \beta_{11}\beta_{21}+\beta_{12}\beta_{22} & \beta_{11}^2+\beta_{22}^2+\sigma_{\varepsilon_2}^2 & \beta_{21}\beta_{31}+\beta_{22}\beta_{32}\\ \beta_{11}\beta_{31}+\beta_{12}\beta_{32} & \beta_{21}\beta_{31}+\beta_{22}\beta_{32} & \beta_{31}^2+\beta_{32}^2+\sigma_{\varepsilon_3}^2\end{bmatrix}\tag{14.1.1974}$$

If we go back to our original example, then we have:

$$\begin{bmatrix}1 & -0.051 & 0.804\\ -0.051 & 1 & 0.981\\ 0.804 & 0.981 & 1\end{bmatrix}=\begin{bmatrix}\beta_{11}^2+\beta_{12}^2+\sigma_{\varepsilon_1}^2 & \beta_{21}\beta_{11}+\beta_{22}\beta_{12} & \beta_{31}\beta_{11}+\beta_{32}\beta_{21}\\ \beta_{11}\beta_{21}+\beta_{12}\beta_{22} & \beta_{11}^2+\beta_{22}^2+\sigma_{\varepsilon_2}^2 & \beta_{21}\beta_{31}+\beta_{22}\beta_{32}\\ \beta_{11}\beta_{31}+\beta_{12}\beta_{32} & \beta_{21}\beta_{31}+\beta_{22}\beta_{32} & \beta_{31}^2+\beta_{32}^2+\sigma_{\varepsilon_3}^2\end{bmatrix}\tag{14.1.1975}$$

We will then see a little further that we can deduce all the saturations (coefficients of the model) from this positive definite matrix!

Now we have two typical ways to determine the parameters of interest! First an iterative way based on the Expectation-Maximization (EM) algorithm that gives us the possibility to determine W and Ψ and another one, named "Principal Factor Analysis Extraction", based on the eigenvalue spectral decomposition (same idea as Principal Component Analysis) to determine only W.

14.1.20.6.4.1 Expectation-Maximization (EM) algorithm solution

Based on this joint Normal distribution, we can further find the following marginal distributions (see properties of Normal distributions at page 723):

- First:

$$P(\vec{x}|\vec{z},\theta)=\mathcal{N}\left(\vec{\mu}_{x|z},\Sigma_{x|z}\right) \tag{14.1.1976}$$

  with:

$$\begin{cases}\vec{\mu}_{x|z}=\vec{\mu}_x+\Sigma_{xz}\Sigma_{zz}^{-1}\left(\vec{z}-\vec{\mu}_z\right)=W\vec{z}\\ \Sigma_{x|z}=\Sigma_{xx}-\Sigma_{xz}^{-1}z_{zx}=WW^T+\Psi-WW^T=\Psi\end{cases} \tag{14.1.1977}$$

- Secondly:

$$P(\vec{z}|\vec{x},\theta)=\mathcal{N}\left(\vec{\mu}_{z|x},\Sigma_{z|x}\right) \tag{14.1.1978}$$

  with:

$$\begin{cases}\vec{\mu}_{z|x}=\vec{\mu}_z+\Sigma_{zx}\Sigma_{xx}^{-1}\left(\vec{x}-\vec{\mu}_x\right)=W^T\left(WW^T+\Psi\right)^{-1}\vec{x}=B\vec{x}\\ \Sigma_{z|x}=\Sigma_{zz}-\Sigma_{zx}\Sigma_{xx}^{-1}\Sigma_{xz}=\mathbb{1}-W^T\left(WW^T+\Psi\right)^{-1}W=\mathbb{1}-BW\end{cases} \tag{14.1.1979}$$

  where we have defined:

$$B=W^T(WW^T+\Psi)^{-1} \tag{14.1.1980}$$

Note that while $P(\vec{z})=\mathcal{N}(\vec{0},\mathbb{1})$ has zero mean and diagonal covariance, the conditional distribution $P(\vec{z}|\vec{x},\vec{\theta})=\mathcal{N}(\vec{\mu}_{z|x},\Sigma_{z|x})$ has non-zero mean $\vec{\mu}_{z|x}$ and non-diagonal covariance $\Sigma_{z|x}$!

The computational complexity for the inversion of the $N\times N$ matrix $WW^T+\Psi$ is $\mathcal{O}(N^3)$. However, by applying the Woodbury matrix identity (see section Linear Algebra page 2035):

$$(\Psi+WW^T)^{-1}=\Psi^{-1}-\Psi^{-1}W(\mathbb{1}+W^T\Psi^{-1}W)^{-1}W^T\Psi^{-1} \tag{14.1.1981}$$

where Ψ as a diagonal matrix can be easily inverted, and $\mathbb{1}+W^T\Psi^{-1}W$ is an $d\times d$ matrix that can be inverted with complexity $\mathcal{O}(d^3)\ll\mathcal{O}(N^3)$.

The model parameters in $\theta=\{W,\Psi\}$ can be estimated based on an observed dataset X by the EM algorithm (see page 6697), an iterative process of the following two steps:

- The E-step:

  Find the expectation of the log likelihood function of the model parameters in θ, to be maximized in the following M-step.

  Assuming all samples in the observed dataset $X=[\vec{x}_1,\ldots,\vec{x}_N]$ are independent and identically distributed (i.i.d.), we can find the "complete data likelihood" function of θ (using the Bayes' relation established in the section of Probabilities page 498):

$$L(\theta|\vec{X},\vec{z})=P(\vec{X},\vec{z}|\theta)=\prod_{n=1}^{N}P\left(\vec{x}_n,\vec{z}|\theta\right)=\prod_{n=1}^{N}P\left(\vec{x}_n|\vec{z},\theta\right)P(\vec{z}|\theta) \tag{14.1.1982}$$

  and the log-likelihood:

$$\ln\left(L(\theta|X,\vec{z})\right)=\ln\left(P(\vec{X},\vec{z}|\theta)\right)=\sum_{n=1}^{N}\left(\ln\left(P(\vec{x}_n|\vec{z},\theta)\right)+\ln\left(P(\vec{z}|\theta)\right)\right) \tag{14.1.1983}$$

  The second term can be dropped as $P(\vec{z}|\theta)=\mathcal{N}(\vec{0},\mathbb{1})$ is independent of the model parameters in θ and therefore irrelevant to the maximization of the log likelihood with respect to θ.

  The expectation of the log-likelihood function above (aka "expected complete data log-likelihood"), denoted by Q, with respect to the latent variable $\vec{z}$ is:

$$\begin{aligned}Q&=\mathrm{E}_{\vec{z}|\vec{x}}\left[\ln\left(L(\theta|\vec{X},\vec{z})\right)\right]=\sum_{n=1}^{N}\mathrm{E}_{z|x_n}\left[\ln P\left(\vec{x}_n|\vec{z},\theta\right)\right]\\&=\sum_{n=1}^{N}\mathrm{E}_{z|x_n}\left(\ln\left[\frac{1}{(2\pi)^{D/2}\left|\Sigma_{x|z}\right|^{1/2}}\exp\left(-\frac{1}{2}\left(\vec{x}_n-\vec{\mu}_{x|z}\right)^T\Sigma_{x|z}^{-1}\left(\vec{x}_n-\vec{\mu}_{x|z}\right)\right)\right]\right)\\&=\sum_{n=1}^{N}\mathrm{E}_{z|x_n}\left[-\frac{D}{2}\ln(2\pi)-\frac{1}{2}\ln|\Psi|-\frac{1}{2}\left(\vec{x}_n-W\vec{z}\right)^T\Psi^{-1}\left(\vec{x}_n-W\vec{z}\right)\right]\\&=-\frac{DN}{2}\ln(2\pi)-\frac{N}{2}\ln|\Psi|-\frac{1}{2}\sum_{n=1}^{N}\mathrm{E}_{z|x_n}\left(\left(\vec{x}_n-W\vec{z}\right)^T\Psi^{-1}\left(\vec{x}_n-W\vec{z}\right)\right)\\&=C-\frac{N}{2}\ln|\Psi|-\frac{1}{2}\sum_{n=1}^{N}\mathrm{E}_{z|x_n}\left(\vec{x}_n^T\Psi^{-1}\vec{x}_n-2\vec{x}_n^T\Psi^{-1}W\vec{z}+\vec{z}^TW^T\Psi^{-1}W\vec{z}\right)\end{aligned} \tag{14.1.1984}$$

  Note that Ψ is diagonal and therefore also symmetric, so is its own inverse Ψ^{-1}, we have:

$$\vec{x}_n^T\Psi^{-1}(W\vec{z})=(W\vec{z})^T\Psi^{-1}\vec{x}_n \tag{14.1.1985}$$

  Also, note that $C=-DN\ln(2\pi)/2$ is a constant independent of $\vec{\theta}$ and is therefore dropped.

- The M-step:

  Find the optimal model parameters in $\theta=\{W,\Psi\}$ that maximize the expectation of the log-likelihood Q obtained in the E-step.

  This is done by setting to zero the derivative of Q with respective each of the two parameters in $\theta=\{W,\Psi\}$:

- The first derivative is:

$$\begin{aligned}\frac{\partial Q}{\partial W}&=\frac{\partial}{\partial W}\sum_{n=1}^{N}\mathrm{E}_{z|x_n}\left(-\vec{x}_n^T\Psi^{-1}\vec{x}_n+2\vec{x}_n^T\Psi^{-1}W\vec{z}-\vec{z}^TW^T\Psi^{-1}W\vec{z}\right)\\&=\sum_{n=1}^{N}\mathrm{E}_{z|x_n}\left[\frac{\partial}{\partial W}\left(2\vec{x}_n^T\Psi^{-1}W\vec{z}-\vec{z}^TW^T\Psi^{-1}W\vec{z}\right)\right]\\&=\sum_{n=1}^{N}\mathrm{E}_{z|x_n}\left(2\Psi^{-1}\vec{x}_n\vec{z}^T-2\Psi^{-1}W\vec{z}\vec{z}^T\right)\\&=2\Psi^{-1}\sum_{n=1}^{N}\left(\vec{x}_n\mathrm{E}_{z|x_n}\left(\vec{z}^T\right)-W\mathrm{E}_{z|x_n}\left(\vec{z}\vec{z}^T\right)\right)=0\end{aligned} \tag{14.1.1986}$$

Solving for W we get:

$$W=\left(\sum_{n=1}^{N}\vec{x}_n\mathrm{E}_{z|x_n}(\vec{z}^T)\right)\left(\sum_{n=1}^{N}\mathrm{E}_{z|x_n}(\vec{z}\vec{z}^T)\right)^{-1} \tag{14.1.1987}$$

where $\mathrm{E}_{z|x_n}(\vec{z})$ and $\mathrm{E}_{z|x_n}(\vec{z}\vec{z}^T)$ can be found in (see previously):

$$\begin{cases}\vec{\mu}_{z|x}=\vec{\mu}_z+\Sigma_{zx}\Sigma_{xx}^{-1}\left(\vec{x}-\vec{\mu}_x\right)=W^T\left(WW^T+\Psi\right)^{-1}\vec{x}=B\vec{x}\\ \Sigma_{z|x}=\Sigma_{zz}-\Sigma_{zx}\Sigma_{xx}^{-1}\Sigma_{xz}=\mathbb{1}-W^T\left(WW^T+\Psi\right)^{-1}W=\mathbb{1}-BW\end{cases} \tag{14.1.1988}$$

Therefore:

$$\begin{cases}\mathrm{E}_{z|x_n}(\vec{z}) & =\vec{\mu}_{z|x_n}=B\vec{x}_n\\ \mathrm{E}_{z|x_n}\left(\vec{z}\vec{z}^T\right) & =\Sigma_{z|x_n}+\vec{\mu}_{z|x_n}\vec{\mu}_{z|x_n}^T=\mathbb{1}-BW+B\vec{x}_n\vec{x}_n^TB^T\end{cases} \tag{14.1.1989}$$

The second equation is due to the fact that $\Sigma_z=\mathrm{E}(\vec{z}\vec{z}^T)-\vec{\mu}_z\vec{\mu}_z^T$. Here $\mathrm{E}_{z|x_n}(\vec{z})$ can be considered as the estimation of the $\vec{z}$, while $\mathrm{E}_{z|x_n}(\vec{z}\vec{z}^T)$ the uncertainty of the estimation.

- The second derivative (we use in this development derivatives of matrices as seen in the section of Linear Algebra page 1976):

$$\begin{aligned}\frac{\partial Q}{\partial\Psi^{-1}}&=\frac{\partial}{\partial\Psi^{-1}}\left[N\ln|\Psi|+\sum_{n=1}^{N}\mathrm{E}_{z|x_n}\left(\vec{x}_n^T\Psi^{-1}\vec{x}_n-2\vec{x}_n^T\Psi^{-1}W\vec{z}+\vec{z}^TW^T\Psi^{-1}W\vec{z}\right)\right]\\&=-N\Psi+\sum_{n=1}^{N}\mathrm{E}_{z|x_n}\left(\vec{x}_n\vec{x}_n^T-2\vec{x}_n\vec{z}^TW^T+W\left(\vec{z}\vec{z}^T\right)W^T\right)\\&=-N\Psi+\sum_{n=1}^{N}\vec{x}_n\vec{x}_n^T-2\sum_{n=1}^{N}\vec{x}_n\mathrm{E}_{z|x_n}(\vec{z})^TW^T+W\sum_{n=1}^{N}\mathrm{E}_{z|x}\left(\vec{z}\vec{z}^T\right)W^T=\mathbb{0}\end{aligned} \tag{14.1.1990}$$

Solving for Ψ we get:

$$\Psi=\frac{1}{N}\operatorname{diag}\left(\sum_{n=1}^{N}\vec{x}_n\vec{x}_n^T-2\sum_{n=1}^{N}\vec{x}_n\mathrm{E}_{z|x_n}(\vec{z})^TW^T+W\sum_{n=1}^{N}\mathrm{E}_{z|x_n}\left(\vec{z}\vec{z}^T\right)W^T\right) \tag{14.1.1991}$$

where diag represents the operation that sets all off-diagonal elements of the right-hand side to zero, so that the resulting matrix Ψ is guaranteed to be diagonal as required. We further replace W in front of the last term above by that in:

$$W=\left(\sum_{n=1}^{N}\vec{x}_n\mathrm{E}_{z|x_n}(\vec{z}^T)\right)\left(\sum_{n=1}^{N}\mathrm{E}_{z|x_n}(\vec{z}\vec{z}^T)\right)^{-1} \tag{14.1.1992}$$

and get

$$\Psi=\frac{1}{N}\mathrm{diag}\left(\sum_{n=1}^{N}\vec{x}_n\vec{x}_n^T-\sum_{n=1}^{N}\vec{x}_n\mathrm{E}_{z|x_n}(\vec{z})^TW^T\right) \tag{14.1.1993}$$

In summary, here is the list of steps in the EM algorithm for FA:

1. Initialize parameters $\theta_{\text{old}}=\{W_{\text{old}},\Psi_{\text{old}}\}$
2. E-step: Based on θ_{old}, find $\vec{\mu}_{z|x_n}$ and $\Sigma_{z|x_n}$ in:

   $$\begin{cases}\vec{\mu}_{z|x}=\vec{\mu}_z+\Sigma_{zx}\Sigma_{xx}^{-1}(\vec{x}-\vec{\mu}_x)=W^T\left(WW^T+\Psi\right)^{-1}\vec{x}=B\vec{x}\\ \Sigma_{z|x}=\Sigma_{zz}-\Sigma_{zx}\Sigma_{xx}^{-1}\Sigma_{xz}=\mathbb{1}-W^T\left(WW^T+\Psi\right)^{-1}W=\mathbb{1}-BW\end{cases} \tag{14.1.1994}$$

   and then $\mathrm{E}_{z|x}(\vec{z})$ and $\mathrm{E}_{z|x}(\vec{z}\vec{z}^T)$ in:

   $$\begin{cases}\mathrm{E}_{z|x_n}(\vec{z}) & =\vec{\mu}_{z|x_n}=B\vec{x}_n\\ \mathrm{E}_{z|x_n}\left(\vec{z}\vec{z}^T\right) & =\Sigma_{z|x_n}+\vec{\mu}_{z|x_n}\vec{\mu}_{z|x_n}^T=\mathbb{1}-BW+B\vec{x}_n\vec{x}_n^TB^T\end{cases} \tag{14.1.1995}$$

3. M-step: Find $\theta_{\text{new}}=\{W_{\text{new}},\Psi_{\text{new}}\}$ by evaluating:

   $$W=\left(\sum_{n=1}^{N}\vec{x}_n\mathrm{E}_{z|x_n}(\vec{z}^T)\right)\left(\sum_{n=1}^{N}\mathrm{E}_{z|x_n}(\vec{z}\vec{z}^T)\right)^{-1} \tag{14.1.1996}$$

   and:

   $$\Psi=\frac{1}{N}\mathrm{diag}\left(\sum_{n=1}^{N}\vec{x}_n\vec{x}_n^T-\sum_{n=1}^{N}\vec{x}_n\mathrm{E}_{z|x_n}(\vec{z})^TW^T\right) \tag{14.1.1997}$$

4. Terminate if convergence criterion is satisfied, otherwise replace θ_{old} by θ_{new} and return to step 2.

14.1.20.6.4.2 Principal Factor Analysis Extraction solution

Now, if we center and reduce the starting vectors containing the measured values, the variance-covariance matrix becomes the correlation matrix as we have proved it during our study of Principal Component Analysis (PCA)! This is why the PCA is the basis of the Factorial Analysis (exploratory) and we then say that we are doing a "Principal Factor Analysis Extraction" (PFAE).

To understand the idea let us recall that we can write the Factor Analysis model in the following matrix form:

$$\bar{Y}=\bar{\beta}_0+L\bar{f}+\bar{\varepsilon} \tag{14.1.1998}$$

If the data are centered and reduced, we will write:

$$\bar{Z}=L\bar{f}+\bar{\varepsilon} \tag{14.1.1999}$$

Now let's play cleverly with an orthogonal matrix S:

$$\bar{Z}=L\bar{f}+\bar{\varepsilon}=L\left(S^TS\right)\bar{f}+\bar{\varepsilon}=\left(LS^T\right)\left(S\bar{f}\right)+\bar{\varepsilon}=L^*\bar{f}^*+\bar{\varepsilon} \tag{14.1.2000}$$

It is thus an alternative notation for the initial model but as there is an infinity of orthogonal matrices, there is an infinity of alternative models.

We denoted during our study of the Principal Component Analysis the matrix of the eigenvalues arranged in decreasing order in the diagonal by Λ and by S the matrix of the eigenvectors. This then gives us using the results of our study of the Principal Component Analysis and from what has just been seen:

$$R=L\cdot L^T=S\Lambda S^T=(S\sqrt{\Lambda})(\sqrt{\Lambda}S^T) \tag{14.1.2001}$$

Using now the property of the transpose seen during our study of Linear Algebra, we have:

$$\sqrt{\Lambda}S^T=(S\sqrt{\Lambda})^T \tag{14.1.2002}$$

Therefore:

$$S\Lambda S^T=(S\sqrt{\Lambda})(S\sqrt{\Lambda})^T \tag{14.1.2003}$$

The matrix:

$$L=S\sqrt{\Lambda} \tag{14.1.2004}$$

therefore does the trick and it is customary to name the components of the matrix L the "factor saturations" and it therefore contains the coefficients of the factors of the implicit linear model when the variables to be explained are centered and reduced. This is enough to give a qualitative idea of the weight of each of the factors.

Some statistical software return what is are named the "loadings" or "factor score" and which corresponds to the expression:

$$\ell=\left((S\sqrt{\Lambda})^T\right)^{-1} \tag{14.1.2005}$$

Whatever the chosen above solution, the factor model assumes that the $D(D+1)/2$ components of its covariance-variance matrix for $\vec{x}$ can be reproduced from the $D\cdot d$ factor loading (weights) w_{ij} and the D specific variances ψ_D. Because we have proved earlier above that:

$$\Sigma_x=WW^T+\Psi \tag{14.1.2006}$$

then when $D=d$ any covariance matrix Σ_x can be reproduced exactly as WW^T, so Ψ can be the zero matrix. It is when d is small relative to D that factor analysis is more useful. In this case, the factor model provides a simple explanation of the covariation in $\vec{x}$ with fewer parameters than $D(D+1)/2$ in Σ_x.

Unfortunately for the factor analyst it is not easy to choose the number of latent variables. If the number of common factors is not determined by a priori considerations, such as by theory or the work of other researchers, the choice of d can be based on the estimated eigenvalues of the principal component analysis.

Given observations $x_1, x_2, \ldots, x_D$ on d generally correlated variables, factor analysis seeks to answer the question: Does the factor model (linear in our case), with a small number of factors, adequately represent the data? In essence, we tackle this statistical model-building problem by trying to verify the covariance relations:

$$\begin{aligned} \text{V}(x_i) &= l_{i1}^2 + \ldots + l_{id}^2 + \psi_i \\ \text{cov}(x_i, x_k) &= l_{i1}l_{k1} + \ldots + l_{id}l_{kd} \\ \Sigma_{zx} &= L^T \end{aligned} \tag{14.1.2007}$$

If the off-diagonal elements of the estimator of Σ_x are small, the variables are not related, and a factor analysis will not provide any useful evidence. If Σ_x appears to deviate significantly from a diagonal matrix, then a factor model can be entertained, and the initial problem is one of estimating the factor loadings w_{ij} and specific variables ψ_i.

It should be also noticed that there is an infinity of solutions. To understand why consider the following model (we use here again the traditional notation in french textbooks):

$$\begin{aligned} y_1 &= \beta_{11}f_1 + \beta_{12}f_2 + \varepsilon_1 = 0.5f_1 + 0.5f_2 + \varepsilon_1 \\ y_2 &= \beta_{21}f_1 + \beta_{22}f_2 + \varepsilon_2 = 0.3f_1 + 0.3f_2 + \varepsilon_2 \\ y_3 &= \beta_{31}f_1 + \beta_{32}f_2 + \varepsilon_3 = 0.5f_1 - 0.5f_2 + \varepsilon_3 \end{aligned} \tag{14.1.2008}$$

The variance-covariance matrix of the above factorial model is then:

$$\text{cov}\,(y_i, y_j) = \begin{bmatrix} 0.5 + \sigma_{\varepsilon_1}^2 & 0.3 & 0 \\ 0.3 & 0.18 + \sigma_{\varepsilon_2}^2 & 0 \\ 0 & 0 & 0.5 + \sigma_{\varepsilon_3}^2 \end{bmatrix} \tag{14.1.2009}$$

But the following model:

$$\begin{aligned} y_1 &= \frac{\sqrt{2}}{2}f_1 + 0 \cdot f_2 + \varepsilon_1 \\ y_2 &= 0.3\sqrt{2}f_1 + 0 \cdot f_2 + \varepsilon_2 \\ y_3 &= 0 \cdot f_1 - \frac{\sqrt{2}}{2}f_2 + \varepsilon_3 \end{aligned} \tag{14.1.2010}$$

also has exactly the same variance-covariance matrix of the factor model as the reader can quickly verify and is therefore also a solution! The reader will be able to verify that the application:

$$\begin{bmatrix} \cos(\theta) & -\sin(\theta) \\ \sin(\theta) & \cos(\theta) \end{bmatrix} \begin{bmatrix} \beta_{11} \\ \beta_{12} \end{bmatrix} = \begin{bmatrix} \beta_{11}\cos(\theta) - \beta_{12}\sin(\theta) \\ \beta_{11}\sin(\theta) + \beta_{12}\cos(\theta) \end{bmatrix} = \begin{bmatrix} \beta'_{11} \\ \beta'_{12} \end{bmatrix} \tag{14.1.2011}$$

for any angle always gives the same variance-covariance matrix (reason for which there is an infinity of possible models for the same theoretical matrix of variances-covariance of the factorial model). So, in the example above, we simply took an angle of $\theta = -\pi/4$ which gives for the first line of the model:

$$\begin{bmatrix} 0.5\cos\left(\frac{\pi}{4}\right)-0.5\sin\left(\frac{\pi}{4}\right) \\ 0.5\sin\left(\frac{\pi}{4}\right)+0.5\cos\left(\frac{\pi}{4}\right) \end{bmatrix} = \begin{bmatrix} 0.5\frac{\sqrt{2}}{2}-0.5\left(-\frac{\sqrt{2}}{2}\right) \\ 0.5\left(-\frac{\sqrt{2}}{2}\right)+0.5\frac{\sqrt{2}}{2} \end{bmatrix} = \begin{bmatrix} \frac{\sqrt{2}}{2} \\ 0 \end{bmatrix} \qquad (14.1.2012)$$

and so on line by line with each pair of coefficients and with the same rotation matrix.

Although factor analysis and principal component analysis are typically labelled as data-reduction techniques, there are significant differences between these two. The objective of principal component analysis is to reduce the number of variables to a few components such that each component forms a new variable and the retained components explain the maximum amount of variance in the data. The objective of factor analysis, on the other hand, is to search or identify the underlying factor(s) or latent constructs that can explain the intercorrelation among the variables.

14.1.20.6.5 T-distributed Stochastic Neighbor Embedding (T-SNE)

"T-distributed Stochastic Neighbor Embedding" (T-SNE) is a machine learning algorithm for visualization developed by Laurens van der Maaten and Geoffrey Hinton (betwen 12002 and 12008 according to holocene calendar). It is a non-linear dimensionality reduction technique well-suited for embedding high-dimensional data for visualization in a low-dimensional space of two or three dimensions. Specifically, it models each high-dimensional object by a two- or three-dimensional point in such a way that similar objects are modelled by nearby points and dissimilar objects are modelled by distant points with high probability.

Remark

It is very important that the reader keep in mind that is designed only for visualizing a dataset in a low (2 or 3) dimension space. We give it all the data we want to visualize all at once. It is not a general purpose dimensionality reduction tool!

The T-SNE algorithm comprises two main stages. First, T-SNE constructs a probability distribution over pairs of high-dimensional objects in such a way that similar objects have a high probability of being picked while dissimilar points have an extremely small probability of being picked. Second, T-SNE defines a similar probability distribution over the points in the low-dimensional map, and it minimizes the Kullback–Leibler divergence (see section Statistical Mechanics page 3542) between the two distributions with respect to the locations of the points in the map. Note that while the original algorithm uses the Euclidean distance between objects as the base of its similarity metric, this should be changed as appropriate.

T-SNE has been used for visualization in a wide range of applications, including computer security research, music analysis, cancer research, bioinformatics, and biomedical signal processing. It is often used to visualize high-level representations learned by an artificial neural network. Indeed, as the reader may already know, deep CNN (convolutional neural networks) are basically black boxes. There is no way to really interpret what's on deeper levels in the network. A common explanation is that deeper levels contain information about more complex objects. But that's not completely true, you can interpret it like that but data itself is just a high-dimensional noise for humans. But, with the help of T-SNE you can create maps to display which input data seams similar for the network.

While T-SNE plots often seem to display clusters, the visual clusters can be influenced strongly by the chosen parametrization and therefore a good understanding of the parameters for T-SNE is necessary. Such "clusters" can be shown to even appear in non-clustered data, and thus may be false findings! Interactive exploration may thus be necessary to choose parameters and validate results. It has been demonstrated that T-SNE is often able to recover well-separated clusters, and with special parameter choices, approximates a simple form of spectral clustering.

Given a set of N high-dimensional objects $\vec{x}_1,\ldots,\vec{x}_N$, T-SNE first computes probabilities p_{ij} that are proportional to the similarity of objects $\vec{x}_i$ and $\vec{x}_j$, defined as follows:

$$p_{j|i}=\frac{\exp(-\|\vec{x}_i-\vec{x}_j\|^2/2\sigma_i^2)}{\sum\limits_{k\neq i}\exp(-\|\vec{x}_i-\vec{x}_k\|^2/2\sigma_i^2)} \qquad (14.1.2013)$$

Note that we have obviously $\sum_j p_{j|i}=1$ for all i.

Remark

It seems that in general all SNE models are written in the form:

$$p_{j|i}=\frac{g(x_i-\vec{x}_j)}{\sum\limits_{k\neq i} g(\vec{x}_i-\vec{x}_k)} \tag{14.1.2014}$$

where g is a given function.

As Van der Maaten and Hinton explained: "The similarity of datapoint $\vec{x}_j$ to datapoint $\vec{x}_i$ is the conditional probability, $p_{j|i}$, that $\vec{x}_i$ would pick $\vec{x}_j$ as its neighbour if neighbours were picked in proportion to their probability density under a Gaussian centered at $\vec{x}_i$."

Now we define:

$$p_{ij}=\frac{p_{j|i}+p_{i|j}}{2N} \tag{14.1.2015}$$

and note that $p_{ij}=p_{ji}$, $p_{ii}=0$ and $\sum_{i,j} p_{ij}=1$.

The bandwidth of the Gaussian kernels σ_i is set in such a way that the perplexity of the conditional distribution equals a predefined perplexity using the bisection method to match a pre-specified perplexity value (Perp). The perplexity is $\text{Perp}(P_j)=2^{H(p_j)}$, where $H(P_j)=-\sum_j p_{i|j}\log(p_{i|j})$, and σ_j is selected so that $\text{Perp}(P_j)=\text{Perp}$. As a result, the bandwidth is adapted to the density of the data: smaller values of σ_i are used in denser parts of the data space.

T-SNE is actually very sensitive to the Perplexity value. Let us see the following value:

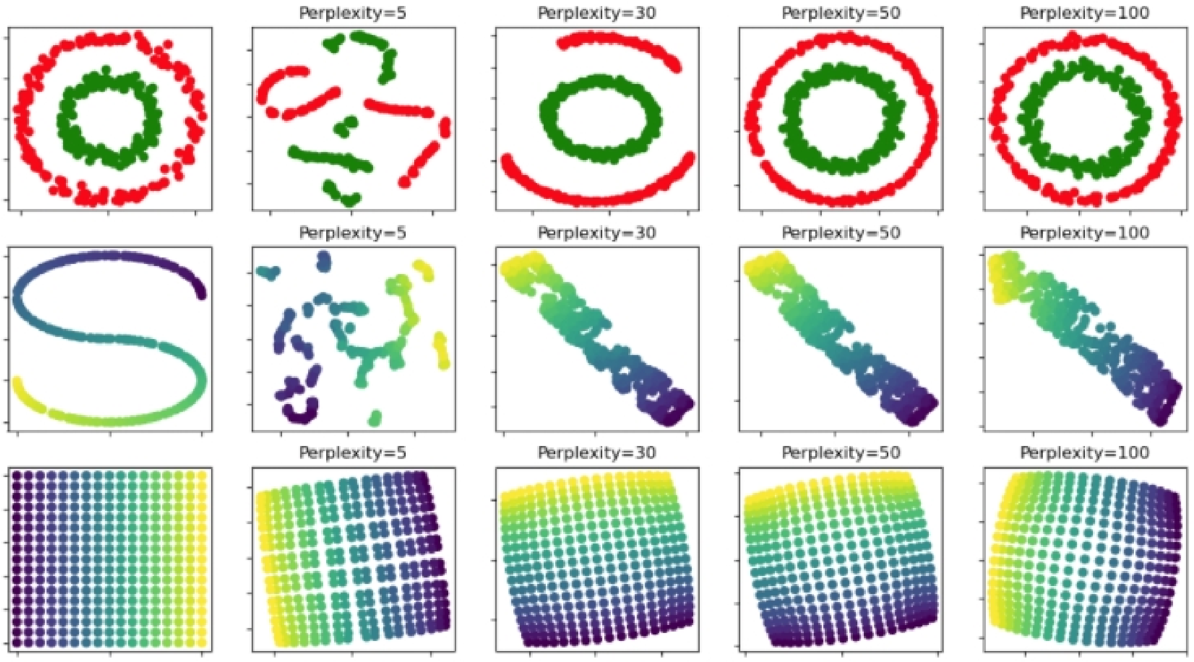


Figure 14.177: T-SNE perplexity sensitivity

Remark

There seems to be no standard way to choose the correct perplexity aside looking at the produced reduced dimension dataset and then assessing if it is meaningful. There are some general facts, eg. distances between clusters are mostly meaningless, small perplexity values encourage small clot-like structures but that's about it. A rule of thumb is to set the perplexity to 5% of the dataset size.

Since the Gaussian kernel uses the Euclidean distance $\|\vec{x}_i - \vec{x}_j\|$, it is affected by the curse of dimensionality, and in high dimensional data when distances lose the ability to discriminate, the p_{ij} become too similar (asymptotically, they would converge to a constant). It has been proposed to adjust the distances with a power transform, based on the intrinsic dimension of each point, to alleviate this.

In other words, in many of the dimensionality reduction techniques (e.g. T-SNE), we try to map the data points from a higher dimension to a lower dimension. While doing so a fundamental problem occurs, the distance between the points at a higher dimension can't be preserved at a lower dimension. This results in a overlapping or erroneous distance between the points at a lower dimension. This problem is named the "Crowding Problem". The T-distribution being heavier tailed helps in this regard.

T-SNE aims to learn a d-dimensional map $\vec{y}_1, \ldots, \vec{y}_N$ (with $\vec{y}_i \in \mathbb{R}^d$ that reflects the similarities $p_{i|j}$ as well as possible. To this end, it measures similarities q_{ij} between two points in the map $\vec{y}_i$ and $\vec{y}_j$, using a very similar approach. Specifically, $q_{j|i}$ is defined as:

$$q_{j|i}^{\text{TSNE}} = \frac{(1 + \|\vec{y}_i - \vec{y}_j\|^2)^{-1}}{\sum_k \sum_{k \neq i} (1 + \|\vec{y}_k - \vec{y}_i\|^2)^{-1}} \tag{14.1.2016}$$

Herein a heavy-tailed Student T-distribution (with one-degree of freedom, which is the same as a Cauchy distribution) is used to measure similarities between low-dimensional points in order to allow dissimilar objects to be modelled far apart in the map. Note that also in this case we set $q_{ii} = 0$.

The locations of the points $\vec{y}_i$ in the map are determined by minimizing the (non-symmetric) Kullback–Leibler divergence (see section Statistical Mechanics page 3542) of the distribution Q from the distribution P, that is:

$$C = \sum_i D_{\text{KL}}(P_i, Q_i) = \sum_j \sum_i p_{j|i} \log \left(\frac{p_{j|i}}{q_{j|i}} \right) \tag{14.1.2017}$$

in which P_i is the conditional probability distribution over all other datapoints given data-point $\vec{x}_i$, and Q_i represents the conditional probability distribution over all other map points given map point $\vec{y}_i$.

The minimization of the Kullback–Leibler divergence with respect to the points $\vec{y}_i$ is performed using gradient descent. The result of this optimization should be a map that reflects the similarities between the high-dimensional inputs well.

Let us see now how to derive the gradient of the KL divergence Loss function for the standard SNE and the T-SNE:

14.1.20.6.5.1 KL gradient of Stochastic Neighbour Embedding (SNE)

The definition of $q_{j|i}$ for SNE is different from that of the T-SNE (thanks to Federico Errica for providing the detailed developments):

$$q_{j|i}^{\text{SNE}}=\frac{e^{-\|y_i-y_j\|^2}}{\sum\limits_{k\neq l}e^{-\|y_k-y_l\|^2}}=\frac{E_{ij}}{\sum\limits_{k\neq l}E_{kl}}=\frac{E_{ij}}{Z_l} \tag{14.1.2018}$$

For what follows we will treat the one-dimensional case to simplify the notations (and we will also omit the SNE exponent).

Notice that $E_{ij}=E_{ji}$. The loss function is defined as:

$$\begin{aligned}C&=\sum_k\sum_{l\neq k}p_{l|k}\log\left(\frac{p_{l|k}}{q_{l|k}}\right)=\sum_{k,l\neq k}p_{l|k}\log\left(\frac{p_{l|k}}{q_{l|k}}\right)=\sum_{k,l\neq k}p_{l|k}\log(p_{l|k})-p_{l|k}\log(q_{l|k})\\&=\sum_{k,l\neq k}p_{l|k}\log(p_{l|k})-p_{l|k}\log(E_{kl})+p_{l|k}\log(Z_k)\end{aligned} \tag{14.1.2019}$$

We derive with respect to a y_i (notice that the first term vanish a it depends only on x_i or x_j but not on any y_i or y_j. To make the derivation less cluttered, we will omit the ∂y_i term at the denominator:

$$\frac{\partial C}{\partial y_i}=\sum_{k,l\neq k}-p_{l|k}\partial\log(E_{kl})+\sum_{k,l\neq k}p_{l|k}\partial\log(Z_k) \tag{14.1.2020}$$

We start with the first term, noting that the derivative are obviously non-zero if and only if each term of the sums contains at least a i. Therefore we can reduce the two sums to only one with two terms (by symmetry):

$$\sum_{k,l\neq k}-p_{l|k}\partial\log(E_{kl})=\sum_j-p_{j|i}\partial\log(E_{ji})=\sum_j-p_{j|i}\partial\log(E_{ij})-p_{i|j}\partial\log(E_{ji}) \tag{14.1.2021}$$

Since $\partial E_{ij}=E_{ij}(-2(y_i-y_j))$ we have:

$$\sum_j-p_{j|i}\cancel{\frac{E_{ij}}{E_{ij}}}\left(-2\left(y_i-y_j\right)\right)-p_{i|j}\cancel{\frac{E_{ji}}{E_{ji}}}\left(2\left(y_j-y_i\right)\right)=2\sum_j\left(p_{j|i}+p_{i|j}\right)\left(y_i-y_j\right) \tag{14.1.2022}$$

We conclude with the second term:

$$\sum_{k,l\neq k}p_{l|k}\partial\log(Z_k)=\sum_k\sum_{l\neq k}p_{l|k}\partial\log(Z_k)=\sum_k\partial\log(Z_k)\sum_{l\neq k}p_{l|k} \tag{14.1.2023}$$

Since $\sum_{l\neq j}p_{l|j}=1$ and Z_j does not depend on k, we can write (changing variable from l to j to make it more similar to the already computed terms):

$$\sum_{j,l\neq k}p_{l|j}\partial\log(Z_j)=\sum_j\partial\log(Z_j)=\partial\log\left(\sum_{k\neq l}E_{kl}\right)=\partial\log\left(\sum_{k\neq l}e^{-\|y_k-y_l\|^2}\right) \tag{14.1.2024}$$

The derivative is non-zero only when $k=i$ or $j=i$ (also, in the latter case we can move Z_i inside the summation because constant) therefore:

$$\begin{aligned}\sum_{j,l\neq k} p_{l|j}\partial\log(Z_j) &= \sum_j \frac{1}{Z_j}\sum_{k\neq j}\partial E_{jk} = \sum_j \frac{E_{ji}}{Z_j}\left(2\left(y_j-y_i\right)\right)+\sum_j \frac{E_{ij}}{Z_i}\left(-2\left(y_i-y_j\right)\right)\\ &= 2\sum_j\left(-q_{j|i}-qi|j\right)\left(y_i-y_j\right)\end{aligned} \tag{14.1.2025}$$

Combining the previous and prior-previous relations we arrive at the final result:

$$\frac{\partial C_{\text{SNE}}}{\partial y_i} = 2\sum_j\left(p_{j|i}-q_{j|i}+p_{i|j}-q_{i|j}\right)\left(y_i-y_j\right) \tag{14.1.2026}$$

14.1.20.6.5.2 KL gradient of T-distributed Stochastic Neighbour Embedding (T-SNE)

Let us do now the same job for T-SNE and for that the reader must remember:

$$q_{j|i}^{\text{TSNE}} = q_{i|j}^{\text{TSNE}} = \frac{\left(1+\|y_i-y_j\|^2\right)^{-1}}{\sum\limits_{k,l\neq}\left(1+\|y_k-y_l\|^2\right)^{-1}} = \frac{E_{ij}^{-1}}{\sum\limits_{k,l\neq} E_{kl}^{-1}} = \frac{E_{ij}^{-1}}{Z} \tag{14.1.2027}$$

For what follows we will treat again the one-dimensional case to simplify the notations (and we will also omit the TSNE exponent).

Notice that $E_{ij}=E_{ji}$. The loss function is defined as:

$$\begin{aligned}C_{\text{TSNE}} &= \sum_{k,l\neq k} p_{l|k}\log\left(\frac{p_{l|k}}{q_{l|k}}\right) = \sum_{k,l\neq k} p_{l|k}\log(p_{l|k})-p_{l|k}\log(q_{l|k})\\ &= \sum_{k,l\neq k} p_{l|k}\log(p_{l|k})-p_{l|k}\log(E_{kl}^{-1})+p_{l|k}\log(Z)\end{aligned} \tag{14.1.2028}$$

We derive with respect to a y_i. To make the derivation less cluttered, we will again omit the ∂y_i term at the denominator:

$$\frac{\partial C_{\text{TSNE}}}{\partial y_i} = \sum_{k,l\neq k} -p_{l|k}\partial\log(E_{kl}^{-1})+\sum_{k,l\neq k} p_{l|k}\partial\log(Z) \tag{14.1.2029}$$

We start with the first term, noting that the derivative is non-zero only when $\forall j$, $k=i$ or $l=i$, and also remembering that $p_{j|i}=p_{i|j}$ and $E_{ji}=E_{ij}$:

$$\sum_{k,l\neq k} -p_{l|k}\partial\log(E_{kl}^{-1}) = -2\sum_j p_{j|i}\partial\log(E_{ij}^{-1}) \tag{14.1.2030}$$

since $\partial E_{ij}^{-1}=E_{ij}^{-2}\left(-2\left(y_i-y_j\right)\right)$ we have:

$$-2\sum_j p_{j|i}\frac{E_{ij}^{-2}}{E_{ij}^{-1}}\left(-2\left(y_i-y_j\right)\right) = 4\sum_j p_{j|i}E_{ij}^{-1}\left(y_i-y_j\right) \tag{14.1.2031}$$

We conclude with the second term. Using the fact that $\sum_{k,l\neq k} p_{kl} = 1$ and that Z does not depend on k or l:

$$\sum_{k,l\neq k} p_{l|k}\partial \log Z = \frac{1}{Z}\sum_{k',l'\neq k'} \partial E_{kl}^{-1} = 2\sum_{j} \frac{E_{ji}^{-2}}{Z}(-2(y_j - y_i)) = -4\sum_{j} q_{i|j}E_{ji}^{-1}(y_i - y_j) \tag{14.1.2032}$$

Combining we arrive at the final result:

$$\frac{\partial C_{\text{TSNE}}}{\partial y_i} = 4\sum_{j}\left(p_{j|i} - q_{j|i}\right)E_{ji}^{-1}\left(y_i - y_j\right) = 4\sum_{j}\left(p_{j|i} - q_{j|i}\right)\left(1 + \|y_i - y_j\|^2\right)^{-1}\left(y_i - y_j\right) \tag{14.1.2033}$$

Keep in mind that T-SNE learns a nonparametric mapping, which means that it does not learn an explicit function that maps data from the input space to the map!!! Therefore, it is not possible to embed test points in an existing map (although we could re-run T-SNE on the full dataset). A potential approach to deal with this would be to train a multivariate regressor to predict the map location from the input data. But if we are trying to apply T-SNE to "new" data, we are probably not thinking about our problem correctly, or perhaps simply we did not understand the purpose of T-SNE.

14.1.20.7 Gradient Boosting

In many supervised learning problems one has an output variable y and a vector of input variables $\vec{x}$ described via a joint probability distribution $P(\vec{x},y)$ (at least for the purposes of theoretical analysis!). Using a training set $\{(x_1,y_1),\ldots,(x_n,y_n)\}$ of known values of $\vec{x}$ and corresponding values of y, the goal is to find an approximation $\hat{F}(x)$ to a function $F(x)$ that minimizes the expected value of some specified loss function $L(y,F(x))$:

$$\hat{F}=\min_{F}\mathrm{E}_{x,y}[L(y,F(x))] \qquad (14.1.2034)$$

The "gradient boosting method" (that personally the author of these lines like better to name "incremental iterative learning") assumes a real-valued y and seeks an approximation $\hat{F}(x)$ in the form of a weighted sum of functions $h_i(x)$ from some class $\mathcal{H}$ of weak learner:

$$\hat{F}(x)=\sum_{i=1}^{M}\gamma_i h_i(x)+c^{te} \qquad (14.1.2035)$$

Keep in mind that the underlying idea is that instead of creating a single model, boosting combines multiple simple models into a single composite model. The idea is that, as we introduce more and more simple models, the overall model becomes stronger and stronger. And for reminder, in boosting terminology, the simple models are named "weak models" or "weak learners".

In accordance with the empirical risk minimization principle, the method tries to find an approximation $\hat{F}(x)$ that minimizes the average value of the loss function on the training set, i.e., minimizes the empirical risk. It does so by starting with a model, consisting of a constant function $F_0(x)$, and incrementally expands it in a greedy fashion:

$$\begin{aligned}F_0(x)&=\min_{\gamma}\sum_{i=1}^{n}L(y_i,\gamma)\\ F_m(x)&=F_{m-1}(x)+\min_{h_m\in\mathcal{H}}\left[\sum_{i=1}^{n}L(y_i,F_{m-1}(x_i)+h_m(x_i))\right]\end{aligned} \qquad (14.1.2036)$$

where $h_m\in\mathcal{H}$ is a base learner function.

Unfortunately, choosing the best function h_i at each step for an arbitrary loss function L is a computationally infeasible optimization problem in general (as least as far as we know for the moment...). Therefore, we restrict our approach to a simplified version of the problem.

The idea is to apply a steepest descent step to this minimization problem. If we consider the continuous case, i.e. where $\mathcal{H}$ is the set of arbitrary differentiable functions on $\mathbb{R}$, we would update the model in accordance with the following equations:

$$\begin{aligned}F_m(x)&=F_{m-1}(x)-\gamma_m\sum_{i=1}^{n}\nabla_{F_{m-1}}L(y_i,F_{m-1}(x_i))\\ \gamma_m&=\min_{\gamma}\sum_{i=1}^{n}L\left(y_i,F_{m-1}(x_i)-\gamma\nabla_{F_{m-1}}L(y_i,F_{m-1}(x_i))\right)\end{aligned} \qquad (14.1.2037)$$

where the derivatives are taken with respect to the functions F_i for $i \in \{1,..,m\}$. In the discrete case however, i.e. when the set $\mathcal{H}$ is finite, we choose the candidate function h closest to the gradient of L for which the coefficient γ may then be calculated with the aid of line search on the above equations. Note that this approach is a heuristic and therefore doesn't yield an exact solution to the given problem, but rather an approximation.

In pseudocode, the generic gradient boosting method is:

1. Training set $\{(x_i, y_i)\}_{i=1}^n$, a differentiable loss function $L(y, F(x))$, number of iterations M.
2. For $m = 1$ to M
   - 2.1. Compute so-named pseudo-residuals:

$$r_{im} = -\left[\frac{\partial L(y_i, F(x_i))}{\partial F(x_i)}\right]_{F(x)=F_{m-1}(x)} \quad \text{for } i = 1, \ldots, n. \tag{14.1.2038}$$

   - 2.2. Fit a base learner (e.g. tree) $h_m(x)$ to pseudo-residuals, i.e. train it using the training set $\{(x_i, r_{im})\}_{i=1}^n$.
   - 2.3. Compute multiplier γ_m by solving the following one-dimensional optimization problem:

$$\gamma_m = \min_\gamma \sum_{i=1}^n L\left(y_i, F_{m-1}(x_i) + \gamma h_m(x_i)\right) \tag{14.1.2039}$$

   - 2.4. Update the model:

$$F_m(x) = F_{m-1}(x) + \gamma_m h_m(x) \tag{14.1.2040}$$

   - 2.5. Output $F_M(x)$

In pseudocode (non-unique and not optimized):

Algorithm 17: Generic gradient boosting tree pseudocode

```
Data: $\{\vec{x}_i, y_i\}_{i=1}^n$
Result: $F_M(\vec{x})$
initialization;
$F_0(\vec{x}) = \arg\min_\gamma \sum_{i=1}^n L(y_i, \gamma)$;
for $m = 1$ to $M$ do
    for $i = 1$ to $n$ do
        $r_{im} = -\left[\frac{\partial L(y_i, F(\vec{x}_i))}{\partial F(\vec{x}_i)}\right]_{F(x)=F_{m-1}(\vec{x}_i)}$;
    tree($h_m(\{\vec{x}_i, r_{im}\}_{i=1}^n)$);
    $\gamma_m = \min_\gamma \sum_{i=1}^n L(y_i, F_{m-1}(\vec{x}_i) + \gamma h_m(\vec{x}_i))$;
    $F_m(\vec{x}_i) = F_{m-1}(\vec{x}_i) + \gamma_m h_m(\vec{x}_i)$;
```

Here is a very nice detailed example developed by antonioACR1 (we only have his pseudonyme sadly) on Stackexchange that is categorized as a special case of gradient boosting named: "least-squares boosting algorithm[70]" (LS Boost).

The example aims to predict salary per month (in dollars) based on whether or not the observation has own house, own car and own family/children. Suppose we have a dataset of three observations where the first variable is *have own house*, the second is *have own car* and the third variable is *have family/children*, and target is *salary per month*. The observations are:

- {Yes,Yes,Yes,1000}
- {No,No,No,25}
- {Yes,No,No,5000}

Choose a number M of boosting stages, say $M=1$. The first step of gradient boosting algorithm is to start with an initial model F_0. This model is a constant defined by $\min\limits_{\gamma}\sum_{i=1}^{3} L(y_i,\lambda)$ in our case, where L is the loss function. Suppose that we are working with the usual loss function:

$$L(y_i,\gamma)=\frac{1}{2}(y_i-\gamma)^2 \tag{14.1.2041}$$

When this is the case, this constant is equal to the mean of the outputs y_i, so in our case:

$$F_0(x_i)=\frac{10000+25+5000}{3}=5008.3 \tag{14.1.2042}$$

So our initial model is $F_0(x)=5008.3$ (which maps every observation x (e.g. {No,Yes,No}) to 5008.3.

Next we should create a new dataset, which is the previous dataset but instead of y_i we take the residuals:

$$r_{i0}=-\frac{\partial L(y_i,F_0(x_i))}{\partial F_0(x_i)} \tag{14.1.2043}$$

In our case, we have for the "alignment accuracy residuals":

$$r_{i0}=y_i-F_0(x_i)=y_i-5008.3 \tag{14.1.2044}$$

So our dataset becomes:

- {Yes,Yes,Yes,4991.6}
- {No,No,No,-4983.3}
- {Yes,No,No,-8.3}

---

[70] As it is based on the usual squared error loss function!

The next step is to fit a base learner h to this new dataset. Usually the base learner is a decision tree, so we use this.

Now assume that we constructed the following decision tree h. We constructed this tree using entropy and information gain formulas (but maybe there is some mistake as the calculations were done by hand, however for our purposes we can assume it's correct!):

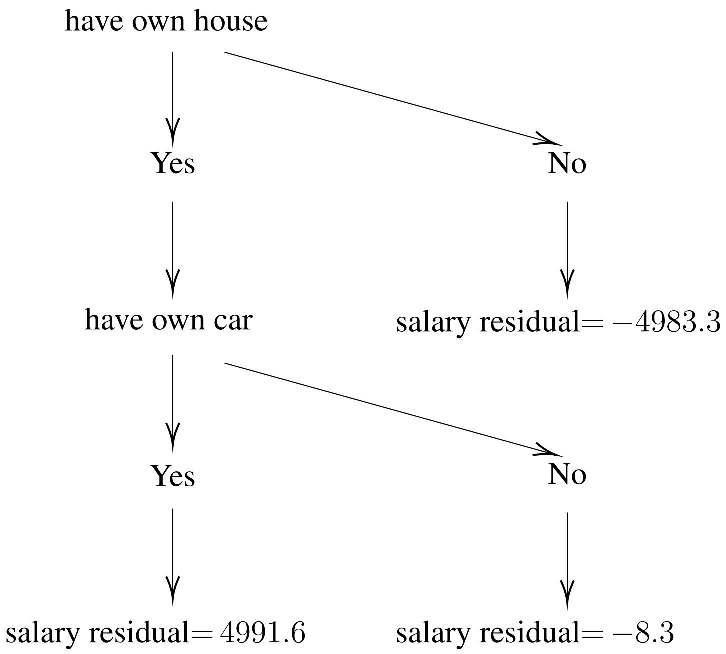

Figure 14.178: **Decision tree base learn for gradient boosting**

Let us denote this decision tree h_0. The next step is to find a constant:

$$\lambda_0 = \min_{\gamma} \sum_{i=1}^{3} L\left(y_i, F_0(x_i) + \lambda h_0(x_i)\right) \tag{14.1.2045}$$

Therefore, we want a constant λ minimizing:

$$\begin{aligned} C = &\frac{1}{2}(10000 - (5008.3 + \lambda \cdot 4991.6))^2 + \frac{1}{2}(25 - (5008.3 + \lambda(-4983.3)))^2 \\ &+ \frac{1}{2}(5000 - (5008.3 + \lambda(-8.3)))^2 \end{aligned} \tag{14.1.2046}$$

This is where gradient descent comes in handy!

Suppose that we start at $P_0 = 0$. We choose the learning rate equal to $\eta = 0.01$. We have:

$$\begin{aligned} \frac{\partial C}{\partial \lambda} = &(10000 - (5008.3 + \lambda \cdot 4991.6))(-4991.6) + (25 - (5008.3 + \lambda(-4983.3))) \cdot 4983.3 \\ &+ (5000 - (5008.3 + \lambda(-8.3))) \cdot 8.3 \end{aligned} \tag{14.1.2047}$$

Then our next value P_1 is given by:

$$P_1 = 0 - \eta \frac{\partial C}{\partial \lambda}(0) = 0 - .01(-4991.6 \cdot 4991.7 + 4983.4 \cdot (-4983.3) + (-8.3) \cdot 8.3) \tag{14.1.2048}$$

We repeat this step N times, and suppose that the last value is P_N. If N is sufficiently large and η is sufficiently small then $\lambda := P_N$ should be the value where:

$$\sum_{i=1}^{3} L(y_i, F_0(x_i) + \lambda h_0(x_i)) \tag{14.1.2049}$$

is minimized. If this is the case, then our λ_0 will be equal to P_N. Just for the sake of it, suppose that $P_N = 0.5$ (so that $\sum_{i=1}^{3} L(y_i, F_0(x_i) + \lambda h_0(x_i)))$ is minimized at $\lambda := 0.5$). Therefore, $\lambda_0 = 0.5$.

The next step is to update our initial model F_0 by $F_1(x) := F_0(x) + \lambda_0 h_0(x)$. Since our number of boosting stages is just one, then this is our final model F_1.

Now suppose that we want to predict a new observation $x = \{\text{Yes}, \text{Yes}, \text{No}\}$ (so this person does have own house and own car but no children). What is the salary per month of this person? We just compute $F_1(x) = F_0(x) + \lambda_0 h_0(x) = 5008.3 + 0.5 \cdot 4991.6 = 7504.1$. So this person earns 7504.1 per month according to our model.

Here is an interesting abstract visualization that may help to understand this incremental iterative learning process (we don't know who is the author of this figure for sure but maybe it's Terence Parr):

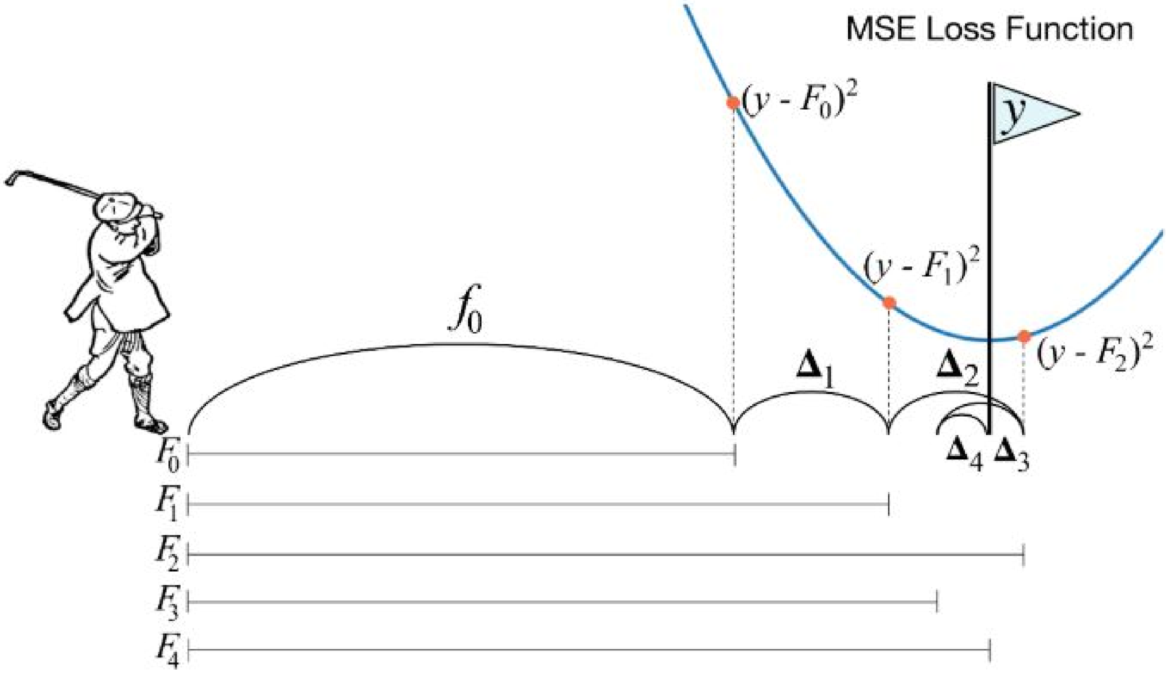

Figure 14.179: **Illustrate visualization of the iterative concept of Gradient Boosting**

Or a more explicit one would be:

Figure 14.180: **Illustrated Gradient Boosting with Trees**

Remark

It should be quite obvious at this level of the book that take a linear regression model as weak learner is a non-sense. Indeed, the minimization of the linear regression Loss function is a closed form problem whose solution is perfectly known and that gives us the best linear unbiased estimator $\vec{\beta}$ out of all possibilities. However, dropping unbiasedness may allow to do a bit better particularly under high multicollinearity.

14.1.20.8 Neural networks

Neural networks made from artificial cell structures are an approach for addressing from a new angle of perspective the problems of perception, memory, learning and non-linear reasoning (in other words ... artificial intelligence, abbreviated "IA") as well as genetic algorithms (see further below). They have also proved to be very promising alternatives to bypass some of the limitations of conventional numerical methods (see autodriven cars, autodriven airplanes, automatic trading systems). Thanks to their parallel processing of information and mechanisms inspired of nerve cells (neurons), they infer emergent properties to solve problems once referred to be as highly complex. Sometimes they result of artificial neurons is so bluffy that even best engineers have difficulties to explain how the neural network could arrive to a given observed performance (an typical non-business well known example is the Google Deep-learning dreaming machine).

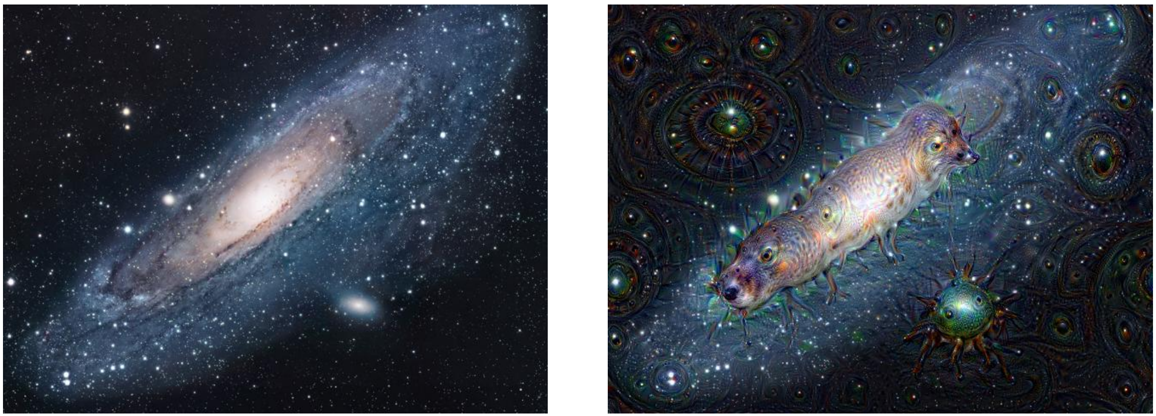

Figure 14.181: **Google Dream Machine test obtained the 12016-09-27 T20:42GMT (source: `http://psychic-vr-lab.com/deepdream`)**

However, the major problem of artificial neurons (as far as we know...) is that they are not able to self-organize, nor to self-structured intelligently by themselves, they can only change weights and change some layer parameters in a range given previously by a human. So we need at this date to proceed heuristically to find the best neural network structure adapted to a problem and this is their large current actual weakness (either using brute force via a database containing millions of models or genetic algorithms that we will see a bit further below).

We will discuss here the main architectures of neural networks. The purpose is not to study them all because they are too many variations (see figure on the next page), but rather to understand the basic internal mechanisms and how and when to use them with a minimal companion example with a common spreadsheet software. We will also discuss some concepts on fuzzy sets and logic (see section Logical Systems page 7136) in the idea that these later are incorporated into some neural network architectures that we will study.

The human brain is said ton contains about 100 billion neurons. These neurons enable us among others to read a text while maintaining regular breathing to oxygenate our blood, activating our heart which ensures efficient circulation of the blood to nourish our cells, etc. After a very long learning path and trial and errors they also enable us to read books, innovate, create, copy concepts and gentle with other people of the same species (but the learning path doesn't work for all human being for all humans machine as some reject respect of life and of differences...).

Each of these neurons is also quit complex. Essentially, it is living tissue and chemistry and application of physics law (as the rest of our body). Neuro-physicists are just beginning to understand some of their internal mechanisms and are also able to influence them since a few decades. We usually think that their different neuronal functions, including memory, is stored at the connections (synapses) between neurons. It is this kind of theory that has inspired most of the artificial neural network architectures (say to be "formal neural networks"). Learning is then the process that consist either to establish new connections, or modify existing one by trial and error or by an external reference (we will focus especially on the latter option).

This brings us to a fundamental question, based on our current knowledge: can we build approximate mathematical models of neurons and make them to possibly perform useful tasks? Well, the short answer is: yes, even if the networks that we develop have only a tiny fraction of the power of the human brain actually (year 12003 according to holocene calendar), and that's the goal here to show how we can do it formally (because technically it is obvious that more powerful are the computer, more impressive will be the results)!

Neural networks are now used in all kinds of application in various fields. For example, there are neural networks developed for: aircraft autopilots, car autopilot, automotive control systems automatic reading of bank checks, automatic reading of postal addresses, signal processing, ballistic missile autopilots, voice synthesis, personal assistant, computer vision systems, market predictions, financial risks assessments, various manufacturing processes, medical diagnosis, oil and gas exploration, robotics, telecommunications, management decisioneering systems, classification and many others. In short, neural networks today have a significant impact and there is a safe bet that their importance will continue to grow in the future.

14.1.20.8.1 Neuron model

The mathematical model of an artificial neuron, or "perceptron" is shown in the figure below (also in the previous figure with the overall summary of classical neural networks). A neuron consists essentially of an "integrator" which performs the weighted sum of its inputs (such as statistical mean ponderated by the inverse number of items!). The result n of that is then transformed by a transfer function f that produces the output a of the formal neuron.

The R neuron inputs correspond to vector correspond traditionally denoted:

$$\vec{p}=\begin{pmatrix}p_1\\p_2\\\vdots\\p_R\end{pmatrix} \tag{14.1.2050}$$

while:

$$\vec{w}=\begin{pmatrix}w_{1,1}\\w_{1,2}\\\vdots\\w_{1,R}\end{pmatrix} \tag{14.1.2051}$$

represents the neuron's vector weight (we distinguish them to prepare ourselves to the study of multiple layers formal neurons... also named "deep learning" systems):

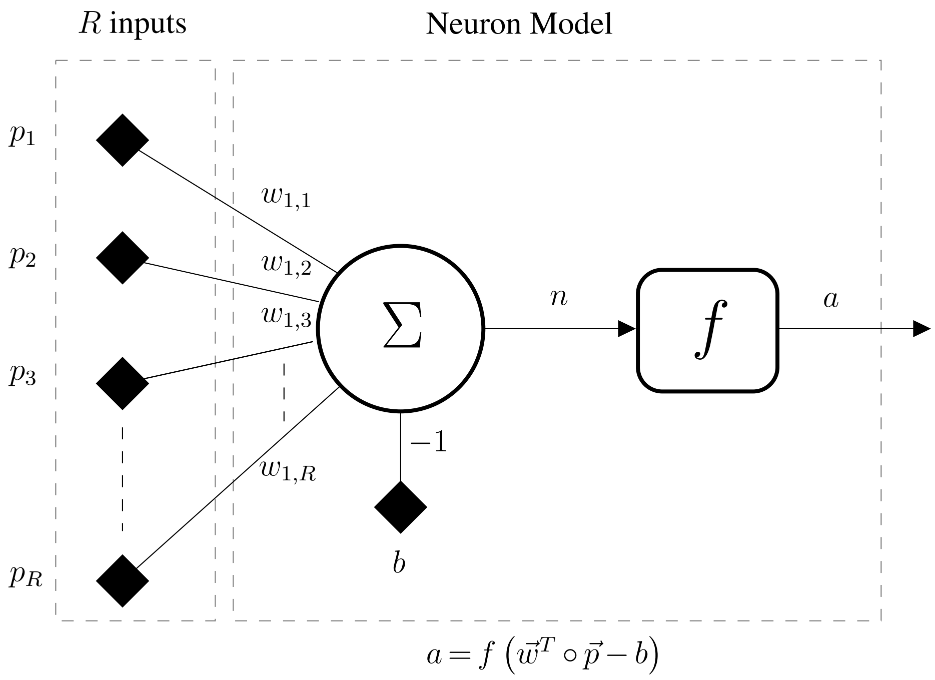

Figure 14.183: **Example of one-layer formal neuron with the input vector and scalar output**

The output of the integrator is defined (as it is an engineering technique) by the following relation (weighted sum minus the bias):

$$n=\sum_{j=1}^{R}w_{1,j}p_j-b=w_{1,1}p_1+w_{1,2}p_2+\ldots+w_{1,R}p_R-b \qquad (14.1.2052)$$

that we can also write in vector form (it could also be written as tensor but ...):

$$n=\sum_{j=1}^{R}w_{1,j}p_j-b=\vec{w}^T\vec{p}-b \qquad (14.1.2053)$$

Such that finally:

$$\boxed{a=f(n)=f\left(\sum_{j=1}^{R}w_{1,j}p_j-b\right)=f\left(\vec{w}^T\vec{p}-b\right)} \qquad (14.1.2054)$$

This output is obviously a weighted sum of the weights and inputs less what we name the "bias b of the neuron" (correction factor determined by trial and error and often null in practice). The weighted sum is named "activation level of the neuron". The bias b is also named "activation threshold of the neuron". When the activation level reaches or exceeds the threshold b, then n, the argument of f, named "activation function", becomes zero or positive of course. Otherwise it is negative.

That latter relation is also sometimes denoted:

$$a=\sigma(n)=\sigma\left(\vec{w}^T\vec{p}-b\right) \qquad (14.1.2055)$$

Remark

There's absolutely no reason for the weights in the linear layer (a.k.a. dense or fully-connected layer) to sum up to anything specific, such as 1.0. They are usually initialized with small random numbers (so initial sum is unlikely to be 1.0).

We can draw a parallel between this mathematical model and some information that we know (or think we know) about the biological neuron. That latter has three main components: the dendrites, the cell body and axon:
